ISBN (e-book) 978-618-86841-7-1

17th INTERNATIONAL CONGRESS
of the Geological Society of Greece

Book of Extended Abstracts
Contents

		Volume A: Papers 001-050	
A/A	**EC**	**AUTHORS and TITLE**	**PAGE**
1	93	Athanasios Agrafiotis, George Papathanassiou and Sotiris Valkaniotis **Monitoring the evolution of landslide phenomena using new technologies location: Pyrra Trikala**	**1**
2	268	Dimitra Amanatidou, Konstantinos Soukis, Christina Stouraiti and Klea Dimitri **Structural study of the Theodorion meta-migmatitic complex (Serbomacedonian massif, northern Greece)**	**3**
3	44	Vasilis Anagnostou, Pavlos Bonatis, Vasileios Karakostas, Christos Kourouklas, Eleftheria Papadimitriou, Angeliki Adamaki, Stefania Alexandra Andriopoulou Mounteanou, George Bathrellos, Stylianos Bitharis, Michalis Foumelis, Ion-Anastasios Karolos, George Kaviris, Elena Papageorgiou, Christos Pikridas, Vassilis Sakkas, Hariklia Skilodimou, Ioannis Spingos and Angelos Zymvragakis **Fostering FAIR approaches to the seismological data life cycle**	**6**
4	43	Vasilis Anagnostou, Eleftheria Papadimitriou, Vasileios Karakostas and Torbjörn Bäck **Detailing the stress pattern in the area of central Ionian Islands**	**12**
5	30	Stefania Alexandra Andriopoulou Mounteanou, George Bathrellos and Hariklia Skilodimou **Flood events over the past 115 years in the Municipality of Patras, southern Greece**	**17**
6	31	Stefania Alexandra Andriopoulou Mounteanou, George Bathrellos, Hariklia Skilodimou, Angeliki Adamaki, Vassilis Anagnostou, Stylianos Bitharis, Pavlos Bonatis, Michalis Foumelis, Vassilis Karakostas, Ion-Anastasios Karolos, George Kaviris, Christos Kourouklas, Eleftheria Papadimitriou, Elena Papageorgiou, Christos Pikridas, Vassilis Sakkas, Ioannis Spingos and Angelos Zymvragakis **HOMEROS project for natural hazards: An example from northern Peloponnese, Greece**	**23**
7	202	Emmanouil Antonakis and Nickolas Zouros **Digital Visualization of Geological Heritage at Lesvos UNESCO Global Geopark: The Role of 3D Animations in** Educational Experiences	**29**
8	82	Nikolaos Antoniadis and Constantinos Loupasakis **Land Subsidence and Flooding in the East Thessaly Plain: A Historical Overview**	**34**

9	205	Alkistis Antonopoulou, Nikolaos Depountis and Sotirios Kokkalas **Geological suitability in remote mountainous settlements using the AHP method. The case study of the settlement of Klepa in Greece**	**38**
10	16	George Apostolopoulos, Alireza Malehmir, Ioannis Vakalas, Haralambos Kranis, Konstantinos Leontarakis, Christos Orfanos, Emmanouil Konstantinidis, Magdalena Markovic, Myrto Papadopoulou, Stylianos Chailas, Emmanouil Skourtsos, Andreas Tzanis and Evaggelos Spyridonos **Legacy data analysis combined with an integrated geological and geophysical survey for geothermal site exploration at Petra-Lesvos, Greece**	**44**
11	256	Konstantina Apostolopoulou, Efthimios Karymbalis, Maria Salomidi and Evangelia G. Drakou **Modelling Coastal Protection as an ecosystem service in the Greek coastal zone**	**50**
12	305	Konstantina Maria Apostolou, Elissavet Feloni and Anastasia Stergiadou **Simulation of Domestic Rainwater Harvesting Systems on Fourni Island, Aegean Sea: Assessing Efficiency Under Historic and Climate Change Scenarios.**	**55**
13	28	Foteini Aravani, Lambrini Papadopoulou, Antonios Koroneos and Alexandros Chatzipetros **Metapelitic assemblages in the contact metamorphic zone of the Varnous plutonite (NW Macedonia, Greece): preliminary results.**	**63**
14	135	Ariadne Argyraki, Artemis Kontomichalou, Zacharenia Kypritidou and Alexandros Liakopoulos **Balancing Precision and Resources: The Effect of Sampling Density in Regional Soil Geochemical Mapping**	**69**
15	318	Stella Arnaouti and Olga-Joan Ktenidou **Seismic resilience of primary water transfer network at Lagadas municipality, North Greece**	**74**
16	23	Nikolaos Arvanitidis, Konstantinos Laskaridis and Christos Christidis **Implementing the Critical Raw Materials Act to explore strategic minerals potential in Greece**	**81**
17	173	Pavlos Asteriou, Dimitrios Sotiriadis, Eleni Petala, Labros Kazelis and Nikolaos Klimis **Assessing the effect of 2023 Evros Wildfire: a new Post-Fire Rockfall Hazard System**	**89**
18	331	Ioannis Athinelis, Eleftheria Basiou, Triantafyllos Falaras and Issaak Parcharidis **Estimation of the displacement components in South Aegean islands as a response to the early 2025 seismicity of the Anydros Islet using Sentinel-1 imagery.**	**96**

19	332	Ioannis Athinelis, Ignacio Castro Melgar, Theodoros Gatsios, Pavlos Krassakis and Issaak Parcharidis **Employing Sentinel-1 imagery to monitor the deformation rate over the caldera of the Santorini Volcanic Island Complex using multitemporal InSAR from January 2023 up to February 2025.**	**104**
20	321	Efstratios Avgerinos, Efthymia Kostopoulou, Ioannis Tegoulias and Christos Giannakopoulos **Impacts of Climate Change on Maritime Conditions and Medicane Formation: Analyzing SST Changes in the Eastern Mediterranean (1940–2023) using Thematic Maps**	**111**
21	128	Pavlos Avramidis, Alexis Ramfos, Ioannis Sarris, Dionisios Christodoulopoulos, Marinos Alexandridis, Maria Michalopoulou, Nikolaos Depountis and Stefanos Papazisimou **Seasonal Water Column Stratification and Heavy Metal Distribution in the Pinios Dam Reservoir: A Comprehensive Environmental Monitoring Study**	**117**
22	158	Antonios Isidoros Avrithis, Efterpi Koskeridou, Evangelia Rentoumi, Evangelos Vlachos and Davit Vasilyan **A Preliminary Review of Microvertebrate and Invertebrate Fauna from the Early Pleistocene of Koukos region (Kos Island, Dodecanese, Greece)**	**119**
23	125	Mohammad Mahdi Badami, Yashar Aghaei and Constantinos Sioutas **Impact of Emission Regulations on the Temporal Trends of Toxicity of PM2.5 in Los Angeles**	**123**
24	235	Athanasia Bakopoulou, Chrysi Dousiaki, Michalis Diakakis, Emmanouil Andreadakis, Spyridon Mavroulis, Maria-Evangelia Gogou, Haralambos Kranis, Assimina Antonarakou and Efthymios Lekkas **Teachers' experience, attitudes and skills on flood events: The case of Daniel storm 2023, Thessaly, Greece**	**127**
25	203	Eftychia-Christina Bardi, Paraskevi Lampropoulou, Alexandros Sergoulopoulos, Aikaterini Rogkala, Panagiota P. Giannakopoulou, Fotis Margaritis, Dimitrios Papoulis, Anastasios Tsinidis, Islam Ihtisham and Petros Petrounias **A (preliminary) comparative gemmological-mineralogical study of quartz crystals derived from Greece and Brazil**	**130**
26	77	Vasiliki Barsaki, Irene Michailidou, Filio Peppa, Georgia Kerdela and Eugenia Moraiti **The UNESCO Global Geopark of Lavreotiki: a pillar for climate change adaptation & the example of sustainable water use, Greece**	**136**
27	96	Vasiliki Barsaki, Panagiotis Voudouris and Eugenia Moraiti **The world class geodiversity of the Lavreotiki UNESCO Global Geopark's minerals, Lavreotiki Municipality, Greece**	**140**
28	261	Vasiliki Barsaki, Irene Zananiri and Eugenia Moraiti **Highlighting the Geological Heritage of the Island of Kythira, Greece**	**143**

29	151	Davide Bartolozzi, Sotiria Kothri, Maria Filomena Loreto, Nomikou, Ganas, Valentina Ferrante, Kei, Fabrizio Balsamo, Lampridou, Ranero and Nikoli **Mapping the geo-hazard elements offshore the Ionian Islands (Western Greece)**	**149**
30	362	Dimitrios-Vasileios Batzakis, Efthimios Karymbalis and Konstantinos Tsanakas **Assessing earthquake-triggered tsunami hazard in Santorini-Amorgos Tectonic Zone: A deterministic simulation-based approach**	**155**
31	161	Konstantina Bejelou, Paraskevi Nomikou, Solveig Bühring, Dimitrios Papanikolaou, Stephanos Kilias, Andrea Koschinsky-Fritsche, Wolfgang Bach, Karsten Haase, Christian Ferreira, Evgenia Bazhenova, Alissa Bach, Yukari Azakura, Danai Lampridou, Areti Belka, Eirini Anagnostou, Effrosyni Varotsou and Sotiria Kothri **Oceanographic survey M192 off Milos reveals tectonic controls on hydrothermal vent distribution in a complex volcanic-tectonic system of the South Aegean**	**162**
32	262	Alexandros Belesis, Ioannis Tsentzos, Maria Belesis and Ioannis Koukouvelas **Storm Daniel flooding of Larissa City: embankments failure the aftermath**	**166**
33	149	Areti Belka, Paraskevi Nomikou, Solveig Bühring, Konstantina Bejelou, Danai Lampridou, Alissa Bach, Sotiria Kothri, Effrosyni Varotsou and Dimitrios Papanikolaou **Morphotectonic analysis of Antimilos volcanic Group**	**173**
34	357	Konstantina Bentana and Nickolaos Zouros **Geoheritage as a tool to engage children with the Sustainable Development Goals in UNESCO Global Geoparks: Best practices in educational activities from Lesvos Island UNESCO Global Geopark**	**180**
35	55	Evangelia Besiou, George Kontakiotis, Iuliana Vasiliev and Assimina Antonarakou **Environmental controls on Globorotalia menardii size variability preceding the Tortonian/Messinian boundary**	**184**
36	61	Pavlos Bonatis, Vasileios Anagnostou, Vasileios Karakostas, Christos Kourouklas, Eleftheria Papadimitriou, Angeliki Adamaki, Stefania-Alexandra Andriopoulou-Mounteanou, George Bathrellos, Stylianos Bitharis, Michael Foumelis, Ion-Anastasios Karolos, George Kaviris, Elena Papageorgiou, Christos Pikridas, Vassilis Sakkas, Hariklia Skilodimou, Ioannis Spingos and Angelos Zymvragakis **Cultivating FAIR principles for multi-hazard assessment**	**188**
37	86	Vasileios Boumpoulis, Maria Michalopoulou, Anastasios Kazolias, Maria Geraga, Nikolaos Depountis and George Papatheodorou **Development of an index-based methodology for assessing coastal vulnerability at a national scale and preliminary results**	**193**
38	207	Evangelia Bouranta and Ioannis Hatzopoulos **Development of a Geographic Information System for the Near-Real-Time Management of the seismic risk. Case study: The city of Mytilene, Lesvos (Greece)**	**197**

39	59	Nicolina Bourli, Chrysanthos Botziolis, Penelope Papadopoulou, Panagiotis Zelilidis, Elena Zoumpouli, George Iliopoulos, Angelos G Maravelis, Efthymios Tripsanas, Ioannis Oikonomopoulos, Aristotelis Pagoulatos and Avraam Zelilidis **Facies and depositional architecture of Upper Miocene tidal flat sedimentation in Kefalonia and Corfu Islands, West Greece**	**203**
40	330	Simon Bufféral, Pierre Briole, Aurélien Dupont, Javier Escartin and Philippe Heinrich **Tsunami Modelling for a Potential Earthquake between Santorini and Amorgos (Greece)**	**204**
41	312	Riccardo Caputo, Iannis Koukouvelas, Giorgos Papathanassiou, Davide Russo, Maria Taftsoglou, Gabriele Tarabusi and Sotiris Valkaniotis **The Greek Database of Seismogenic Sources (GreDaSS) version 3.0. A compilation of potential seismogenic sources (Mw> 5.5) in the Aegean Region**	**211**
42	2	Ismar S. Carvalho, Maria Helena P. Henriques and Giuseppe Leonardi **Sousa Dinosaur Valley, Brazil: The largest record of Lower Cretaceous dinosaur footprints in South America and its influence in local communities**	**217**
43	279	Stylianos Chailas and Andreas Tzanis **A Preliminary 3D Gravity Model for the pre-Volcanic Basement of Lesvos Island, Greece**	**223**
44	296	Paraskevi Chantzi, Sofia Doani and Konstantinos Albanakis **Sediment dynamics in the Sperchios river basin and their influence on stevia cultivation**	**229**
45	299	Angelos Chasiotis, Elissavet Feloni and Panagiotis Nastos **Sustainable Practices for Resilient Hydrosystems at a Municipal Level: Insights from the Greek Island of Chios**	**232**
46	271	Theodora Chatzakou, Aikaterini Tsiri, Antonios Koroneos, Ioanna Gerontidou and Alexandros Drakoulis **Kentavros plutonite (Thrace, Greece): Geochemistry and Petrogenesis**	**237**
47	51	Efstratia Chatzi, Evangelia-Theodora Derdemezi and Georgios Tsilimigkas **The Impact of Urban Sprawl on Areas of Natural and Cultural Heritage and Geoheritage. Evidence of Lemnos island, Greece**	**243**
48	255	Emmanouil Chatziangelis, Vasileios Boumpoulis and Nikolaos Depountis **Slope failures of friable sandstone in coastal areas. A Case study from Western Greece.**	**248**
49	248	Nikolaos Panagiotis Chatzigogos, Agisilaos Poulios and Thomas Makedon **Settlements in residual soils**	**254**
50	253	Alexandros Chatzipetros and Vassiliki Samantzi **Geotopes of Thessaly (central Greece) and their educational approach**	**259**

Volume B: Papers 051-100

A/A	EC	AUTHORS and TITLE	PAGE
51	350	Dimitrios Chatzistratis, Isavela Monioudi, Theodoros Chalazas, Olympos Andreadis, Konstantinos Moschopoulos, Antonis Chatzipavlis, Fotis Psarros and Adonis Velegrakis **Flood risk of a touristic island beach under Climate Change: Komi beach Chios**	**265**
52	182	Themistoklis Chatzitheodosiou, Ioannis Farmakis, Dimitra Papouli, George Stoumpos, George Prountzopoulos and Vassilis Marinos **Three Years of Progress in Digital Applications and Monitoring Utilizing 3D Reality Capture Technologies for Landslide Hazard Mitigation, the Case in Evritania, Central Greece**	**269**
53	314	Eleftheria Christodoulopoulou, Olga Ktenidou and Grigorios Tsinidis **Mapping and Categorization of damage on the built and natural environment caused by the 2023 Daniel and Elias storms in Mount Pelion, Greece**	**274**
54	7	Demerios Constantinides **ERBE SYMPOSIUM 2027– LAVRION GREECE: Honouring the Values of Geo-Mining Heritage**	**278**
55	11	Salomé C. Custódio, Maria Helena Henriques and Artur A. Sá **The Geoheritage of the "Atlantic Geopark" Project (Central Portugal) at a Glance**	**284**
56	70	Panagiota Dalgkitsi, Alfred Uchman, Chrysanthos Botziolis, Panagiotis Zelilidis, Nicolina Bourli and Avraam Zelilidis **The transitional deposits from carbonates to clastic in the Pindos foreland basin: an example from the Mazia village, Ioannina region, Greece**	**290**
57	210	Maria Georgia Dasoula, Zafeiria Roumelioti, Efthimios Sokos and Sotirios Kokkalas **Statistics on seismic moment tensors for the Aegean Sea and surrounding area: preliminary results**	**291**
58	206	Stamatia Deligianni and Alexandros Chatzipetros **Environmental Seismic Intensity Scale (ESI 2007)**	**297**
59	223	Klea Dimitri, Christina Stouraiti, Dimitra Amanatidou and Konstantinos Soukis **The Triassic post-collisional high-K alkali-calcic granites in the Vertiskos Unit, Serbo-Macedonian Massif: insights from Miriofito granite, Kerkini complex, Greece**	**303**
60	146	Evangelia Dimou, Angeliki Papoutsa, Vasilios Pletsas, Nikolaos Zegkinoglou, Stephanos Kilias, Paraskevi Nomikou and Paraskevi Polymenakou **Biogenicity of Arsenic Sulfide Biomorphous Structures in Deep-Sea Hydrothermal Vents, Kolumbo Arc Volcano: Morphological, Mineralogical and Geochemical Evidence**	**307**
61	143	Vasiliki Grigoria Dimou, Olga Koukousioura, Gyorgy Less, Maria Triantaphyllou, Margarita Dimiza, Georgios Syrides and Martin Langer **Microfacies and species richness analyses of middle-late Eocene western Thrace Basin (Neotethys Ocean, Greece): Paleoenvironmental evolution and species-richness hotspot revealed**	**314**

62	242	Panagiotis Sotirios Dittopoulos and Alexandros Chatzipetros **Using alternative methods to promote geoheritage: the Koziakas Mt., central Greece, case study.**	**317**
63	54	Antonia Dretaki and Alexandros Chatzipetros **Assessment of fault hazard in the broader area of Sitia, Eastern Crete**	**323**
64	264	Antonia Dretaki, Panagiotis Sotirios Dittopoulos, Alexandros Chatzipetros, Vasilios Papavasiliou, Nikolaos Paspaliaris, Georgios Tsirakakis and Evangelos Perakis **Formation of Sitia's Geopark (Crete Island, Greece) caves in correlation with the structural setting of the area**	**329**
65	27	Hara Drinia and George Zafeiropoulos **Enhancing Geoheritage through GEOAM: A Case Study of Tinos Island, central Aegean Sea, Greece**	**336**
66	244	Hara Drinia and Georgios Zafeiropoulos **Tinos Island, Aegean Sea, Greece, Geopark: A Pioneering Initiative in Climate Change Resilience and Geoconservation**	**339**
67	13	Christos Drougas, Efstratios Kelepertzis, Zacharenia Kypritidou, Evangelia Sigala, Christos Roumpos, Georgios Louloudis, Eleni Mertiri and Evangelos Oikonomopoulos **Hydrogeochemical Characteristics of Alfeios River and the wider hydrographic Network in the Lignite Basin Area of Megalopolis**	**342**
68	71	Panagiotis Elias, Gaetano Festa, Lauro Chiaraluce, Pascal Bernard, George Kaviris, Christos Evangelidis, Efthimios Sokos, John Clinton, Alexandru Marmureanu, Simona Colombelli, Mariano Supino, Dimitris Paronis, Vassilis Karastathis, Men-Andrin Meier, Semih Ergintav, Alessandro Vuan, Tomas Fischer, Stanka Sebela, Dimitris Paliatsas, Anna Serpetsidaki and Andreas Karakonstantis **EU funding to integrate cutting-edge methodological and technological solutions, enabling the development of a next-generation network of Near Fault Observatories across Europe (project TRANSFORM²)**	**348**
69	315	Martin Engi, Andreas Gialoglou, Panayiotis Koutsabasis, Valentin Laurent and Constantinos G. Mavrogonatos **The Syros GeoPark Project**	**351**
70	342	Christos Evangelidis and Ioannis Fountoulakis **The 2024–2025 Seismic Sequence in the Santorini-Amorgos Region: High-Resolution Seismological Insights into a Volcano-Tectonic Crisis**	**356**
71	250	Dionysia Fasoli and Elizabeth Stathopoulou **Tooth enamel meso- and microstructure of fossilized Hipparionine horses of Pikermi (Attica, Greece)**	**359**
72	208	Charalampos Fassoulas, Spyridon Staridas and Emmanouel Nikolakakis **Local driven protection of a tectonic geosite, in Crete, Greece: The Paligremnos Protected Landscape**	**363**

73	354	Charalampos Fassoulas, R. Tamborrino, P. Bolca, G. Marra, G. Mezzalama, V. Tackacs, N. Leonhardmair and M.E. Demir **Assessing the management of Arkalochori EQ crisis in Crete, Greece under the implementation of RESILIAGE project in order to strengthen community resilience**	**368**
74	136	Eugenia Fatourou, Aikaterini Kafetzidou, Fabienne Marret, Konstantinos Panagiotopoulos and Katerina Kouli **Quaternary eustatic cycles and their impact on the Paleoceanography of the Gulf of Corinth (NE Mediterranean Sea)**	**374**
75	227	Kyriaki Fellachidou and Georgios Lazaridis **Underground rivers in Greece**	**377**
76	292	Christos Filis, Emmanuel Skourtsos, Armela Korovesai, Emmanuel Andreadakis, Eleni Kapourani, Nikolaos Karalemas and Apostolos Alexopoulos **Preliminary estimation of the recession coefficient of the "Kefalari Agios Ioannis" spring, Dimitsana, Peloponnesus, Greece**	**381**
77	336	Michael Foumelis, Elena Papageorgiou, Elisa Trasatti, Deodato Tapete, Stylianos Bitharis, Christos Pikridas and Costas Papazachos **Role of Earth Observation in Monitoring Santorini–Anydros Volcano-Tectonic Crisis**	**386**
78	204	Kalliopi Elli Fragkouli, Georgios Drakatos, Spyridon Pavlides and Sotirios Sboras **Seismotectonic Features of the 2023 Strong Earthquake Sequence in Southeast Turkey.**	**389**
79	62	Dimitris Galanakis, Dimitris Sakellariou, Sotiris Sboras, Spyros Pavlides, Kyriaki Iordanidou, Charalambos Georgiou, Athanasios Ganas, Yiannis Koukouvelas, Charalampos Kranis, Spiros Lalexos, Theodora Rondoyanni and Efthymios Lekkas **The Hellenic DataBase of Active Faults (HeDBAF): a new national geodatabase**	**393**
80	120	Odysseus Galanis and Areti Panou **An investigation of the use of deep-neural-network-based seismic arrival time picking methods for the automatization of earthquake sequence monitoring: The case of the November 3, 2024 MW 5.3 Kassandra earthquake**	**397**
81	37	Erasmia Galazoudi, George Bathrellos, Hariklia Skilodimou, Ioannis Koukouvelas and Konstantinos Nikolakopoulos **Evolution of map-making from prehistoric times to the Middle Ages**	**403**
82	22	Athanassios Ganas, Dimitrios Anastasiou, Georgios Mavropoulos, Ioannis Karamitros, Konstantinos Nikolakopoulos and Varvara Tsironi **Ground motion monitoring with low-cost multi-GNSS installations in Achaia, western Greece**	**408**
83	343	Athanassios Ganas, Pierre Briole, Varvara Tsironi, Georgios Goutsos, Nicolaos Madonis, Eustratios Liadopoulos and Ioannis Mintourakis **Geodetic monitoring of the 2024–2025 Santorini volcanic unrest using GNSS and InSAR data: preliminary results**	**413**

84	21	Athanassios Ganas, Francesco Carnemolla, Ioannis Karamitros, Nikolaos Madonis and Vasileios Georgakopoulos **Geodetic monitoring of the Methana volcano (central Greece) using campaign GNSS data: preliminary results**	**417**
85	254	Athanassios Ganas, Vasilis Kapetanidis, Varvara Tsironi, Andreas Karakonstantis and Ioannis Karamitros **Integrated monitoring of the Milos geothermal site (Cyclades, Greece) using InSAR, GNSS and local seismic network data**	**422**
86	102	Athanassios Ganas, Varvara Tsironi, Georgios Goutsos, Eirini Efstathiou, Christina Tsimi, Nikolaos Madonis and Vasileios Georgakopoulos **NOAFAULTs: 12-yrs of studies and investigations towards building a geospatial database for active faults in Greece and surrounding areas**	**427**
87	307	Amalia Gasteratou and Effie Kostopoulou **Climatological analysis and Trend Assessment of Climate Indices in two forest areas of Greece experienced extreme fire events in 2023.**	**430**
88	33	Alexandra Gemitzi, Odysseas Kopsidas, Foteini Stefani, Apostolos Polymeros, Vasilis Bellos and George Falalakis **A flood hazard assessment tool using satellite based high resolution land cover dataset within Google Earth Engine**	**436**
89	358	Gonca Gençalioğlu Kuşcu and Göksu Uslular **How medial tephra records contribute to proximal tephrochronology: Case study of Nisyros Volcano**	**441**
90	169	Maria Georgaki, Hrissi Karapanagioti, Małgorzata Wojtaszek-Kalaitzidi and Stavros Kalaitzidis **Evaluation of PAHs sorption behavior in coals and cokes**	**444**
91	138	Maria Nefeli Georgaki, Athanasios Georgakis, Dimosthenis Sarigiannis and Nerantzis Kazakis **Groundwater Quality Evaluation of Thessaly and Peloponnese: Data Analysis of 2019 year and Evidence of Degradation**	**448**
92	309	Georgios P. Georgalas, Polychronis Kolokoussis, Sofia Laskari and Konstantinos Soukis **Automatic Detection and Extraction of Geological Lineaments on Amorgos Island Using Satellite Data and Open-Source Software**	**454**
93	87	Ioanna Gerontidou and Antonios Koroneos **Major and trace element analysis on geological samples using WD-XRF on pressed pellets**	**458**
94	142	Dina Ghikas and Anna Batsi **The Art of Stone in Grevena-Kozani UGGp: Community-led Conservation Efforts**	**465**

95	63	Christina Giamali, George Kontakiotis and Assimina Antonarakou **Paleoecological imprints of pteropod assemblages and their response to sapropel S1 conditions in the eastern Mediterranean Sea**	**468**
96	212	Panagiota P. Giannakopoulou, Aikaterini Rogkala, Paraskevi Lampropoulou, Petros Koutsovitis, Maria Kalpogiannaki, Vasileios Giamas, Odyseas Seikatis, Ihtisham Islam and Petros Petrounias **Correlation study of overland and marine aggregates capable to be used in various construction applications**	**472**
97	69	Anna Giannakou, Nikolaos Soulakellis, Nikolaos Zouros and Dimitrios Kavroudakis **Estimation of an empirical relationship for calculating quantities of demolished materials through three-dimensional visualization of buildings affected by the earthquake of June 12, 2017, in Vrisa, Lesvos.**	**477**
98	282	Katerina Giouri, Christos L. Stergiou, Vasilios Melfos, Lambrini Papadopoulou, Nikolaos Kantiranis, Irena Peytcheva and Elitsa Stefanova **Preliminary results on the toxic elemental accumulation in the Fe-oxides of the stream sediments from Palea Kavala, Northern Greece**	**482**
99	311	Salvatore Giuffrida, Letizia Anderlini, Shannon Graham, Francesco Carnemolla, Fabio Brighenti, Giorgio de Guidi, Flavio Cannavò and Riccardo Caputo **Investigating the interseismic coupling degree of the northern Apennines external Arc in Emilia Romagna region, (northern Italy).**	**488**
100	117	Antonela Gjika, Christina Stouraiti, Panagiotis Voudouris, Konstantinos Laskaridis, Marianthi Anastasatou, Constantinos Mavrogonatos and Harald Strauss **Geochemical and Mineralogical Study of the Antimony (Sb)-mineralization at the north Pelion region, Magnesia, Greece**	**491**

Volume C: Papers 100-150

A/A	EC	AUTHORS and TITLE	PAGE
101	355	Konstantinos Gkogkas, Costas Papazachos, Nikolaos Chatzis, Dominikos Vamvakaris, Eleni Karagianni, Chrisa Ventouzi, Alexandros Vellis, Nikolaos Anterriotis-Kalpakidis, Dimitrios Madelis, Parthena Paradisopoulou, Eleni Aidona and Christos Pikridas **SantoArray: Densifying station coverage in Santorini amidst the Amorgos-Anydros earthquake swarm crisis**	**494**
102	337	Marilia Gogou, Nafsika Ioanna Spyrou, Spyridon Mavroulis, Niki Evelpidou, Maria Mavrouli, Efthimis Lekkas and Assimina Antonarakou **Assessment of assembly point suitability in tsunami-prone South Aegean coasts after the 2025 Santorini-Amorgos earthquake swarm and related risk reduction measures**	**498**
103	165	Vasilis Golfinopoulos, David J. W. Piper, Avraam Zelilidis, Georgia Pe-Piper, Penelope Papadopoulou, Nicolina Bourli and George Iliopoulos **Palaeoenvironmental Interpretation and Soft Sediment Deformation of the Ionian Basin Lower Jurassic Formations in Astakos (Western Greece)**	**504**
104	234	Georgios Goutsos, Vasiliki Kouskouna, Georgios Sakkas and Nikolaos Sakellariou **A decade of data: Updating the Hellenic Macroseismic Database for historical earthquakes**	**508**
105	18	Ioannis Grendas and Zafeiria Roumelioti **Seeking for dependencies of the high frequency "kappa" parameter of earthquake spectrum on weather/climate conditions**	**514**
106	326	Georgios Grimpylakos **Digital model of Hydrological components, Mean annual Temperature, Precipitation and Evapotranspiration in Macedonia, Greece**	**521**
107	75	Maria Groumpou, Ioannis Koukouvelas, Konstantinos Nikolakopoulos, Josep Sanjuan, Penelope Papadopoulou and George Iliopoulos **The Pheneos palaeolake in N. Peloponnese, Greece**	**527**
108	131	Maria Grylionaki, Nikolaos Theodoulidis, Areti Panou and Panagiotis Chatzidimitriou **Estimation of soil vulnerability index in the metropolitan area of Thessaloniki (Greece)**	**530**
109	9	Levent Gülen **Seismotectonics of the NE Aegean region: The Lesvos Island and the Gulf of Edremit**	**531**
110	366	Erdal Gumus, Nikolas Zouros **The rocks connect us: Volcanic geoheritage of Lesvos Geopark (Greece) and Ida Madra Geopark (Türkiye)**	**537**
111	324	Petros Hadjicostas and Evi Kazamia **Assessing Climate Change Impacts on Troodos Mountain (Troodos UNESCO Global Geopark area) Through Methodological Approaches and Community Engagement in the ClimEmpower Project**	**542**

112	4	Maria Helena Henriques, Salomé C. Custódio and Ismar S. Carvalho **Geoconservation in Portugal: an overview**	**543**
113	247	Iatrou Alexandra, Karakostas Dimitrios, Fragkiskos Markozanes, Aikaterini Karditsa and Serafeim Poulos **Beach retreat due to sea level rise induced by climate Change: The case of the Korasida, Heromylos and Limnionas beaches of south Evia facing the Aegean Sea.**	**549**
114	294	George Iliopoulos, Penelope Papadopoulou, Ilias Valiakos and Nickolas Zouros **Contribution to the stratigraphic study of the pyroclastic Formations of the Lesvos Petrified Forest, Lesvos Island, Greece.**	**552**
115	209	Dimitrios Ioannidis, Emmanouil Katrivanos and Alexandros Chatzipetros **Geological study of the basement structure in the wider area of Filiro (Circum-Rhodope Belt, Central Macedonia, Greece)**	**558**
116	313	Despoina Ioannidou and Olga-Joan Ktenidou **Integrating Geotechnical Data and Site Response Analyses in the Municipality of Chalandri, Athens, Greece**	**564**
117	319	Angelos Kannelos Irakleidis and Olga Joan Ktenidou **Seismic vulnerability of cultural heritage. The case of the archaeological museum of Rhodes: building performance, safety of the public and exhibits**	**570**
118	157	Alexandros Wilfred Irakliotis and George Papathanassiou **Rock slope stability analysis on the road axis of Kleisoura – Kastoria, Greece**	**576**
119	140	Aikaterini Kafetzidou, Eugenia Fatourou, Konstantinos Panagiotopoulos, Fabienne Marret, Olga Koukousioura and Katerina Kouli **Relict Taxa and Refugial Dynamics in the Corinth Gulf: Insights from the Pollen Record**	**579**
120	94	Aikaterini Kafetzidou, Olga Koukousioura, Vassilis Zotiadis and Katerina Kouli **Rare Insights in the Oligocene flora of Thrace (Greece): Preliminary results from the Rhodopi Petrified Forest**	**581**
121	1	Maria Kaimakami **Mapping the geological landscape of NW bay of Navarino through time**	**583**
122	50	Maria Kakavas, Aggeliki Kyriou, Konstantinos Nikolakopoulos and Ioannis Koukouvelas **The influence of DSMs spatial resolution on rockfall simulation.**	**587**
123	8	Christina Kalaitzi and Dimitris Kostopoulos **The late Ruscinian leporid Trischizolagus (Leporidae, Lagomorpha) from Megalo Emvolon (Thessaloniki, Greece)**	**594**
124	171	Panagiotis Kalaitzis, Michael Foumelis, Antonios Mouratidis and Nikolaos Soulakellis **Multiscale Geo-visualization Dashboard of Persistent Scatterer Interferometry SAR Data, Lesvos Island, Greece**	**596**

125	221	Iraklis Kalogeropoulos, Georgios Lazaridis and A. Tsekoura **Methodology of cave mapping: comparison of surveys**	**601**
126	174	Kalpogiannaki Maria, Aikaterini Rogkala, Panagiota P. Giannakopoulou, Petros Koutsovitis, Paraskevi Lampropoulou, Petros Petrounias, Dimitrios Papoulis, Nikolaos C. Koukouzas and Panagiotis Pomonis **Geoeducational and Geotourism values of geological resources as novel path for Geosciences Education**	**605**
127	111	Isidoros Kampolis, Panagiotis Voudouris and Evgenia Moraiti **The pseudokarst at the Kaki Thalassa Bay reveals unknown ancient mining activities (Lavreotiki UNESCO Global Geopark)**	**610**
128	258	Christos Kanellopoulos, Vasiliki Aggelatou and Christos Papatrechas **Preliminary results of black sands in Corfu Island (Ionian Sea, Greece).**	**614**
129	220	Christos Kanellopoulos, Dimitrios Galanakis, Leonidas Moforis, Sotiris Sboras, Olga Chalkiadaki, Nikolaos Xirokostas and George Vougioukalakis **Preliminary results on Agios Efstratios island (NE Aegean Sea, Greece) geology.**	**617**
130	214	Christos Kanellopoulos, Dimitrios Galanakis, Sotiris Sboras, Kyriaki Iordanidou, Leonidas Moforis, Nikolaos Xirokostas, Olga Chalkiadaki and George Vougioukalakis **Pagasitikos volcanism (Lichades-Kamena Vourla-Achillio-Mikrothives-Porfyrio-Psathoura): Preliminary results on a Quaternary tectonically related volcanism.**	**620**
131	35	Konstantina Kantareli and Vassilis Sakkas **Investigating crustal deformation of Zakynthos Island using Satellite Interferometry (InSAR): pre- and post- seismic analysis of the October 25, 2018 earthquake**	**623**
132	80	Vasilis Kapetanidis, Ioannis Spingos, Christofer Kaltsas and George Kaviris **Application of a machine-learning model for the determination of focal mechanisms in the area of the Corinth Rift Laboratory Near-Fault Observatory (CRL NFO), Central Greece**	**629**
133	58	Athanasia Theodora Karachaliou, Dimitrios Vogiatzis and Nikolaos Kantiranis **Preliminary results of physicomechanical properties of lightweight mortars using palygorskite as sand replacement**	**636**
134	172	Özlem Karagöz and Onur Tan **Microtremor array explorations and the importance of local site effect in Western Türkiye**	**642**
135	335	Vasileios Karakostas, Anthony Lomax, Vasilis Anagnostou, Eleftheria Papadimitriou, Valerio Acocella, Stephen Hicks and Pierre Henry **The 2025 seismicity burst in the Santorini – Amorgos seismovolcanic zone**	**646**
136	367	P. Karanis **Climate changes, neglected and emerging diseases**	**651**

137	167	Efstratios Karantanellis, Vassilios Marinos and Anika Braun **AI-Driven Approaches for Landslide Modeling: Challenges and Opportunities**	**653**
138	226	Georgia Karountzou, Maria-Roi Panagiotaki, Dionisis Semitekolos and Costas Charitidis **Evaluation of Greek clay for pottery applications**	**656**
139	361	Jens Karstens, Paraskevi Nomikou, Marius Isken, Michelle Maree Parks, Vincent Drouin, Emilie E.E. Hooft, Thomas R. Walter, Mahmud Haghshenas Haghighi and Dimitris Anastasiou **The 2025 seismic crisis reveals a coupled magma feeding system at Santorini and Kolumbo**	**657**
140	280	Theodora Karympali **The role of painting as a historical indicator of relative sea-level change: a review**	**659**
141	154	Marianthi Katheri, Olga Koumoutsakou and Assimina Antonarakou **Challenges and Opportunities in the AI Era: Promoting Earth Science Education for Deaf and Hard of Hearing Students**	**666**
142	347	Ioannis Katsafados, Dimitrios Anastasiou, Melissinos Paraskevas, Maria Tsakiri, Paraskevi Nomikou and Costas Synolakis **Preliminary results of displacements from the recent seismic and volcanic crisis in the Santorini Island complex, Greece**	**668**
143	90	Anna Katsigera, Paraskevi Nomikou, Paraskevi Polymenakou, Sergio Sciré Scappuzzo, Gianluca Lazzaro, Aggelos Mallios, Valsamis Ntouskos, Sotiris Spanos, Christos Antoniou, Andrea Luca Rizzo, Manfredi Longo, Javier Escartin, Konstantinos Karantzalos, Walter D Alessandro, Lars-Eric Heimburger, Stephanos Kilias, Theodoros Mertzimekis, Fausto Grassa, Danai Lampridou, Eirini Anagnostou and Vasiliki Papadimitriou **SANTORY shallow seafloor observatory: First time series data from an active submarine volcano**	**674**
144	176	Chrysoula Katsora, Evaggelos Levadiotis, Ourania Tzoraki and Nektaria Papadopoulou **Flash drought assessment: insights from Lesvos island, Greece**	**677**
145	251	Katerina Kavoura, Garyfalia Konstantopoulou and Panagiotis Paschos **Rainfall-induced landslides in Corfu island: effectiveness of the regional scale landslide susceptibility map**	**681**
146	201	Nerantzis Kazakis, Ioanna Sideri, Maria Margarita Ntona, Vasiliki Stavropoulou, Dimitra Lampropoulou, Eleni Zagana and Konstantinos Voudouris **Origin of nitrate pollution in groundwater of Mygdonia Plain, Greece**	**685**
147	104	Shoaib Ahmed Khan, Theodora Tsourou, Emmanuel Skourtsos, Konstantinos Soukis, Ioannis Michailidis, Elisavet Skampa and Maria Triantaphyllou **Micropaleontological and paleoenvironmental study of carbonate intercalations within Boeotia (Greece) clastic formations**	**691**

148	79	Georgia Kitsaki, Christos L. Stergiou and Haritakis Papaioannou **"Vikos-Aoos Geopark: Toponyms as a Link Between Geological Heritage and Culture"**	**693**
149	241	Charalampos Kkallas, Costas Papazachos and Basil Margaris **A Duration Model for Strong Seismic Motions of Intermediate-Depth Earthquakes in the Southern Aegean and its implication for stochastic simulations**	**695**
150	49	Foivos Klimis, Olga Sykioti, Efthimios Karymbalis and Isaak Parcharidis **Lunar Pits: Statistical Analysis of Morphometric and Geophysical Properties**	**700**
151	92	Aliki Kokkala, Vassilis Marinos and George Papathanassiou **Utilizing engineering geological database for urban geohazard assessment: a case study from Thessaloniki, Greece**	**706**
152	276	Sotirios Kokkalas, Vasileios Psarros and Petros Koutsovitis **Diapiric structures in evaporites of Western Greece as potential geoenergy storage areas.**	**709**

Volume D: Papers 151-200

A/A	EC	AUTHORS and TITLE	PAGE
153	281	Eleni Kolaiti, Nikolaos Soulakellis, Georgios Tataris and Nikos Mourtzas **The Argo-Beachrock Project: web mapping and geovisualisation of beachrocks using UAS along the coast of the Argolic Gulf, Greece**	**715**
154	353	Eleni Kolaiti, Nikolaos Zouros and Nikos Mourtzas **The Corinth Canal (Greece): monumentality and protection**	**721**
155	179	Maria Kolendrianou, Zacharenia Kefalogianni, Agapi Kalomoiri and Charalampos Fassoulas **Synergies for geo- education: materials and initiatives from Psiloritis UNESCO Global Geopark and the Center for Environmental Education and Sustainability of Anogia, (Crete) Greece.**	**728**
156	156	Pavlina Kolyva, Olga Koumoutsakou and Assimina Antonarakou **The Role of Fairy Tales in Fostering Geoscience Understanding in Early Childhood**	**735**
157	119	Georgios Kontokostas and Assimina Antonarakou **Application of the educational proposal for Geoscience: Geology in secondary education through educational geopaths in the urban environment.**	**737**
158	260	Orestis Kontopidis, Alexandros Theocharis, Nikolaos Koukouzas, Jan Burda and Ioannis Zevgolis **Interpretation of CPTu data for mining slope stability assessment in reclamation projects: The case of pit Lake Most, Czech Republic**	**740**
159	259	Orestis Kontopidis, Alexandros Theocharis and Ioannis Zevgolis **A semi-quantitative multi-hazard approach for Tailings Storage Facilities**	**745**
160	124	Efterpi Koskeridou, Christos Psarras, Evangelia Rentoumi, Ioannis Giaourtsakis and Marija Bošnjak **The role of the museums in the geoscience education– examples from the Museum of Paleontology and Geology of the National and Kapodistrian University of Athens, Greece and the Croatian Natural History Museum, Croatia**	**750**
161	17	Panagiotis Kosmas, Constantinos Loupasakis, Vasiliki Eleftheriou, Rozalia Christodoulopoulou and Antigoni Vrouva **Ultrasonic analysis of the structural stones of the Parthenon at the Acropolis of Athens – Investigation of the physical / mechanical properties and integrity control of the grouted Joints**	**753**
162	180	Georgia Kostaki, Hans-Juergen Gawlick, Adamantios Kilias, Sigrid Missoni, George Ghon and Emmanouil Katrivanos **The Koziakas Mélange Unit: New perspectives on Its Mesozoic paleogeographic and geotectonic evolution (Central Greece)**	**757**

163	308	Effie Kostopoulou, Christos Giannakopoulos, Constantinos Nefros and Constantinos Loupasakis **Assessing Climate Extremes as Drivers of Geohazards in Greece**	**763**
164	122	Sotiria Kothri, Paraskevi Nomikou, Maria Filomena Loreto, César Rodríguez Ranero, Danai Lampridou, Elisavet Nikoli, Irene Merino, Valentina Ferrante, Serafeim Poulos and Athanassios Ganas **Submarine geomorphological structures in the Ionian Sea, Greece**	**769**
165	66	Christina Kotsakostoudi, Anna Bourliva, Christina Mytiglaki, Lambrini Papadopoulou and Nikolaos Kantiranis **Heavy metal concentrations in indoor house dusts from the city of Thessaloniki, N. Greece: a small-scale study**	**773**
166	103	Artemis Kotsomitopoulou, Nikolaos Tsaparas and Galazoudi Erasmia **New Clypeaster fossils from South Crete (Rodakino, Rethymno)**	**778**
167	310	Athanasios Koukoulis and Markos Xenakis **Measurements of soil gas emissions (Radon and Thoron) in the municipality of west Lesbos, Stypsis – Petras, and correlation with tectonic structures (Rift Zone) of the subsidence coast of Petra**	**782**
168	152	Olga Koukousioura, Paraskevi Nomikou, Adam Woodhouse, Shun Chiyonobu, Paraskevi Polymenakou, Tim Druitt, Steffen Kutterolf, Thomas Ronge, Sarah Beethe, Alexis Bernard, Carole Berthod, Hehe Chen, Acacia Clark, Susan DeBari, Sofia Della Sala, Tatiana Fernandez-Perez, Ralf Gertisser, Christian Hübscher, Raymond Johnston, Christopher Jones, Kumar Batuk Joshi, Anna Katsigera, Stephanos Kilias, Gunther Kletetschka, Xiaohui Li, Michael Manga, Molly McCanta, Iona McIntosh, Abigail Metcalfe, Antony Morris, Katharina Pank, Vasiliki Papadimitriou, Ally Peccia, Jonas Preine, Masako Tominaga, Yuzuru Yamamoto, Takeru Yoshimoto and Dimitrios Papanikolaou **Foraminiferal response to a giant shallow-marine pyroclastic-flow-eruption from ancestral Santorini discovered by IODP Expedition 398 – Objectives, challenges and results of deep drilling into Christiana-Santorini-Kolumbo volcanic field**	**789**
169	139	Olga Koukousioura, Konstantinos Panagiotopoulos, Eugenia Fatourou, Aikaterini Kafetzidou, Paula Diz, Katerina Kouli and Patrick Grunert **Late Quaternary dynamics of paleoenvironments and ecosystems in the Gulf of Corinth (eastern Mediterranean): IODP Expedition 381**	**792**
170	100	Nikolaos Koukouzas, Pavlos Tyrologou, Christos L. Stergiou, Julio Carneiro, Paula Fernández-Canteli, Christina Karatrantou and Stamatina Asimakopoulou **Characterization of Sandstone Formations in the Mesohellenic Trough for CO2 Storage: Insights from the Integration of Optical Mineralogy, Geochemistry, and Automated Imaging Techniques**	**794**
171	153	Olga Koumoutsakou and Assimina Antonarakou **Unveiling the Potential of AI in Geoscience Education: A Student-Centered Perspective**	**800**

172	245	Vasiliki Koumpou, Serafeim Poulos, Aikaterini Karditsa, Stylianos Petrakis and Vasileios Kapsimalis **An insight to grain size composition of the beach sediment along the north coast of the Messiniakos Gulf (Greek Mainland).**	**803**
173	105	Alexandros Aristotelis Koupatsiaris and Hara Drinia **A systematic review of grey literature in Greek universities repositories to uncover Greek UNESCO Global Geoparks**	**805**
174	98	Alexandros Aristotelis Koupatsiaris and Hara Drinia **Assessing Educators' Sense of Place and Geoethical Awareness at the 4th Summer School of Sitia UNESCO Global Geopark**	**810**
175	41	Christos Kourouklas, Pavlos Bonatis, Eleftheria Papadimitriou and Vasileios Karakostas **Fault–based recurrence models and occurrence probabilities of large earthquakes (M≥6.0) in the Corinth Rift, Greece**	**817**
176	191	Petros Koutsovitis, Gerasimina Pahaki, Vasileios Giamas and Lemonia Kalantzi **A preliminary petrographic approach to the pyroclastic tuffs in the island of Tilos**	**824**
177	187	Petros Koutsovitis and Aikaterini Papaioannou **A preliminary petrographic approach of the altered Triassic volcanic lavas in Argolis, Greece**	**828**
178	183	Petros Koutsovitis, Konstantinos Tetisis and Georgia Kolovadi **Petrographic evidence for the metamorphic conditions in ultramafic rocks at Makrymalli – Evia Island**	**830**
179	36	Petros Koutsovitis, Michiel van der Meulen, Tirza van Daalen, Pavlos Tyrologou, Nikolaos Koukouzas, Alkiviadis Sideridis, Christos Karkalis, Michel Grégoire, Petros Petrounias, Theodoros Ntaflos and Konstantinos Lentas **An outline on some of the recently reported granitoids from St. Martin Island**	**831**
180	64	Evlampia Kouzeli, Olga Sykioti, Konstantinos Nikolakopoulos, Saeid Asadzadeh, Friederike Koerting and Daniel Schläpfer **Mineral mapping using satellite multispectral and hyperspectral data for a pyrite mine in the frame of the m4mining project**	**833**
181	298	Kalliopi Kravari and Dimitrios Emmanouloudis **A Novel Approach to Flood and Drought Management in Arid Regions using Multi-Agent Systems**	**840**
182	218	Phaedra Kravvariti, Andreas Tzanis, Vasileios Sakkas and Haralambos Kranis **Contemporary distributed block deformation in the South Aegean Sea (Greece), deduced by the analysis of continuous GNSS measurements**	**846**
183	291	Konstantina Krotka, Fikos Ilias and Papathanassiou George **Geophysical investigation of landslide phenomena in the Perivoli area, Grevena, using the electrical resistivity tomography method**	**852**

184	325	Olga-Joan Ktenidou, Antonia Papageorgiou, Fevronia Gkika, Erion-Vasilis Pikoulis, Kalliopi Fragouli, Fanis Chalaris, Spyros Liakopoulos, Ziya Cekinmez, Panagiotis Savvaidis and Christos Evangelidis **A holistic proposition for assessing reference station conditions**	**858**
185	6	Erwin Kunz **The Xerias Window near Argos (Peloponnesus)**	**863**
186	290	Anastasios Kyriakos, Grigorios Aarne Sakellaris, Vasilios Melfos, Christos L Stergiou, Lambrini Papadopoulou and Nikolaos Kantiranis **Mineralogy and Geochemistry of the Non-Sulfide Zinc-Lead Deposits, Thasos Island, North Aegean, Greece**	**864**
187	175	Anastasios Ladas, Vasileios Melfos, Lamprini Papadopoulou and Nikolaos Kantiranis **Study of the geochemical distribution of uranium and thorium in the soils of the Sarigiol Basin, Kozani, and their environmental significance.**	**870**
188	285	Lida Lakidi, Nafsika Ioanna Spyrou, Michalis Diakakis, Christos Filis, Evelina Kotsi, Spyridon Mavroulis, Emmanuel Skourtsos, Haralambos Kranis and Efthymios Lekkas **Flood Dredge Spoils Mapping with the Use of UAS and GIS: The Case of 2020 Evia Flood**	**876**
189	322	Aggelos Lamprakopoulos and Nikolaos Zouros **Contribution to the neotectonic study of West Lesvos**	**882**
190	213	Georgios Lazaridis, Bogdan Onac, Jo De Waele, Konstantinos Vouvalidis, Spyridon Gkelis, Vasilis Gerovasileiou, Konstantinos Trimmis, Kimon Papadimitriou, Panagiotis Georgiakakis, Kaloust Paragamian, Despina Dora, Savvas Paragkamian, Markos Digenis, Foteini Sdraka, C. Alexandropoulou, T. Alikakou, C. Arvaniti, N. Chatzinikolaou, K. Chavanidis, X. Georgopoulou, A. Giannopoulou, D. Koumparelou, C. Lytra and I. Simoglou **Field-Work Methods in Speleology: A Multidisciplinary Training Approach**	**888**
191	219	Georgios Lazaridis, Foteini Sdraka, M. E. Georgiadou, A. Batsi, D. Gkikas, Despina Dora and Konstantinos Trimmis **Evaluation of karst geosites in Grevena-Kozani UNESCO Global Geopark**	**892**
192	217	Georgios Lazaridis, Christos L. Stergiou, Alexandros Chatzipetros, Konstantinos Stamoulis, Despina Dora, Xenia Georgopoulou, Konstantinos Vouvalidis, Evangelos Nikolaou, Panagiotis Paschos, Georgia Kitsaki and Haritakis Papaioannou **Utilizing Information and Communication Technology for geosite development: The case of sulfuric acid caves in the Vikos-Aoos UNESCO Global Geopark**	**898**
193	148	Vasiliki Lianou and Petros Tsakiridis **Management of solid wastes from offshore oil drilling, based on their geochemical properties: A case study from the Prinos facilities in the Northern Aegean Sea.**	**903**
194	215	Eleni M. Liapi, George Iliopoulos and Nikolaos Zouros **Palaeobotanical study of the Vrisaki flora from the Lesvos Petrified Forest**	**906**

195	364	Marco Liuzzo, Cinzia Federico, Fausto Grassa, Christos Kanellopoulos, Kostas Kyriakopoulos, Spyros Lalechos, Maria Manousaki, Barbara Nisi, Giancarlo Tamburello, Franco Tassi, Orlando Vaselli, George Vougioukalakis, Antonio Paonita, Francesca Bianco and Walter D'Alessandro **Preliminary results of the fluid geochemistry surveillance campaigns on Santorini island (Greece) after the 2025 Anydros seismic sequence**	**912**
196	25	Athanasios Lois, Dimitrios Giannopoulos and Efthimios Sokos **Automated Seismic signals' identification: A statistical criterion for decreasing the false alarm rate; Implementation on synthetic data.**	**913**
197	123	Maria Filomena Loreto, Valentina Ferrante, Marco Ligi, Filippo Muccini, Camilla Palmiotto, Lorenzo Petracchini, Stefania Romano, Athanassios Ganas, Andrea Argnani, Alessia Conti, Marco Cuffaro, Alenssandra Pensa, Sotiria Kothri, Danai Lampridou, Irene Merino, Cesar R. Ranero and Paraskevi Nomikou **Mapping the active Faults affecting Ionians Islands, Western Hellenic Arc**	**917**
198	101	Georgios Lyras, Athanassios Athanassiou, Alexandra van der Geer, George Kontakiotis, Evangelia Besiou and Assimina Antonarakou **The Early Pleistocene vertebrate fauna of Vatera, Lesbos, Greece**	**922**
199	317	Parina Machaira, Effie Kostopoulou, Christos Giannakopoulos, Myrto Gratsea and Gianna Kitsara **Assessing the impact of climate change on olive cultivation in the Peloponnese, Greece: A long-term analysis using climate indices**	**925**
200	144	Efthymios Magkoufis, Athanassios Ganas, Konstantinos Nikolakopoulos and Betty Charalampopoulou **A WebGIS platform for the multiparametric monitoring of ground deformation and critical infrastructures under the name PROION**	**931**
201	246	Mangifesta M., Scalella G., Sciarra N. **An example of DsGSDs in Abruzzo Region (Central Italy): the complex case of Civitella del Tronto**	**935**
202	38	Emmanouil Manoutsoglou **The 'treasure' of aeolianites on the coastal front of Marathopoli Dialiskari, Messinia, Western Coast of the Peloponnese: rhizoliths petrified forest and historical abandoned quarries**	**939**
203	47	Emmanouil Manoutsoglou, Nikolaos Andronikidis, Ilias Lazos, Georgios Kritikakis, Nikolaos Economou, Emmanouil Steiakakis, Georgios Xiroudakis and Antonios Vafeidis **Monitoring sea water intrusion at Samaria Gorge National Park**	**945**

Volume E: Papers 201-250

A/A	EC	AUTHORS and TITLE	PAGE
204	26	Kyriaki Manta, Grigoris Rousakis, Maria Geraga, George Papatheodorou, Dimitris Sakellariou and Aristomenis Karageorgis **Preliminary results on sedimentological characteristics of Mass Transport Deposits (MTDs) during the Amorgos tsunami 1956: sediment provenance and geochemical elements.**	**949**
205	341	Spyridon Mavroulis, Andromachi Sarantopoulou, Maria Mavrouli, Assimina Antonarakou and Efthymios Lekkas **Increased preparedness in anticipation of an imminent disaster: actions during the early 2025 Santorini – Amorgos (Aegean Sea, Greece) earthquake crisis and lessons learned**	**955**
206	277	Vasileios Mazarakis, Konstantinos Tsanakas, Noam Greenbaum, Dimitrios Vasileios Batzakis, Alessia Sorrentino, Ioannis Tsodoulos, Kanella Valkanou and Efthimios Karymbalis **Application of GIS-Based Multicriteria Decision Analysis and Analytic Hierarchy Process for Flood-Hazard Mapping in the Messapios River Basin, Central Evia Island, Greece**	**962**
207	287	Margarita Melfou, Panagiotis Voudouris, Reiner Klemd, Manuel Keith, Alexandre Tarantola, Vasilios Melfos, Lambrini Papadopoulou and Nikolaos Kantiranis **Indium and tellurium enrichment in sulfides and sulfosalts at the Pefka high- to intermediate-sulfidation epithermal deposit, Rhodope, Greece**	**969**
208	84	Ioannis Michalakis, Adonis Photiades and Spyros Staridas **An Overview of Geological Map Sheets of Crete by HSGME**	**975**
209	20	Ioannis Michalakis and Eleni Tsolaki **Water Wells in Crete: Distribution by Municipality, Use, and Ownership—Results of a Systematic Inventory in Greece**	**981**
210	12	Ioannis Michalakis, Eleni Tsolaki, Constantinos Loupasakis, Konstantinos Voudouris and Charalampos Kontoes **Preliminary Results on Land Subsidence Induced by Groundwater Overexploitation Using Copernicus Sentinel Data: Insights from the Messara Basin, Crete**	**987**
211	118	Maria Michalopoulou, Nikolaos Depountis, Eleni Zagana and Pavlos Avramidis **Application of geochemical indices for heavy metal evaluation in the Pinios Dam, Greece**	**993**
212	127	Sofia Michalopoulou, Sara Faulwetter, Dionisios Christodoulopoulos, Alexis Ramfos and Pavlos Avramidis **The impact of aquaculture units on Copper (Cu) concentrations in marine sediments**	**999**
213	196	Georgios Michas **Spatiotemporal diffusion variability in seismic swarms**	**1004**
214	137	Zoe Misiri, Spyridon Lainas and Nikolaos Depountis **Hellenic Landslide Platform (He.L.P.): A Geospatial Landslide Inventory for Western Greece**	**1009**

215	78	Leonidas Moforis, George Kontakiotis, Assimina Antonarakou, Alexandra Zambetakis-Lekkas, Ahmad Sajjad, Panagiotis Paschos, Dimitrios Galanakis, Christos Kanellopoulos, Sotiris Sboras, Hammad Tariq Janjuhah, Ilias Lazos and Vasileios Karakitsios **Biostratigraphy, Sedimentary Microfacies, and Depositional Environment of the Paleocene-Early Eocene Calciturbidites in Gardiki Section (Epirus, Western Greece)**	**1014**
216	349	Isavela Monioudi, Dimitrios Chatzistratis, Adonis Velegrakis, Anastasios Risgos, Antonis Chatzipavlis, Antigoni Nikolaou and Olympos Andreadis **The geospatial characteristics of an island beach: the case of Kos, Greece**	**1018**
217	29	Eugenia Moraiti, Panagiotis Voudouris and Vassiliki Barsaki **Innovative educational programs at the Lavreotiki UNESCO Global Geopark: the ERASMUS+ "ARTeMIS" Program Action for Research and Teaching Mineral exploration Inclusive School, Greece**	**1023**
218	53	Hara Moshou and Hara Drinia **Empowering Future Generations: Incorporating Geo – Environmental Education on Climate Change into Greek Compulsory Education**	**1025**
219	19	Nikos Mourtzas, Antonis Gkiolas, George Papacharalambous, Anastassios Tsakonas and Eleni Kolaiti **Slope stability rehabilitation in the traditional settlement of Chora, Andros Island, Greece**	**1030**
220	32	Harry Moustakas, Zafeiria Roumelioti, Efthimios Sokos and Christos Evangelidis **The Horizontal-to-Vertical Spectral Ratio Method for Underground Voids Detection: Testing Over Mycenaean Tombs**	**1036**
221	194	Lemonia Moysidou, Ermioni Eirini Papadopoulou, Stavros Proestakis, Nikolaos Zouros and Nikolaos Soulakellis **Multiscale 3D mapping and Geovisualization of a Petrified Forest Park in Lesvos, Greece, using UAV.**	**1042**
222	301	Ch. Mpakopoulou, D. Tsesmelis, K. Kalogeropoulos, K. Vasilakou, E. Feloni, E. Zervas and A. Tsatsaris **Investigating Drought Dynamics in Greece Using Climate and Meteorological Indicators**	**1048**
223	40	Jan Mrlina **Density modeling based on gravity survey at faulted area around Aigion, Gulf of Corinth, Greece**	**1054**
224	39	Jan Mrlina **Gravity monitoring at Santorini volcanic island, Greece**	**1060**
225	147	Valentini Navrozidou, Olga Koukousioura, Sofia Doani, Peter Frenzel, Maria Triantaphyllou, Konstantinos Albanakis and Georgios Syrides **Ostracod-based environmental reconstruction of Lake Koronia, (Central Macedonia-Greece) during the Holocene**	**1066**

226	14	Constantinos Nefros, Gianna Kitsara, Constantinos Loupasakis and Christos Giannakopoulos **Rapid Detection of Landslides Triggered by Mediterranean Cyclones Using Google Earth Engine and Open-Access Data**	**1068**
227	112	Elisavet Nikoli, Paraskevi Nomikou, Evangelos Tasioulas, Christophis Koroneos, Kalliopi Sakkali, Georgios Koukourakis, Panagiotis Nastos, Varvara Antoniou, Dimitrios Emmanouloudis, George Pehlivanides and Aristidis Batis **Integrating Volcanic Geoheritage and Community Engagement: The Case of Nisyros aspiring UNESCO Global Geopark**	**1073**
228	293	Ioanna Nikolopoulou, Gian Maria Bocchini, Marco Roth, David Essing, Rebecca Harrington, Anna Serpetsidaki, Ioannis Fountoulakis, Christos Evangelidis and Efthimios Sokos **The 2024 March 29, 5.9 ML Strofades Earthquake (Greece) and its Seismic Sequence: Relocation, Focal Mechanism Solutions and Stress Inversion**	**1075**
229	141	Stefania Nisio, Sergio Madonna, Giancarlo Ciotoli, Gentili Francesco and Livio Ruggieri **Sinkholes, roads and exceptional transports, a risk to be assessed**	**1079**
230	108	Paraskevi Nomikou, Elisavet Nikoli, Evangelos Tasioulas, Christophis Koroneos, Kalliopi Sakkali, Georgios Koukourakis, Panagiotis Nastos, Varvara Antoniou, Dimitrios Emmanouloudis, George Pehlivanides and Aristidis Batis **Nisyros Geopark: A Living Laboratory of Volcanic Geoheritage in the South Aegean**	**1085**
231	129	Maria Margarita Ntona, Vasiliki Stavropoulou, Dimitra Lampropoulou, Eleni Zagana, Christos Pouliaris and Nerantzis Kazakis **Assessment of groundwater quality and seasonal dynamics in Chortiatis, northern Greece: Insights for sustainable resource management**	**1088**
232	24	Panos Ntontos **Evaluation of National Groundwater Monitoring Network at the Peloponnese, Greece**	**1094**
233	189	Efthymios Ntouros, Nikolaos Sofis, Maria Ellie Damoulianou, Margarita Iatrou, Tassos Grammatikopoulos, George Papaptheodorou and Stavros Kalaitzidis **Characteristics of REE mineralization in bauxite strata and in bauxite residue deposited into the Corinth Gulf, Greece**	**1100**
234	231	Grace Paez, Karla Vizuete, Alexis Debut, Mario Cruz-D'Howitt, Juan José Ortiz and Theofilos Toulkeridis **Characterization and timing of charcoal in geoheritage sites preserved by major volcanic destructions – Geoarcheological and paleo-environmental considerations in Ecuador**	**1103**
235	346	Gerasimos Papadopoulos, Ioanna Triantafyllou, Constantinos Siettos and Konstantinos Spiliotis **Foreshock-aftershock discrimination in real-time during the 2025 seismic cluster near Santorini volcano, Greece, based on earthquake statistics and complex networks theory**	**1108**

236	65	Theodoros Papadopoulos, Sofia Pechlivanidou, Michael Foumelis and Christos Pennos **Image-based grain size analysis of coastal sediments**	**1110**
237	85	Ermioni Eirini Papadopoulou, Stavros Proestakis, Christos Nikolaos Anagnostopoulos and Nikolaos Soulakellis **Development of a cartographic web application for monitoring the Corinth Canal using UAV data**	**1113**
238	236	Evdokia Papadopoulou and Alexandros Chatzipetros **An integrated approach using Remote Sensing and the Environmental Seismic Intensity Scale ESI 2007 for three major earthquakes in the Aegean region**	**1118**
239	185	Penelope Papadopoulou, Charalampos Fassoulas, George Iliopoulos, Georgia Kitsaki, Maria Kolendrianou, Elina Mikroulea, Charitakis Papaioannou, Dimitris Pattakos, Vaggelis Perakis, Maria Tsoni and Iro Tsimpri **Expertise on Specifications – Evaluation Criteria and Design of a Special Label for Local Agrotourism Products and Services: a cooperation for the benefit of four Greek UNESCO Global Geoparks!**	**1123**
240	232	Penelope Papadopoulou, George Iliopoulos, James Bendle, Kimon Christanis, Stavros Kalaitzidis, Eleni Liapi, Konstantinos Perleros, Nikolaos Soulakelis, Marianthi Tzortzi and Nikolaos Zouros **West Akrocheiras section: a pilot multi-proxy palaeoenvironmental analysis**	**1126**
241	238	Antonia Papageorgiou, Olga-Joan Ktenidou, Vasilis-Erion Pikoulis and Efthimios Sokos **Comparing broadband and strong-motion data using collocated sensors in the HP network, Greece**	**1132**
242	200	Elena Papageorgiou, Michael Foumelis, Pascal Dominique, Pavlos Bonatis, Daniele Raucoules, Marcello De Michele and Eleftheria Papadimitriou **Groundwater changes and induced seismicity influencing surface deformation in post-mining landscapes**	**1134**
243	134	Maria Papailiopoulou, Paraskevi Apostolopoulou, Vasiliki Stavropoulou, Christos Pouliaris, Nerantzis Kazakis and Eleni Zagana **Hydrochemical characterization of multi-layer porous aquifer of Larissos system, Peloponnese**	**1136**
244	288	Maria Papailiopoulou, Krystalia Chrisanthakopoulou, Vasiliki Stavropoulou, Christos Pouliaris, Nerantzis Kazakis and Eleni Zagana **Assessment of the groundwater vulnerability using DRASTIC method in Larissos watershed, Greece**	**1142**
245	132	Chara Papailiou, Maria Kolendrianou and Charalampos Fassoulas **RescueME, a Research Action that focuses on the enhancement of the resilience of coastal cultural landscapes in Europe.** **The case study of Psiloritis UGGp, Crete, Greece**	**1147**

246	89	Haritakis Papaioannou, Christos L. Stergiou, Spiros Staridas, Aristotelis Stagkikas and Georgia Kitsaki **Innovative Efforts in Geotourism: The Vikos-Aoos UNESCO Global Geopark**	**1152**
247	113	Dimitrios Papanikolaou, Paraskevi Nomikou and Danai Lambridou **Volcanism and the metamorphic core complexes of Rhodope and Cyclades**	**1157**
248	150	George Papathanassiou, Sotiris Valkaniotis and Maria Taftsoglou **The influence of stratigraphy for the generation of surface evidence of liquefaction phenomena; case study Piniada, Greece**	**1160**
249	365	Costas Papazachos, George Vougioukalakis, Stylianos Bitharis, Christos Pikridas, Michael Foumelis, Chrysanthi Ventouzi, Charalambos Kkallas, Eleni Karagianni, Domenikos Vamvakaris and Elena Papageorgiou **Monitoring the Santorini Volcano for 3 decades (1995–2025) by ISMOSAV and its role for the early detection of the 2011–2012 and 2024–2025 intra-caldera unrests**	**1162**
250	168	Angeliki Papoutsa, Stephanos Kilias, Nikolaos Zegkinoglou, Vasilios Pletsas, Rebecca Avoukatou, Paraskevi Nomikou, Paraskevi Polymenakou, Andrea Somogyi and Qasid Ahmad **Effects of boiling and seawater mixing on hyper-enrichment of antimony in active polymetallic seafloor massive sulfide hydrothermal diffusers at the Aegean Kolumbo volcano**	**1168**
251	116	Evaggelia Pappa, Costas Papazachos and Nikolaos Chatzis **VS30 Estimation from P-Wave Seismograms: Exploring a Frequency-Domain Approach for Stations Located in Sedimentary Basins**	**1174**
252	348	Melissinos Paraskevas, Ioannis Katsafados, Dimitrios Anastasiou, Maria Tsakiri, Paraskevi Nomikou and Costas Synolakis **Preliminary results of High-Resolution Microgravity Monitoring During the 2025 Santorini Unrest**	**1180**
253	3	Panagiotis Paschos **Stone bridges. Resilience to catastrophic phenomena**	**1184**

Volume F: Papers 251-300

A/A	EC	AUTHORS and TITLE	PAGE
254	266	Nikoleta Passali, Grigorios Aarne Sakellaris, Margarita Melfou, Lamprini Papadopoulou and Nikolaos Kantiranis **Mineralogy and Geochemistry of the polymetallic nodules of the Clarion Clipperton Zone, NE Pacific.**	**1187**
255	197	Adamantia Paschali Patouchi, Ioannis Panagiotopoulos and Dimitrios Vandarakis **A Pilot Study of Erosion in the Mavro Lithari Beach, part of the Highly Urbanized Coastal Zone of the Eastern Saronic Gulf, through the use of drone technology**	**1193**
256	352	Spyros Pavlides, Vassilis Karastathis, Evangelos Mouzakiotis, Sotiris Sboras, Alexandros Chatzipetros and Ilias Lazos **Active Faulting in Santorini and the recent intra-caldera (2024–2025) seismic activity along the Kameni-Fira Fault line**	**1197**
257	95	Spyros Pavlides, Sotirios Sboras, Ilias Lazos, Evaggelos Mouzakiotis and Vassilios Karastathis **The Fira fault, Santorini (Thera): morphotectonic, geomorphological and seismological evidence of fault activity**	**1199**
258	252	Eleni Pegioudi and Alexandros Chatzipetros **Geological routes on Ammouliani Island, northern Greece**	**1205**
259	286	Christos Pennos, Maria Perraki, Sofia Pechlivanidou, Rannveig Øvrevik Skoglund, Christos Salmas, Eleni Vasileiou, Yorgos Sotiriadis and Markos Vaxevanopoulos **Assessing Microplastic Pollution in Atzinolakas caves, Crete: Implications for Remote Karst Aquifers**	**1210**
260	97	Dimitris Pepas, Vassilios Marinos, Pavlos Nomikos and Charalampos Saroglou **Investigating the failure characteristics of several rock types using the Acoustic Emission technique**	**1216**
261	106	Argyrios Periferakis, Lamprini Troumpata, Aristodemos-Theodoros Periferakis and Konstantinos Periferakis **Coal and Asbestos Mining-Induced Pulmonary Pathologies: Radiological Diagnosis and Associated Challenges**	**1222**
262	295	Eftychia Peristeridou, Vasilios Melfos, Panagiotis Voudouris, Lambrini Papadopoulou, Jaroslav Pršek and Nikolaos Kantiranis **Mineralogical composition and mineral chemistry of the listvenite-hosted mineralization in Kato Vyrsini area, Thrace, Greece**	**1228**
263	107	Adonis Photiades, Isidoros Kampolis, Ioannis Vakalas and George Deligiannakis **The geological structure of the Myrtoan Sea islets**	**1234**

264	243	Serafeim Poulos, George Alexandrakis, Aikaterini Karditsa, Stamatina Lesioti, Markozanes Markozanes, Ioannis Katritsis and Nikolaos Kampanis **Assessment of the exposure of coastal sectors of the Greek Mainland to hazards induced by climate change, using the Coastal Hazard Wheel**	**1238**
265	88	Dimitrios Pyrgakis, Vasiliki Stavropoulou, Eleni Kaskani, Maria Papailiopoulou, Christos Pouliaris, Dimitra Lampropoulou, Eleni Zagana, Konstantinos Chalikakis and Nerantzis Kazakis **Hydrogeological and hydrochemical investigations of Selinous basin region**	**1242**
266	188	Dimitra Rapti **Assessment of natural and anthropogenic contamination of the sediments in the Sacca di Goro lagoon (Po river delta, northern Italy)**	**1248**
267	184	Dimitra Rapti **The role of hydrogeology in the sustainable exploration of shallow geothermal resources**	**1250**
268	192	Dimitra Rapti, George Papathanassiou, Sotiris Valkaniotis, Maria Taftsoglou and Riccardo Caputo **Liquefaction susceptibility in delta environments: the case of the Po delta area (northern Italy)**	**1252**
269	351	Georgia Rapti and Ourania Tzoraki **Investigation of legislation and tools for coastline demarcation: the coastline along the Kalamas delta in Thesprotia as a case study**	**1254**
270	109	Aikaterini Rogkala, Petros Petrounias, Panagiota P. Giannakopoulou, Petros Koutsovitis, Maria Kalpogiannaki, Paraskevi Lampropoulou and Harilaos Tsikos **Remnants of oceanic crust of Edessa ophiolite (North Greece): Petrographic and geochemical characteristics**	**1260**
271	283	Zafeiria Roumelioti and Nikitas Katsaitis **Shallow Depth P-wave Velocity Profiling Using Seismic Interferometry: The CORSSA Site**	**1265**
272	76	Artemios Roussos, Efstratios Kelepertzis, Zacharenia Kypritidou, Epameinondas Aivatzidis, Christos Drougas, Emmanouil Vassilakis, Panagiotis Voudouris and Nikolaos Zouros **Soil Geochemical Mapping on Lesvos Island, Greece**	**1271**
273	199	Aikaterini Maria Rozi and Zafeiria Papadimitriou **Pluto is lost!**	**1275**
274	198	Davide Russo and Riccardo Caputo **Rheological behaviour along the Hellenic Subduction Zone and the Adria-Eurasia continental collision**	**1277**

275	345	Dimitris Sakellariou, Ioannis Morfis, Isidoros Livanos, Alexandros Varesis, Stylianos Petrakis and Vasilis Kapsimalis **Marine geological-geophysical data may contribute to the understanding of the early 2025 seismic activity in the Santorini-Amorgos Zone**	**1285**
276	15	Dimitris Sakellariou, Ioannis Morfis, Dimitris Vandarakis, Isidoros Livanos and Ioannis Kourliaftis **Airborne and marine survey of the 8th June 2023 earthquake-triggered coastal collapse at Mylos Gialtron, North Evia: Contribution to the understanding of coastal zone vulnerability**	**1287**
277	339	Vassilis Sakkas, Christos Pikridas, Athanasios Ganas, Dimitrios Anastasiou, Panagiotis Elias, Stylianos Bitharis, Konstantinos Chousianitis, Konstantinos Raptakis, Vasilis Kapetanidis, George Kaviris, Stratos Liadopoulos, Nikolaos Voulgaris, John D. Alexopoulos and Evangelos Lagios **Continuous GNSS Geodetic Networks. A Powerful Tool for Monitoring and Understanding Complex Volcanic Environments: The Case of Santorini Volcano During the Seismic Crisis of 2024–2025**	**1293**
278	164	Vassilis Sakkas, Andreas Tzanis and Evangelos Lagios **Ground Deformation in Nisyros Volcano (Greece) Determined by GPS and SAR Interferometric Techniques**	**1295**
279	91	Myrsini-Ifigeneia Samothraki, Zacharenia Kypritidou and Ariadne Argyraki **Comparison of dermal bioaccessibility of potentially toxic elements contained in modern and ancient cosmetics**	**1300**
280	130	Panagiotis Sampatakakis, Marietta Theodoropoulou, Maria Tzima and Christos Christidis **Result of an inventory program (SAMY) of boreholes of various uses and their contribution to the water balances of groundwater systems.**	**1305**
281	334	Eirini Sardeli, Kyriaki Pavlou, Andreas Karakonstantis, Alexandros Athanasopoulos, Sokratis Pappas and Filippos Vallianatos **The 2025 Santorini Swarm: Spatiotemporal Distribution and Coulomb Stress Changes. Preliminary Results**	**1310**
282	363	Charalampos Saroglou, Vasileios Kallimogiannis, Athina Tsirogianni and Georgia Klironomou Stabilisation of volcanic rock slopes in traditional settlements. The case of Petra, Lesvos Island	**1315**
283	327	Loukas Savvelos and Nikolaos Zouros **Mapping pyroclastic formations at the Lesvos Petrified Forest, Greece the Akrocheiras hill pyroclastic sequence**	**1320**
284	359	Loukas Savvelos and Nikolaos Zouros **Mapping pyroclastic formations at the Lesvos Petrified Forest, Greece the Bali Alonia area pyroclastic sequence**	**1326**

285	133	Vanessa Schifano, Lorenza Li Vigni, Luciana Randazzo, Lorenzo Brusca, Sergio Bellomo, Sergio Calabrese and Walter D'Alessandro **Travertine deposits of Greece, a mineralogical and geochemical study**	**1332**
286	229	Vahram Serobyan, Taniel Danelian and Araiyk Grigoryan **The Upper Devonian sequence of the Noravank and Ertych geosites in Armenia: stratigraphy and geotouristic potential**	**1337**
287	74	Alkiviadis Sideridis, Evangelos Koutsoumpis, Katerina Mytakidou, Maria Boumpouka, Vasiliki Anevlavi and Paraskevas Rousopoulos **Marble as an educational fabric interweaving cultural and geological heritage, the case study of ancient Philippi site rock art, Kavala, Greece**	**1342**
288	42	Paraskevi Sklavounaki, Vasiliki Tzafaridi, Thomas Hasiotis, Stefanos Missias and Aristeidis Paleokrassas **First record of pockmarks in the North Aegean Trough**	**1344**
289	115	Loukia Skontovolou, Paraskevi Lampropoulou, Ioannis Baskoutas, Christina Raptopoulou, Panagiota P. Giannakopoulou, Aikaterini Rogkala, Aggeliki Kareli, Prokopis Savvatis and Petros Petrounias **Mineralogical and petrographic characterization of different limestones used as raw materials in the cement production**	**1347**
290	270	Emmanuel Skourtsos, Christos Filis, Emmanuel Vassilakis, Aliki Konsolaki, Evangelia Kotsi and Efthimios Lekkas **The role of the epikarst zone in the influx of water and the manifestation of humidity at the Holy Monastery of Kleiston, Mount Parnitha, Attica, Greece**	**1352**
291	52	Emilia Sofianska, Konstantinos Athanassoulis, Dimitrios Tarenides and Maria Gkagka **Composition and physicochemical properties of muds from the Evros river delta, Thrace district (Northern Greece) and their potential use in pelotherapy**	**1358**
292	222	Nikolaos Sofis, Efthymios Ntouros and Stavros Kalaitzidis **REE distribution in the b1 bauxite strata of the Parnassos–Giona Unit, Greece**	**1364**
293	225	Sophia Sotiropoulou, Michail Kalaitzis, Emmanuel Skourtsos, Dimitris Sakellariou and Haralambos Kranis **Plio-Quaternary tectonics and evolution of Southwestern Lesvos Island and Lesvos Basin, Greece: Transtensional deformation and relationship with the July 2017 earthquake activity**	**1367**
294	275	Kimon Soultanis, Konstantinos Soukis and Maria V. Triantaphyllou **Discovering the geoheritage of Skiathos Island (Northern Sporades, Greece)**	**1373**
295	5	Natalia Spanou **Cyclone Daniel's Impact: A Study of Geohazards in Meteora, Greece**	**1375**

296	284	Nafsika Ioanna Spyrou, Michalis Diakakis, Spyridon Mavroulis, Georgios Deligiannakis, Emmanuel Andreadakis, Christos Filis, Evelina Kotsi, Zacharias Antoniadis, Maria Melaki, Marilia Gogou, Katerina-Navsika Katsetsiadou, Eirini-Spyridoula Stanota, Emmanuel Skourtsos, Emmanuel Vassilakis and Efthymios Lekkas **Combining Ground and UAV Mapping for GIS-Based Assessment of Flash Flood Impact Severity: Application of the FFISS to the 2009 and 2020 Evia (Greece) Floods**	**1378**
297	163	Panagiotis Stamatis, Michaela Doukari and Kostas Topouzelis **Evaluating Airborne LiDAR and RGB Imagery for Accurate Shoreline Detection**	**1384**
298	303	Thomas Stavropoulos and Elissavet Feloni **Domestic Rainwater Harvesting Tanks' Sizing under Climate Change Conditions in Nisyros Island**	**1391**
299	340	Maria Stavropoulou, Konstantinos Soukis, Haralambos Kranis, Emmanuel Skourtsos and George Exadaktylos **Numerical modeling of fault genesis in the Santorini-Amorgos basin: an interplay of tectonic forces and magmatism**	**1396**
300	263	Christos L. Stergiou, Haritakis Papaioannou, Grigoria-Vasiliki Dimou, Eftychia Peristeridou, Margarita Melfou, Aristeidis G. Stamatiadis, Vasilios Melfos, Olga Koukousioura and Georgia Kitsaki **Sedimentary, Metamorphic, and Igneous Rocks in Harmony: Unveiling the rocky microcosm of the Vikos-Aoos UNESCO Global Geopark**	**1401**
301	240	Christos L. Stergiou, Grigorios-Aarne Sakellaris, Margarita Melfou, Vasilios Melfos, Lambrini Papadopoulou and Christos Stefanou **Insights from the mineralogy and mineral chemistry of the antimony mineralization at Philadelphio, Vertiskos Unit, Northern Greece**	**1407**
302	265	Spyridon Strongylis, Grigorios Aarne Sakellaris, Nikolaos Kantiranis and Alexandros Chatzipetros **Threshold Value Analysis in Geochemical Mapping for Gold-Only Vein-Type Mineralization**	**1413**
303	160	Maria Taftsoglou, Sotiris Valkaniotis, George Papathanassiou and Sotirios Argyroudis **Liquefaction risk assessment of airport infrastructure using geological data and remote sensing techniques**	**1419**

Volume G: Papers 301-358

A/A	EC	AUTHORS and TITLE	PAGE
304	159	Maria Taftsoglou, Sotiris Valkaniotis, George Papathanassiou, Vassilis Ntouvartzis, Dimitra Rapti and Riccardo Caputo **A correlation of liquefaction phenomena with the surficial geology of point bar deposits; case studies 2021 Damasi, Greece, 2023 Kahramanmaraş, Türkiye and 2010–2011 Christchurch, New Zealand**	**1423**
305	110	Onur Tan and Özlem Karagöz **Earthquake hazard implications for Lesvos (Midilli) and the surrounding region**	**1427**
306	60	Despoina Tektonidou, Panagiotis Voudouris, Constantinos Mavrogonatos, Federica Zaccarini, Vassilios Melfos, George Soulamidis, Ariadni Afroditi Georgatou, Evgenia Serfa, Degao Zhai, Manuel Keith, Alexandre Tarantola, Stylianos Tombros, Dimitrios Alifieris, Margarita Melfou, Evangelia Zygouri and Christos Kanellopoulos **The Megala Therma-Katsilemonas gold-silver mineralization, Lesvos island, Greece: a new alkalic-type epithermal deposit in Greece?**	**1430**
307	45	Dimosthenis Telemenis, Spyridon Bellas, Evangelos Vavouranakis and Emmanouil Manoutsoglou **Source rock potentiality of the late Miocene sapropelic layers of Gavdos island, Greece, based on geochemical and stratigraphic data**	**1436**
308	297	Alexia Theocharaki, Maria Nikopoulou, Stefanos Karampelas, Kantiranis Nikolaos, Stavros Oikonomidis and Lambrini Papadopoulou **Study of "Corundum" Samples from the Collection of the Mineralogical – Petrological Museum at Aristotle University of Thessaloniki, Greece**	**1441**
309	368	Tonbol K.M. **Climatic Variability and Wind Pattern Shifts in Alexandria: Twenty Years of Data to Guide Coastal Resilience in Northern Egypt**	**1447**
310	306	Aris Toska and Elizabeth Stathopoulou **The effect of microorganisms in the fossilization of skeletal material**	**1448**
311	224	Theofilos Toulkeridis, Aaron Addison, Silviu Constantin and Grace Tatiana Páez-Barrera **Ecuadorian candidates for the World Natural Heritage List – The Triple Volcano and Tayos caves**	**1451**
312	99	Maria Triantaphyllou, Elisavet Skampa and Vasiliki-Grigoria Dimou **A review of calcareous nannofossil biostratigraphic studies in the Hellenic territory (Greece): the contribution of the Micropaleontology Collection of the Laboratory of Historical Geology and Biogeosciences (NKUA)**	**1456**
313	181	Efstathia Tringa and Konstantia Tolika **Assessing Future Climate Change Risk to Cultural Heritage of Greece: A Case Study of Mycenae and Delos**	**1460**

314	228	Francesco Tripodi **Preliminary results of GEM (Gaseous elemental mercury) concentration in interstitial soil and free gases from Mt. Etna, Sicily**	**1462**
315	145	Fani Tripolitsiotou, Ariadne Argyraki and Hara Drinia **"Unfolding the Fold"- An Introduction to the Geology of Greece Through a Museum Kit by the Natural History Museum of Arsakeia Schools**	**1465**
316	249	Fani Tripolitsiotou, Hara Drinia and Ariadne Argyraki **Exploring Urban Geotourism Through Geomythology: A Geotrail from Faliro Bay to Vouliagmeni Peninsula, Attiki Region, Greece**	**1468**
317	304	Alexandros Troupakis, Elissavet Feloni, Kleomenis Kalogeropoulos and Andreas Tsatsaris **Exploring Social Perceptions of Water Scarcity and Local Water Resource Management in Greece: Insights from a National Survey**	**1471**
318	289	Dimitrios Tsagkas, Foteini Chalkiopoulou, Giorgos Kanakidis and Alexia Charmalia **Contribution of Engineering Geology to the rescuing and enhancing of cultural works and constructions. Case study: The fountain at the Antaeus and Gennaios Kolokotronis streets' junction in the Amalia Merkouri Square in Petralona.**	**1475**
319	274	Konstantinos Tsanakas, Alessia Sorrentino, Gaia Mattei, Pietro Patrizio Ciro Aucelli and Efthimios Karymbalis **Preliminary results on the mapping of uplifted marine terraces in the Laconic Peninsula, SE Peloponnese, Greece**	**1481**
320	272	Panagiota-Elpida Tsekoura, Marianthi Stefouli, Ioannis Vakalas, Eleni Vasileiou and Maria Perraki **Applications of satellite data analysis in the exploration of geothermal systems: The case of the Methana Peninsula, Greece**	**1487**
321	193	Anastasios Tsikrikis, Vassilis Marinos and Theodosis Papaliangas **The influence of mineralogy on the nondilatant friction angle of rock fractures**	**1493**
322	73	Dora Tsipra and Hara Drinia **Exploring Participant Experiences in a Geoconservation Program in Apano Meria, Syros island, Greece**	**1499**
323	56	Varvara Tsironi, Jean-Mathieu Nocquet, Athanassios Ganas, Efthimios Sokos and Ioannis Koukouvelas **Crustal Block Kinematics in Western Greece using geodetic data**	**1502**
324	278	Ioannis Tsodoulos, Efthimios Karymbalis, Maria Ferentinou, Andrew Green, Konstantinos Stamoulis and Christina Gallousi **Optically Stimulated Luminescence (OSL) dating of a shell midden layer at Umhlanga Rocks, Natal North Coast, South Africa**	**1505**

325	162	Maria Tsoni, Eleni Koumoutsou and George Iliopoulos **Chelmos- Vouraikos Unesco Global Geopark 2024: Advancing Conservation, Education, and Community Engagement**	**1511**
326	267	Theodora Tsourou, Eleni Anastasia Markoglou, Taniel Danelian, Constantine Parinos, Alexandra Gogou and Maria Triantaphyllou **Deep sea agglutinated foraminifera from the surface sediments of NE Mediterranean Sea**	**1514**
327	257	Theodora Tsourou, Nikolaos Sakoulas, Aggeliki Paraskevopoulou, Ifigeneia Perraki and Maria Triantaphyllou **Stratigraphic assignment of the Mesozoic shallow carbonate succession of Epos Mountain, Chios Island, Greece**	**1517**
328	269	Andreas Tzanis, Stylianos Chailas and Evaggelos Spyridonos **The geothermal prospect of the NW Lesvos Island, Greece: Three-dimensional magnetotelluric and gravity exploration**	**1519**
329	126	Marianthi Tzortzi, Federico Lugli, Thomas Tütken, Vasilis Golfinopoulos, George Iliopoulos and Andreas Darlas **Tracking mobility of Late Pleistocene ruminants using enamel strontium isotope analysis of teeth from Melitzia Cave, Mani Peninsula (Greece)**	**1525**
330	114	Nikolas Vagionakis, Konstantinos Diamantis, Maria Stavropoulou and Emmanouil Andreadakis **Application of UAVs in Rockfall Hazard Assessment and Mitigation Measures in the Vrachon Theatre, Byron Area, Greece**	**1528**
331	186	Dimitra Valavani, Penelope Papadopoulou, Peter Frenzel, Mauro Alivernini, Maria Tsoni, Maria Groumpou, Theodora Tsourou, Silvia Kolomaznik, Magdalena Kreuzheck and George Iliopoulos **Boosting Cave Ostracods Biodiversity: A case study from the Cave of the Lakes (Chelmos Vouraikos UNESCO Global Geopark, Peloponnese, Greece) with report of a new species of Trapezicandona**	**1534**
332	369	Valavani Eleni, Siarkos Ilias, Tzoraki Ourania **Overview of Legislation and Tools for Stram Flood Risk Assessment**	**1538**
333	328	Ilias Valiakos, Konstantina Bentana and Nikolaos Zouros **Conservation and Interpretation of Fossiliferous Sites in the Lesvos Island UNESCO Global Geopark**	**1539**
334	155	Sotiris Valkaniotis, Dimitra Rapti, Maria Taftsoglou, George Papathanassiou and Riccardo Caputo **Geomorphological mapping and lithological heterogeneity as tools for the assessment of liquefaction likelihood: Piniada Valley case study (central Greece)**	**1544**

335	211	Sotiris Valkaniotis, Maria Taftsoglou, Domna Samara, George Papathanassiou, Konstantia Tolika, Caterina Zei and Themistoklis Chatzitheodosiou **Development of a Medicane-induced landslide inventory with field and remote sensing data; 2023 Storm Daniel, central Greece**	**1547**
336	230	Kanella Valkanou, Efthimios Karymbalis and Konstantinos Tsanakas **Investigating the interaction between Flood Hazard and Soil Erosion in Northern Evia Island, Greece, using GIS Morphometric Analysis**	**1550**
337	216	Aikaterini Vardava, Vasilios Kyriakopoulos, Emmanuel Skourtsos and Christos Filis **Preliminary results on geological and hydrogeological conditions in Vilia, Attica, Greece**	**1555**

Abstract

This study utilizes Unmanned Aerial Vehicles (UAVs) and advanced 3D modeling techniques to monitor and analyze the evolution of a significant landslide in Pyrra, Trikala, following the severe weather event known as Daniel in 2023. Specifically**,** In September 2023, Greece was impacted by the severe weather event known as Daniel, which led to intense rainfall and caused widespread natural disasters in Thessaly, including extensive landslides and floods (Dimitriou et al.,2024). The village of Pyrra in Trikala was notably affected, experiencing a large-scale landslide. This study focuses on documenting and monitoring this landslide to understand its progression over time.

Objectives: The primary objectives of this study was to employ advanced geospatial technologies to capture detailed data on the landslide and to use this data to monitor its evolution. (Highland & Bobrowsky, 2008). By doing so, the study aims to contribute to a better understanding of landslide dynamics and inform future mitigation strategies.

Geological setting: The landslide in Pyrra, occurred in an area consisting mainly of Pindus flysch. The failure mechanism of the landslide is a translational slide influenced by pre – existing cracks, the geometry of the slope and dye to the continuous rainfall.

Methods: The methodology involves multiple steps. Initially, high-resolution aerial imagery of the landslide area was captured using UAVs. These images were processed using photogrammetric methods, specifically the Structure from Motion (SfM) technique, to create detailed 3D models of the terrain. CloudCompare software was employed to analyze the changes in the landscape by comparing datasets collected at two different times: October 2023 and June 2024. The software's C2C (Cloud-to-Cloud) and M3C2 (Multiscale Model-to-Model Cloud Comparison) methods were used to quantify the displacement of materials and provide a comprehensive assessment of the landslide's evolution.

Results: The analysis revealed substantial material displacement and changes in the morphology of the landslide. The generated 3D models offer a detailed visualization of the impacted region, showing significant shifts in terrain and volume changes. Quantitative analysis revealed the extent of material movement and highlighted critical areas of instability.

Figure 1 Point cloud representation of the landslide, generated from UAV imagery using SfM techniques.

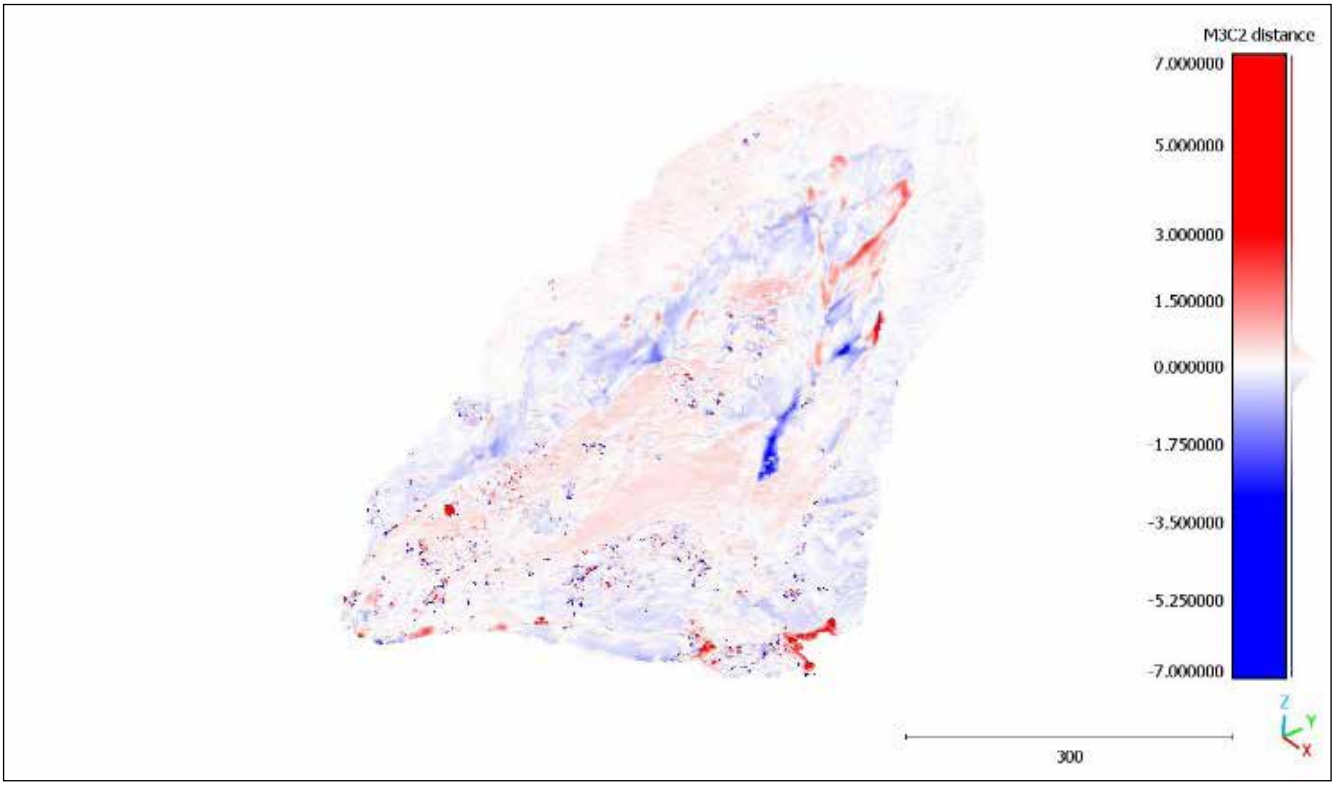

Figure 2 Detection of surficial displacement based on the M3C2 method. With red color depicts the areas where we have removal material and in blue the locations where we have deposited material.

Conclusions

The use of UAVs combined with advanced software tools like CloudCompare proved highly effective in monitoring and analyzing the landslide phenomena. This approach enables detailed observation and documentation of the landslide over time and provides valuable information for developing risk assessment and mitigation strategies. These findings of this study emphasize the potential of modern geospatial technologies in enhancing our understanding of landslide behavior and improving disaster response planning (Lacroix, 2020).

EXTENDED ABSTRACT 002

Structural study of the Theodorion meta-migmatitic complex (Serbomacedonian massif, northern Greece)

Amanatidou Dimitra[1], Soukis Konstantinos[1], Dimitri Klea[1], Stouraiti Christina[1]
(1) National and Kapodistrian University of Athens, dimitraam@gmail.com

Introduction

This paper presents the results of detailed mapping (1:10.000 scale) tectonostratigraphic and structural study on the high-grade metamorphic rocks of Vertiskos Unit, exposed in the Theodorion area (Northern Greece), which shows that they form an east-dipping sequence affected by at least three ductile deformation events.

Geological Setting

The high-grade SerboMacedonian Massif (SMM), exposed in northern Greece, represents the structurally highest crustal block of the Hellenides. It is bounded to the west by the low-grade Circum Rhodope metasediments and the Vardar ophiolitic rocks (Peonias Unit) and to the east by the high-grade rocks of the Rhodope Massif (Kockel et al., 1977; Kilias et al., 1999; Papanikolaou 2021). The SMM is subdivided into two main units: the overlying Vertiskos Unit and the underlying Kerdylia Unit. The contact is decorated by lenses of metamorphosed basic to ultrabasic rocks comprising the Volvi-Therma-Gomati complex, and it has been characterized as a top-SW Cenozoic detachment (Sokoutis et al., 1993). Geochronological data revealed that Vertiskos Unit includes late Proterozoic Pan-African rocks intruded by early (Silurian) and late (Carboniferous) Paleozoic granites and pegmatites and later on by Triassic A-type Arnea-Kerkini granites (Christofides et al., 1999, 2007; Himmerkus et al., 2007, 2009; Poli et al., 2009; Abbo et al., 2020). During the Mesozoic - Cenozoic period, the SMM was involved in the prolonged closing of the Neotethyan Vardar oceanic basin (Pe-Piper and Piper 2002; Papanikolaou 2021).

Tectonostratigraphy - Structural data

Detailed mapping along an NE transect revealed that the Theodorion area comprises three formations (Figure 1a-d): a lower migmatitic gneiss, an overlying biotite gneiss, and the uppermost garnet-mica schists. The overall structural thickness of the sequence reaches 1000m. The lowermost migmatitic gneiss shows a coarse-grained granitic core surrounded by typical gneissic layers with typical mineral assemblage, including feldspars + quartz ± biotite ± muscovite + opaque. It has to be noted that the granitic core is also foliated but not as strongly as the gneissic cover. At the transition zone between the two lithologies, high-grade structures such as ptygmatic folding are often observed (Figure 2a). The overlying biotite gneiss is lithologically quite heterogeneous and includes alternating biotite-rich schistose and gneissic layers, with a typical mineral assemblage of feldspars + quartz + biotite ± muscovite + opaque. Amphibolitic lenses are intercalated in places with mineral assemblage hornblende + epidote + plagioclase ± pyroxene + opaque. The uppermost garnet-mica schists include more aluminum-rich lithologies such as muscovite and garnet porphyroblasts and typical mineral assemblage muscovite + quartz + garnet ± biotite ± feldspars + opaque.

All the rocks present a roughly east-northeast-dipping gneissic layering with a coarse-grained foliation Sn and an east-north-east plunging stretching lineation Ln. In the microscopic scale, Sn is formed by alternating layers of quartz, felspar and quartz+biotite+white mica aggregates. Isoclinally folded quartz veins reveal that Sn is an axial planar foliation to Bn isoclinal folds, which have folded an older Sn-1 foliation, now observed as inclusion traces in feldspar porphyroblasts. Kinematic indicators such as S-C fabrics and garnet porphyroblasts show a consistent top-to-E or NE sense of shear. The entire sequence and the Sn are further folded by macro-to-mesoscale asymmetric SW-verging NW-SE open to tight folds, producing a fine-grained Sn+1 foliation associated with an Ln+1 intersection/stretching lineation trending NW-SE. Locally, Sn is reworked by a mylonitic Sn+1 foliation. On a microscopic scale, Sn+1 is formed by quartz+biotite aggregates (Figure 2b). The fold vergence indicates a top-SW tectonic transport for this event. Finally, distributed top-to-SW shear bands crosscut all previous structures.

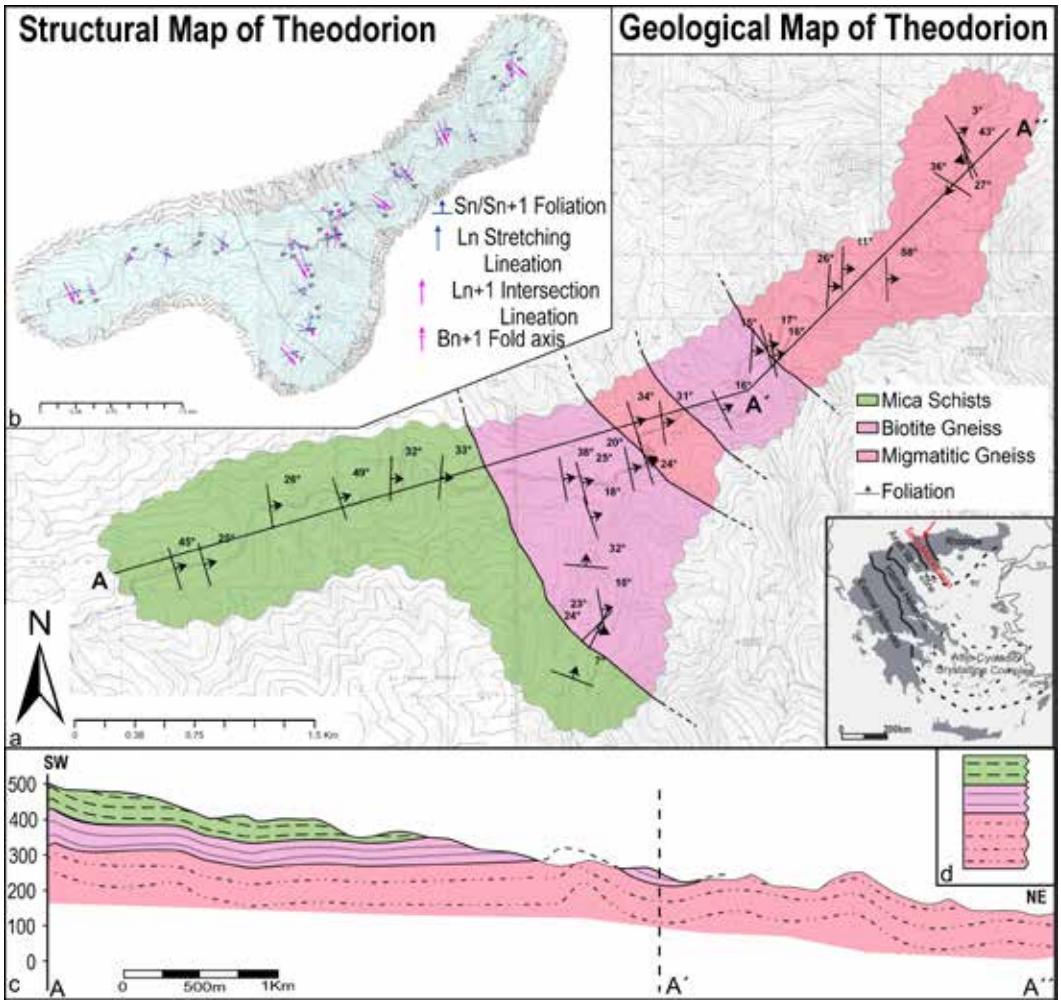

Figure 1a-d. a-b) Geological and structural map of the Theodorion area. Inlet shows the location of the study area. c-d) SW-NE crosssection A-A´-A´´ showing the structure of the Theodorion area and tectonostratigraphic column.

Figure 2a-b a) Close view of the lowermost migmatitic gneiss, red arrow indicating ptygmatic folds. b) Photomicrograph of the biotite gneiss showing the oblique Sn foliation folded by a greenschist-facies Sn+1 foliation (XZ section +polars).

Discussion - Conclusions

Our detailed mapping showed that a northeast-dipping sequence of high-grade rocks exists in the Theodorion area. The lowermost migmatitic gneiss and biotite gneiss represent prealpine basement lithologies of granitic or migmatitic protoliths that underwent high-grade metamorphism through multiple tectonometamorphic events as reported by previous researchers (Pe-Piper and Piper 2002 and references therein; Himmerkus et al., 2007, 2009; Abbo et al., 2020). The origin of the uppermost mica schist is less straightforward to conclude. It could represent a metasedimentary cover, in which case, based on existing geochronological data for the Vertiskos Unit basement rocks, it could be the late Proterozoic to early Paleozoic cover of the granitic precursors. On the other hand, given that these rocks have participated in several orogenic events, a meta-migmatitic origin cannot be excluded.

As for the structural history of these rocks, the early Dn-1 and Dn events could be associated with the Mesozoic (late Jurassic-Cretaceous) history related to the Vardar closure and subsequent deformation. The Dn+1 event could correspond to the Eocene thrusting of the Serbomacedonian Massif on the Circum Rhodope and the Vardar ophiolites. The late-stage top-SW shear bands probably accompanied the late Eocene-Oligocene exhumation of the underlying Kerdylia Unit.

Introduction

Natural disasters such as earthquakes floods and landslides expose communities living within hazard-prone areas to significant risks, particularly in today's increasingly interconnected world, making the need for advancement in multi-hazard assessment techniques critical. The HOMEROS project seeks to tackle the challenges presented by those advancements, focusing on seismology, geodesy and geology and leveraging cutting-edge technical solutions tailored to the big data era. HOMEROS makes strides in standardizing research methods, fostering collaboration, and improving the ability to understand and foresee natural hazards through Open Science practices. The project focuses on assessing hazard in high-risk areas in Greece, known for their significant seismic activity, major earthquake occurrence, floods, and landslides, through its transparent, reproducible and widely accessible research products. Data and tools developed by the project will strictly adhere to the FAIR principles (Findable, Accessible, Interoperable, Reusable), thereby maximizing their value for the scientific community, policy makers and stakeholders. HOMEROS will compile earthquake catalogues and assess ground deformation products to provide a comprehensive evaluation of seismic hazard. Furthermore, it will enhance knowledge of flood and landslide hazards, contributing to more effective mitigation efforts.

Project objectives

The HOMEROS project seeks to fulfill the critical need for reliable and standardized methods to assess multiple hazards in an increasingly dynamic risk environment. Harnessing the potential of Open Science and interdisciplinary collaboration, the project strives to expand scientific understanding, support data-informed decision-making, and strengthen community resilience. Its goals are centered around three core pillars:

- Utilization of platforms, such as the European Open Science Cloud (EOSC) and the Environmental Research Infrastructure (ENVRI) (Adamaki & Vermeulen, 2023) for the creation of accessible and efficient ecosystems for interdisciplinary data sharing. This effort builds on prior integration efforts in ENVRI projects and promotes FAIR principles, ensuring usability and reproducibility of research outputs.
- Development of methodologies and workflows for integrating and utilising diverse datasets, including geodetic, seismic and geological data to create detailed physical models, visualization products, such as maps, and data inventories. These efforts seek to aid in the advancement and enhancement of multi-hazard assessment.
- Fostering collaboration and communication among research institutions, infrastructures, and projects. Scientific results will be shared through Open Access publications, workshops, and educational resources.

This paper presents data, workflows and results from the HOMEROS project, related to a specific swarm-like seismic excitation that occurred during the 2024 February – April period in the offshore area to the west of Asos village, Kefalonia island. This work includes preliminary findings from the project, highlighting the collaboration between the participating institutions and the potential for clear and reproducible scientific results by the adherence of available seismic datasets to FAIR principles.

Study area

The areas chosen as case studies for the HOMEROS project are the central Ionian Islands, along with the western Gulf of Corinth. These areas exhibit high deformation rates (Pikridas et al., 2016, Bitharis

et al., 2024), frequent occurrences of strong earthquakes (e.g., Papadimitriou et al., 2017; Kaviris et al., 2021; Sakkas et al., 2022) and destructive floods and landslides (Bathrellos et al., 2017, Skilodimou et al., 2018). More than 50% of the seismic energy in Europe is released in Greece, placing earthquakes among the most impactful geohazards in the country, highlighting the need for a reliable seismic hazard model. A comprehensive evaluation of seismic hazard for such areas can be achieved by Peak Ground Acceleration (PGA) and Peak Ground Velocity (PGV) calculations, alongside site-specific analysis (Uniform Hazard Spectra – UHS and hazard curves) in towns that exhibit the highest population in the study areas (e.g., Kaviris et al., 2022, 2024).

The preliminary results presented in this paper concern the rigorous swarm taking place in 2024 in the offshore area west of Asos village of Kefalonia island. The study area is part of the Kefalonia Transform Fault Zone (KTFZ), which dominates the central Ionian Islands, which is the most seismically active area in the Mediterranean (Figure 1). Specifically, the swarm–like activity that lasted more than two months is located in a thoroughly studied part of the KTFZ, that is recognized as an extensional duplex transfer zone that links the northern (Lefkada) with the southern (Kefalonia) branches of the KTFZ (Karakostas et al., 2015). This stepover zone consists of small sub–parallel fault segments, striking roughly WSW–ENE, deflecting the azimuth of the main fault branches. Since only moderate magnitude earthquakes are known to have occurred in this area, this swarm–like excitation raises scientific concern for the exploitation of the large amount of seismological data that were collected during the activity and the exploitation of the collected data for deciphering the dynamic and kinematic properties of the activated structures. Advancing knowledge of the seismotectonic properties will provide valuable insight in assessing seismic hazard in the broader central Ionian Islands region.

Methods and data

High quality seismic data from regional networks are essential for the compilation of earthquake catalogue and the production of efficient data pipelines ready for multidisciplinary utilization. HOMEROS aims to exploit a benchmark seismic dataset for the February – April 2024 Central Ionian Islands swarm – like activity –among others–, containing more than 2000 earthquakes to explore integration opportunities for enhanced data exchange e.g., data pipelines between research groups of various disciplines, interested in leveraging seismic data for their research. This will be achieved by taking advantage of the resources provided by the EOSC and the ENVRI cluster. This effort also seeks to demonstrate the added value of these services, integrating their tools and services for multi–disciplinary research. Availability of both the relocated benchmark seismic catalogue and the raw waveform dataset will be enhanced following FAIR principles and Open Science practices, ensuring the ease of access to the data. To facilitate interoperability, the relocated catalogue will be provided in the QuakeML schema, a widely used form of seismological data representation, in a modular XML form, able to contain a variety of information, including moment tensors. The waveform dataset will be provided in miniSEED format, accompanied by the corresponding metadata for each station used to collect the data.

Along with providing ease of access to the benchmark data, HOMEROS aims to provide open–source tools for managing, obtaining, processing and visualizing seismic data. To this end, interactive coding platforms such as Jupyter Labs, will be utilized for better dissemination of the developed workflows and tools to scientists from different disciplines (e.g., in the form of Jupyter Notebooks), since an essential component of the project is to ensure the reproducibility, interoperability and ease of access of all research outputs of HOMEROS.

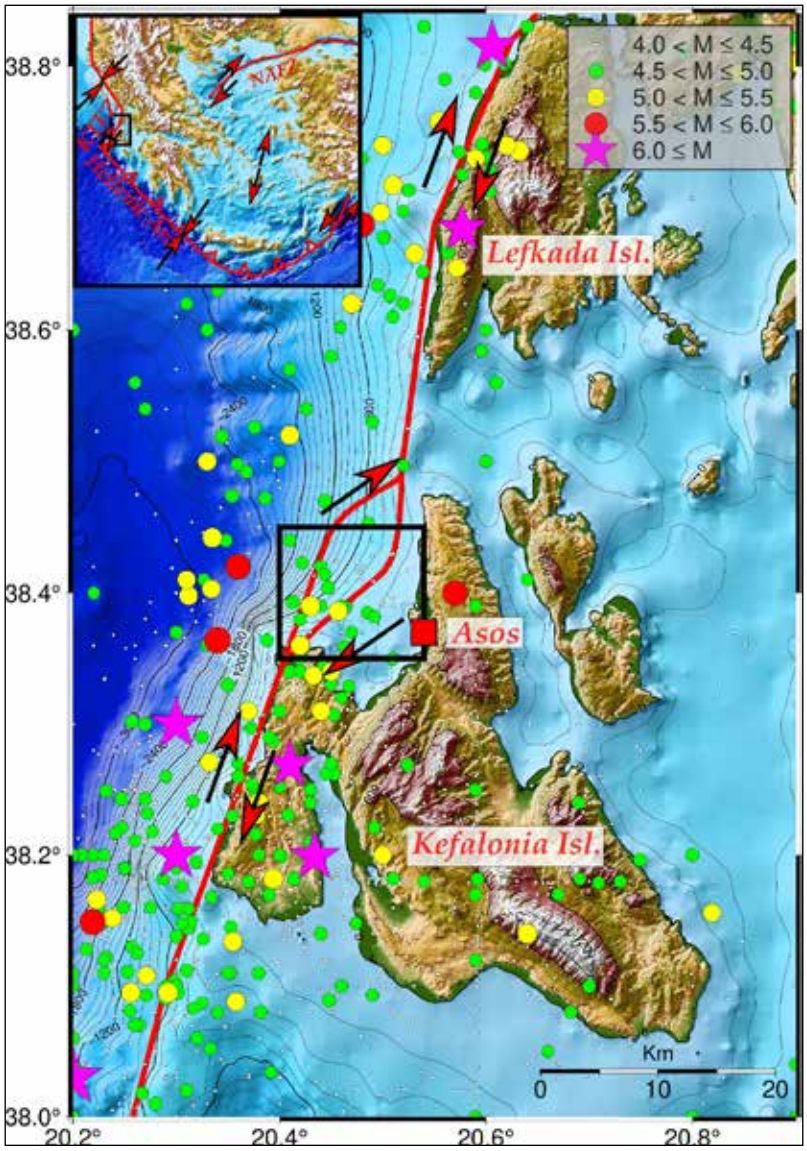

Figure 1: Map of the study area of the central Ionian islands. Circles and stars of different colors and sizes denote seismicity in the region since 1970, according to the legend. The area is placed within the context of the seismotectonics of the Aegean in the map inset, along with major structures of the region, marked with red lines. The main fault segments of the KTFZ, along with the extensional stepover area are denoted with red lines on the map of the study area. Arrows show the relative movement of the faults. The black rectangle encloses the region where the February – April 2024 seismic swarm took place, whereas the red rectangle denotes the location of Asos village

Exploitable results

The primary output for the seismology part of the HOMEROS project multi–hazard outputs, will be open–access datasets, including earthquake catalogues and waveform inventories. It is essential that these datasets will adhere to FAIR principles and be publicly available through platforms such as EPOS ERIC, ENVRI repositories, and other widely used repositories (e.g., GitHub, Zenodo). The benchmark seismic dataset for the February–April 2024 central Ionian Islands swarm-like activity contains over 2000 earthquakes with information on their relocated epicenters, depths, origin time, along with focal

mechanisms for a number of them (Figure 2). The waveform dataset of the swarm contains raw data along with station metadata for 14 seismic stations of the central Ionian Islands. Another key outcome is the development of clear and reproducible research workflows documented through interactive tools such as Jupyter Notebooks. These workflows will showcase the integration of seismic data with various datasets and methodologies, allowing researchers to replicate and tailor the processes for comparable studies, while also providing means of preliminary visualization of the data without the need of prior knowledge of complex tools developed for specific scientific disciplines. In our case, Jupyter notebooks containing complete workflows, along with instructions for waveform data homogenization and earthquake magnitude estimation will be provided.

Type	**Description**	**Format**
Raw data	Seismic Waveforms	miniSEED
Metadata	Station Metadata	StationXML (.xml)
Raw data	Earthquake Catalogues	QuakeML (.xml)
Raw data	Focal mechanisms	QuakeMl (.xml)
Interactive notebook	Waveform dataset homogenization and Magnitude Estimation	Jupyter Notebook
Interactive notebook	Seismic data fetching and simple visualization	Jupyter Notebook

Table 1. Summary of expected data products for the February–April 2024 central Ionian Islands swarm-like activity case study of the HOMEROS project.

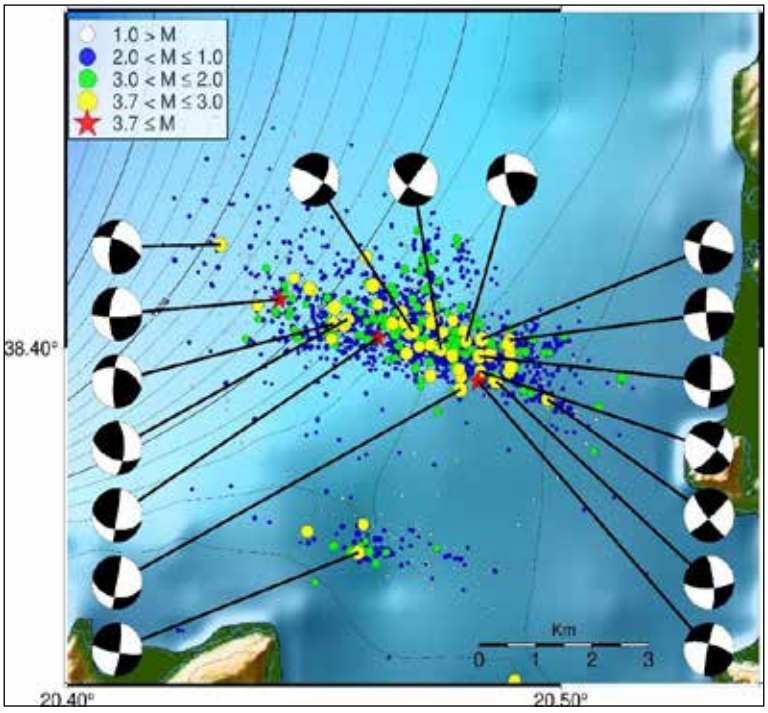

Figure 2: Relocated epicenters of earthquakes that occurred in the study area during the 24/02/2024 – 24/04/2024. Colored dots denote earthquakes with 0.1 ≤ M ≤ 3.7, according to legend. The focal mechanisms of the 17 strongest earthquakes of the excitation are also presented, shown as equal area lower hemisphere projections. The excitation catalog, along with focal mechanisms, is currently available as a preliminary dataset (Anagnostou, 2025) and will be enhanced and finalized with clear metadata and reproducibility information, adhering to FAIR principles through the HOMEROS project.

A workflow along with instructions on obtaining seismic data from open access databases for specific temporal and spatial restrictions and visualizing them on simple maps (Figure 3) will be provided. These workflows will illustrate the combination of diverse datasets and methodologies, empowering researchers to replicate and modify the processes for related studies. Comprehensive documentation for each workflow, presented through interactive notebooks, will act as a best-practice reference for future multidisciplinary research endeavors.

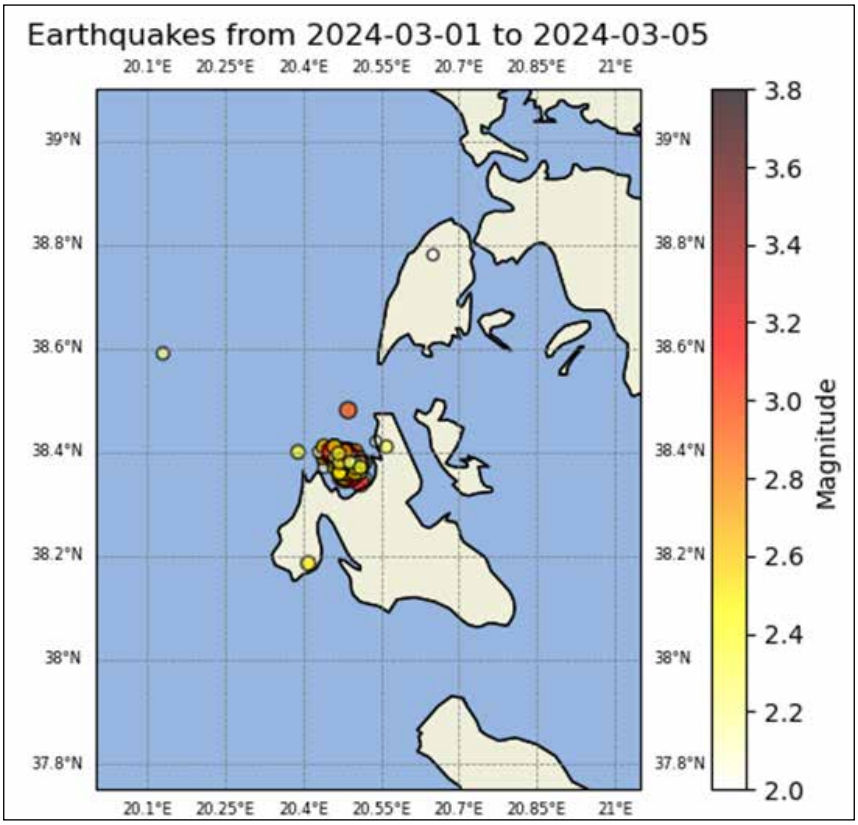

Figure 3: Simple map created using the Seismic data fetching and visualization notebook, presenting earthquakes for the study area during the first 5 days of March 2024, when the excitation activity was peaking. Colored epicenters correspond to the magnitude color bar on the right side of the figure. Data obtained from public EMSC catalogues.

Conclusions

HOMEROS represents an important step forward in addressing the rapidly growing ramifications of multi-hazard assessment. Through unifying data from various scientific fields and embracing Open Science principles, the project addresses critical challenges in making hazard assessment thorough and accessible. By providing seismic datasets and developed workflows following FAIR principles, HOMEROS seeks to propel forward multidisciplinary collaboration and provide clear, reproducible scientific results. The project lays the foundation for scalable and interoperable tools and approaches to understanding natural hazards and their complex interactions. By focusing on a specific case study in a high–risk area such as the central Ionian Islands, we seek to demonstrate the practicality of our developed workflows, the accessibility of our seismic datasets and their potential for further utilization and application from researchers beyond the Earth sciences disciplines. Finally, the outputs comprising open–access data, scientific publications, and training modules, will provide valuable resources for policy–making and disaster management, contributing to a safer and more resilient society.

Background

The Kefalonia Transform Fault Zone (KTFZ) is the most seismically active area in the Mediterranean and consists of two major branches, the Lefkada fault segment to the north and the Kefalonia fault segment to the south. KTFZ acts as an active boundary between the subduction zone of the remnants of the oceanic lithosphere of the Eastern Mediterranean that subducts under the Aegean microplate to the south and the continental collision between the Eurasian plate and the Adriatic Microplate to the north. The tectonic activity in the region is reflected in the rapid crustal deformation rates of the region and subsequently the frequent occurrence of strong earthquakes ($M_w \geq 6.0$) that occurred during both the historical and instrumental era of seismology. Those strong earthquakes and their temporal distribution can be explained due to stress transfer between closely located fault segments (Papadimitriou, 2002) and as such, studying those stress interactions is an integral part of understanding the long-term tectonic loading in the region.

For better understanding of the kinematics and the distribution of continental deformation that is occurring within the brittle crustal layer in the study area, we assess the regional stress field by inverting focal mechanisms. Contemporary stress field in an area is a result of processes that operate at significantly different spatial scales (Zoback, 1992). Forces that are linked to major tectonic movements such as ridge push and slab pull affect the stress field at large wavelengths, beyond 2000 km and are considered first–order sources of stress field perturbation. At intermediate wavelengths (between 2000 and 500 km) the crustal stress field is affected by processes such as orogenic lithospheric flexure (Zoback, 1992) with those processes representing second order sources of stress field disturbances. Third order patterns of crustal stress field are linked to small–scale variations (<100km) that are produced by processes such as active faulting and at times these variations may lead to the nucleation of potentially destructive earthquakes (Hergert and Heidbach, 2011). Detailed knowledge of the contemporary stress field characteristics of high–risk areas, such the central Ionian Islands region is valuable for possible investigations of stress triggering sensitivity due to the coseismic slip of strong earthquakes.

Objectives

The main objective of this paper is to present crustal stress data for the area of central Ionian Islands, inferred from the inversion of 485 focal mechanisms using the SATSI inversion method of Hardebeck and Michael (2006) and specifically the MSATSI implementation of the method (Martinez–Garzon et al., 2014). We seek to better detail the stress field by binning the focal mechanism dataset according to known structures in the area and producing a representative focal mechanism for each subarea based on the stress inversion results. Previous work in defining the stress pattern has been done for the Greek region (e.g., Kapetanidis & Kassaras, 2019) including our study area. We focus on detailing the stress pattern around the main branches of the KTFZ along with the transfer zone that connects them and has been identified as an extensional stepover zone (Karakostas et al., 2015).

Data and Method

Our dataset contains 485 focal mechanisms and was compiled from data obtained from a variety of sources, mainly published works (Hatzfeld et al., 1995; Louvari et al., 1999; Benetatos et al., 2004, 2005; Pondrelli et al., 2004, 2007, 2011; Karakostas & Papadimitriou, 2010; Karakostas et al., 2015; Papadimitriou et al., 2017; Kostoglou et al., 2020) along with routine solutions from various observatories (GCMT, ETH, HUSN, GEOFON). In cases of duplicate solutions, we prioritized the focal mechanism computed by published works over routine solutions. MSATSI deals with the ambiguity of the fault-plane solution by allowing the user to explicitly specify the probability that each input fault plane solution is thought to be the real one. We used the typical 50% value for our inversions. Focal mechanisms that correspond to seismicity occurring below crustal depths (>30km) were discarded in order to constrain the stress patterns to crustal, third order levels. The KTFZ comprises five major fault segments with striking from 12° to 40°, with fault lengths between 12–40km and rake values that exhibit right–lateral strike–slip faulting (Kourouklas et al., 2023). Four out of the five segments bound the western coastlines of the Lefkada and Kefalonia Islands and were identified

as the causative faults of four of the strongest earthquakes that occurred in the study area during the 21st century (Karakostas et al., 2004, 2015; Papadimitriou et al., 2017). The fifth segment is located offshore, south of Kefalonia and was associated with the 1983 M_w=7.0 earthquake (Scordilis et al., 1985). The gridding scheme for our focal mechanism dataset follows the segmentation of the KTFZ for its five segments, with an additional grid point located in the stepover zone that connects the northern Kefalonia segment with the southern Lefkada segment (Figure 1).

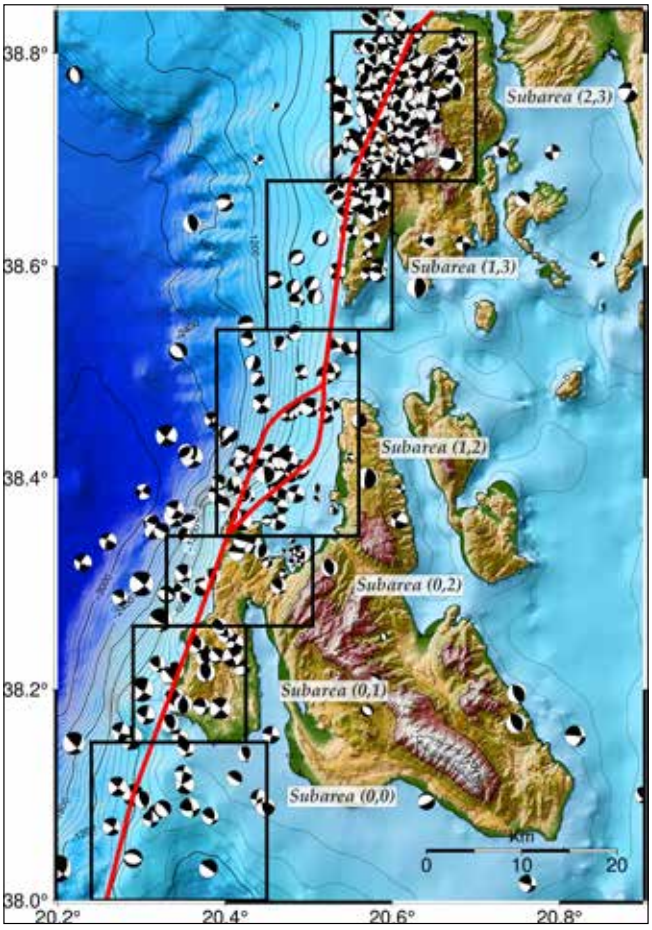

Figure 1: Map of the study area of the central Ionian Islands along with the major fault segments of the KTFZ and the extensional stepover area, denoted with red lines and enclosed by rectangles that correspond to the subareas or grid points containing the focal mechanisms used in the inversion. The focal mechanisms are shown as equal area lower hemisphere projections.

After compiling and subdividing our dataset to their corresponding subareas, securing that each one comprises at least 20 focal mechanisms to ensure robustness of results, we perform stress inversion for each subset, by applying the SATSI inversion algorithm. The algorithm inverts focal mechanism data for spatially and/or temporally variable stress field, using a damped least–squares inversion method to obtain a smoothed solution (stress tensor) for each subarea while avoiding data singularities. MSATSI provides the orientation of the three principal axes, as well as a relative stress magnitude quantity (R):

$$R = \frac{\sigma_1 - \sigma_2}{\sigma_1 - \sigma_3} R = \frac{\sigma_1 - \sigma_2}{\sigma_1 - \sigma_3} \quad (1)$$

where σ_1, σ_2, σ_3 are the magnitudes of the principal stress axes obtained from the deviatoric stress tensor. This way, the R value quantifies whether the magnitude of the intermediate principal stress σ_2 is closer to the magnitude of the most compressive or the least compressive principal stress. MSATSI calculates the optimal damping parameter by performing a series of inversions with varying values and comparing the resulting data misfit to the degree of

heterogeneity of the solution (model length). The chosen damping parameter is found on the trade–off curve of the two values, corresponding to the point that minimizes both the data misfit and the model length. Finally, we assess the uncertainties of our results using a bootstrap resampling method. We perform resamplings at least 20 times the number of our data for each grid point, specifying the confidence interval of the uncertainties at 95%. Finally, we construct a representative focal mechanism for each grid point, according to the best stress tensor derived from our methodology.

Exploitable Results

The results of the damped stress inversion are presented in Figure 2 and Table 1. We observe that in all grid points, the plunge and azimuth of the principal stress axes agree as expected with a strike–slip faulting regime, with low plunge values of both the σ_1 and σ_3 principal stress components. Our data constrain the plunge and azimuth of the principal stress axes adequately for the Kefalonia branch of the KTFZ, the stepover zone north of Kefalonia and the southern Lefkada grid point. In the case of the northern Lefkada (grid point 2, 3) subarea, we observe higher uncertainties in the plunges of both the σ_3 and the σ_2 principal stress components. Assessing these uncertainties through bootstrap resamplings, we find that they are mainly concerned with the plunges of the σ_3 axis. This, along with the value of the relative stress ratio R, indicate a stronger normal faulting component in this subarea and thus extensional characteristics. R values for the southern Lefkada (grid point 1, 3) and the stepover zone (grid point 1, 2) are found to be 0.45 and 0.41, respectively. Values of R closer to 0.0 evidence extensional component of the prevailing regional stress field, whereas values approaching to 1.0 are indicative of rather transpressional regimes. This is present in the north Kefalonia (grid point 0, 2) south Kefalonia (grid point 0, 1) and offshore Kefalonia (0,0) subareas, where the relative stress magnitude values increase, evidencing a stronger compressive stress component as we move towards the southern edge of the KTFZ. Nevertheless, the R values for all subareas under study remain relatively close to the 0.5 value, meaning the dominant faulting that characterize the regional stress regime is strike–slip. Following the World Stress Map project guidelines (Zoback, 1992) we calculate the azimuth of the maximum horizontal stress axis for every grid point. We observe as expected, that the maximum compression axis σ_1 corresponds to the S_{Hmax} and strikes SW–NE. Using the calculated best solutions for the P and T axes geometrical characteristics, we produced six representative focal mechanisms, one for each grid point. All are pointing towards a strike–slip stress regime, with the one nodal plane striking NNE–SSW and the second (conjugate) WNW–ESE.

Grid point (X,Y)	Optimal σ_1 Trend and Plunge	Optimal σ_2 Trend and Plunge	Optimal σ_3 Trend and Plunge	Relative Stress Magnitude	Representative Focal Mechanism					
					Nodal Plane 1			Nodal Plane 2		
					Strike	Dip	Rake	Strike	Dip	Rake

Table 1: Stress inversion results and representative focal mechanisms corresponding to the optimal principal stress axes for each grid point of our study area.

Summary and Conclusions

An effort has been exerted to detail the third–order stress field patterns that dominate the area of central Ionian Islands, the most seismically active part of the broader Aegean area drawing significant interest for its seismotectonic properties. Taking advantage of the wealth of data provided by the rigorous scientific work done on the region, we find consistent stress field characteristics, typical of dextral strike – slip stress regime. Relative stress magnitude

values for each subarea, point towards a notable extensional component to the northern parts of our study area, corresponding to the Lefkada KTFZ fault segments and the extensional duplex zone that connects the southern and northern KTFZ branches, whereas evidencing a transition towards a more transpressional regime towards the Kefalonia branch to the south. Nevertheless, the study area is dominated by the strike–slip fault motions of the KTFZ, indicated by the maximum compression axis being equal to the SH_{max} while the intermediate stress axis plunging steeply in every grid point.

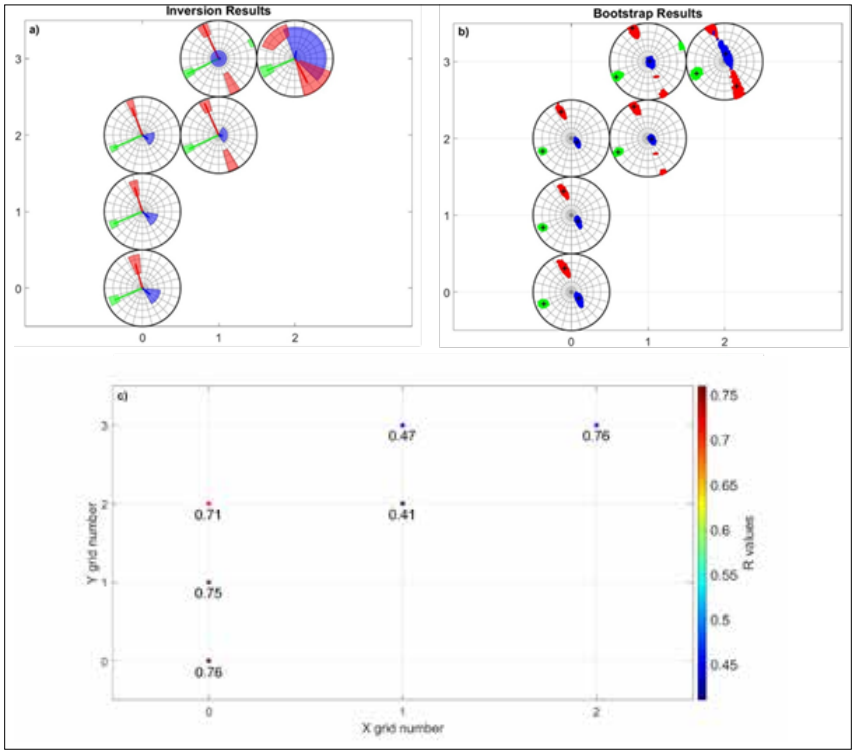

Figure 2: a) Inversion results for the 6 grid points of our study area. Optimal solutions for trend and plunge of the principal stress components σ_1, σ_2, σ_3 (colored green, blue and red, respectively) plotted on Wulff stereographic projection plots, each corresponding to a numbered subarea, according to Table 1. The respective colored areas denote the axes uncertainties in plunge and trend. b) Same as a, but presenting the trend and plunge scatter of the principal stress axes, after 2000 bootstrap resamplings for 95% confidence interval. Black crosses denote the optimal solution for each axis. c) Relative Stress Magnitudes for each of the 6 grid points

BULLETIN OF THE GEOLOGICAL SOCIETY OF GREECE, SP. PUBL.

EXTENDED ABSTRACT 005

Flood events over the past 115 years in the Municipality of Patras, southern Greece

Andriopoulou Mounteanou S.A.[1], Bathrellos G.D.[1], Skilodimou H.D.[1]
(1) University of Patras, Greece, geo13014@ac.upatras.gr

Introduction

Natural hazards are physical phenomena that can cause substantial harm to both the natural world and human environments. These hazards arise from endogenic or exogenic processes, such as tectonic activity or climate change, which can alter landforms and influence natural hazards, often directly affecting human activities (Migiros *et al.,* 2011, Kamberis *et al.,* 2012, Skilodimou *et al.,* 2014, Kokinou *et al.,* 2015, Bathrellos *et al.,* 2017, Bathrellos *et al.,* 2018).

Floods are natural events that have occurred throughout geological history, resulting from excessive surface runoff. Floodplains are formed through sediment deposition when rivers overflow their banks. They are considered favorable locations for human settlement due to their fertile soils, flat terrain, ease of excavation, and proximity to water sources. These advantages have encouraged the development and urbanization of floodplains, leading to an increase in flood-related disasters. Despite efforts to mitigate flooding through structures like dams, levees, and river channeling, the damage caused by floods continues to rise (Bathrellos and Skilodimou, 2006, Bathrellos, 2007, Skilodimou *et al.,* 2024).

Floods are a common occurrence in certain regions of the world. In urban settings floods are among the most hazardous natural events. The impacts of flooding extend beyond environmental damage, encompassing social and economic consequences as well. Floods can harm urban infrastructure and agricultural lands, and in severe cases, they can even result in the loss of human lives (Bathrellos *et al.,* 2016).

Between 2000 and 2024, there have been more than 400 major floods, including several catastrophic events floods that affected over 1.9 million people in Europe, claiming more than 2,000 lives and causing economic losses estimated at over 70 billion Euros (EM-DAT, 2024). Flooding is a frequent natural hazard in Greece, with numerous severe events occurring over the 25 years. These floods have led to the tragic loss of over 72 lives and caused extensive damage to properties, buildings, infrastructure, and the environment. Their effects have significantly disrupted both the national and rural economies with the financial impact surpassing 1 billion (Skilodimou *et al.,* 2021, EEA, 2024).

Objectives

This study highlights the flood events and their impacts in the Municipality of Patras from 1909 to 2024. In detail, the study explores the hydrological basins of the rivers within the study area, the occurrences of flooding, the regions impacted, and the damage inflicted on the urban infrastructure, particularly focusing on buildings. Furthermore, the study analyzes the occurrence of floods in particular areas and establishes a correlation between the impacted regions and the damaged structures.

Study area

The study area (Fig. 1A) includes the drainage basins of the Glafkos, Diakoniaris, Meilichos, Haradros and Selemnos river located in the northern Peloponnese region of southern Greece (Fig. 1B). These rivers discharge into the Gulf of Patras. The areas of the drainage basins are as follows: Glafkos River covers 108.5 km², Diakoniaris River spans 26.5 km², Meilichos River encompasses 22 km², Haradros River covers 25 km², and Selemnos River occupies 17.8 km², resulting in a total combined area of 199.8 km².

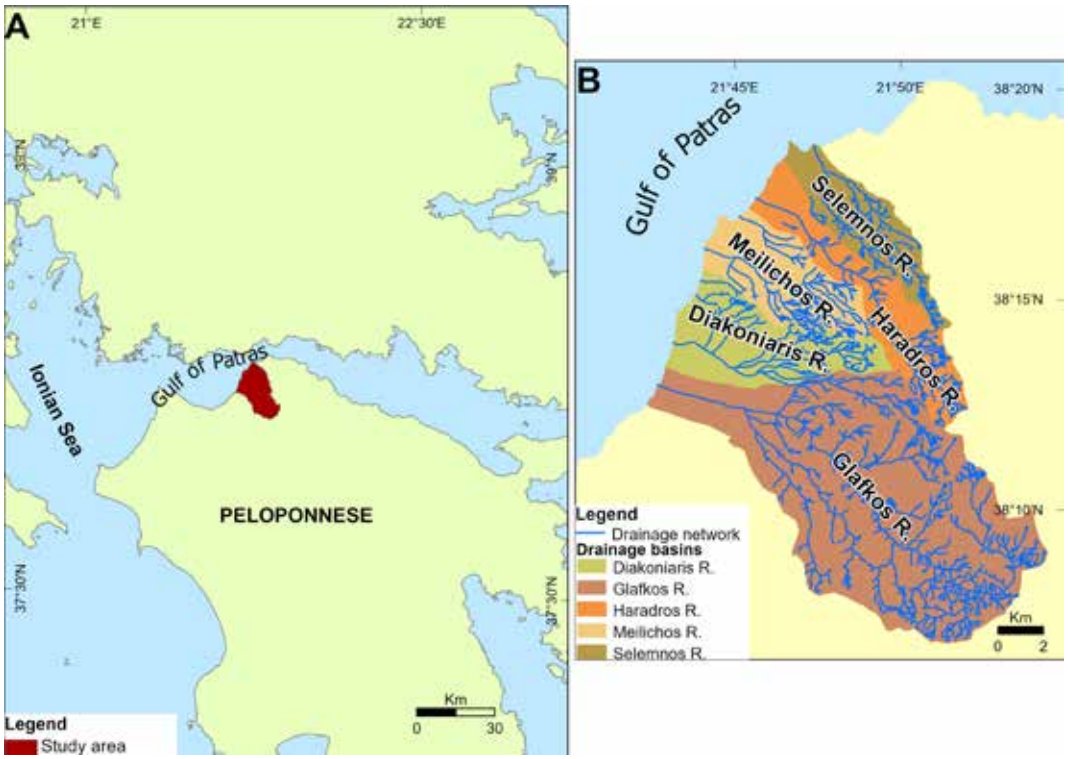

Figure 1. (A) Location map of the study area, (B) a map of the drainage networks and basins of the study area.

Methodology - Data

The data collected in the context of the current research were:

- Collection data from online sources (Ministry of Environment and Energy, 2017, METEO, 2024).
- Fact-checking the provided information and gathering additional details (UEDNPEI, 2014).

This study focused on key elements such as the flood locations, dates of occurrence, extent of the flooded area, types of damages, and the total damage caused by each flood event.

The data collection was initially carried out by consulting meteo.gr, which provides material on floods that have occurred between 2000 and 2024. Additional information, like the number of flooded buildings and the districts that these events occurred, was gathered from local newspapers. Following this, a search was performed on the official Press Museum website using filters and keyword searches to identify older flood events. The affected areas were determined from this data, and Google Earth was utilized for detailed calculations of the impacted regions. Thematic maps were then generated using ArcGIS Pro.

A temporal statistical analysis was performed to determine the number of events, the flooded area (in km^2), the number of affected buildings, and human casualties impacted by floods throughout the 115-year period. The frequency of flood occurrences in each district of Patras during this period was analyzed. Furthermore, data from Urban Atlas 2018 (Copernicus, Urban Atlas 2018, 2021) were used to evaluate the extent of the urban structure and to calculate the Building Cover Ratio (BCR) impacted by flooding.

Results

A total number of 20 flood events were recorded in the drainage basins of the Glafkos, Diakoniaris, Meilichos, Haradros and Selemnos rivers. Table 1 outlines the year in which floods occurred and the corresponding river, the affected area and the specific districts, the number of impacted buildings, and the human casualties. Over the 115-year period, there was only one instance of human casualties, occurring in 2001, which resulted in the loss of two lives.

Table 1. Classes of the year of the flood event, river that contributed for the phenomenon, flooded area, number of buildings that were casualties and people that lost their life

YEAR	RIVER	AREA (km2)	AFFECTED DISTRICTS	FLOODED BUILDINGS
1909	DIAKONIARIS	0.28	PSAROFAI, GIROKOMIO	40
1917	GLAFKOS	0.12	LEFKA	0
1927	GLAFKOS-HARADROS	1.12	MPOZAITIKA, KASTELOKAMPOS, MPEGOULAKI, ITIES	80
1931	GLAFKOS	0.24	ITIES, KRIA ITEON	25
1935	GLAFKOS	0.13	ITIES, KRIA ITEON	20
1940	DIAKONIARIS	0.62	AG. AIKATERINI, AG. PARASKEVI, TASI, GIROKOMIO, VILLA LADOPOULOU, AG. IOANNIS PRATSIKA	100
1956	DIAKONIARIS - GLAFKOS	2.03	MPEGOULAKI, PSAROFAI, AG. GEORGIOS LAGOURA, ZAROUCHLEIKA, AG. IOANNIS PRATSIKA, LAGOURA, AG. AIKATERINI, ITIES, KRIA ITEON	250
1959	HARADROS	0.22	SKAGIOPOULIO	100
1960	GLAFKOS	0.03	ITIES	0
1962	DIAKONIARIS - GLAFKOS-MEILICHOS - HARADROS-SELEMNOS	3.25	EGLIKADA, AG. AIKATERINI, AG. IOANNIS PRATSIKA, ITIES, AGYIA, AG. GEORGIOS LAGOURA, PSAROFAI, PROASTIO, SKAGIOPOULIO	4,000

1997	DIAKONIARIS	3.01	EGLIKADA, AG. AIKATERINI, AG. IOANNIS PRATSIKA, AG. GEORGIOS, LAGOURA, PSAROFAI, GIROKOMIO	1,500
2001	DIAKONIARIS	0.28	ZAROUCHLEIKA	150
2002	DIAKONIARIS	0.01	CENTER	2
2013	MEILICHOS	0.05	AGYIA	0
2021	MEILICHOS	0.21	VOUTENI, KOTRONI	40
2024	GLAFKOS	0.01	ITIES	0

The Municipality of Patras consists of just over 50 districts, with this study focusing on the main districts, including and those that have experienced flooding.

Figure 2 depicts the drainage basins of the Glafkos, Diakoniaris, Meilichos, Haradros, and Selemnos rivers, along with the spatial distribution of flooded areas across each district and drainage basin. Notably, in the Diakoniaris River basin, the flooded area results from multiple flood events over different years. This basin has the largest flooded area, covering approximately 3 km². It also exhibits the highest level of urban development among the studied hydrological basins and has experienced a significant number of flood events. In contrast, the Selemnos River basin has the smallest flooded area.

Figure 3 illustrates the number of flood events across various districts in Patras. Ities has the highest frequency, with six flooding events, making it the most affected district in Patras, other significantly affected districts include Psarofai (4 flooding events), Ag. Aikaterini, Girokomio, Kria Iteon and several others with 3 events each. Many regions, including Ketes and Anthoupoli recorded only one flooding event. Some, appear to have no significant recorded flooding frequency, indicated by the absence of bars. Notably, 40% of the districts have been affected by flooding multiple times emphasizing the recurrent nature of the issue.

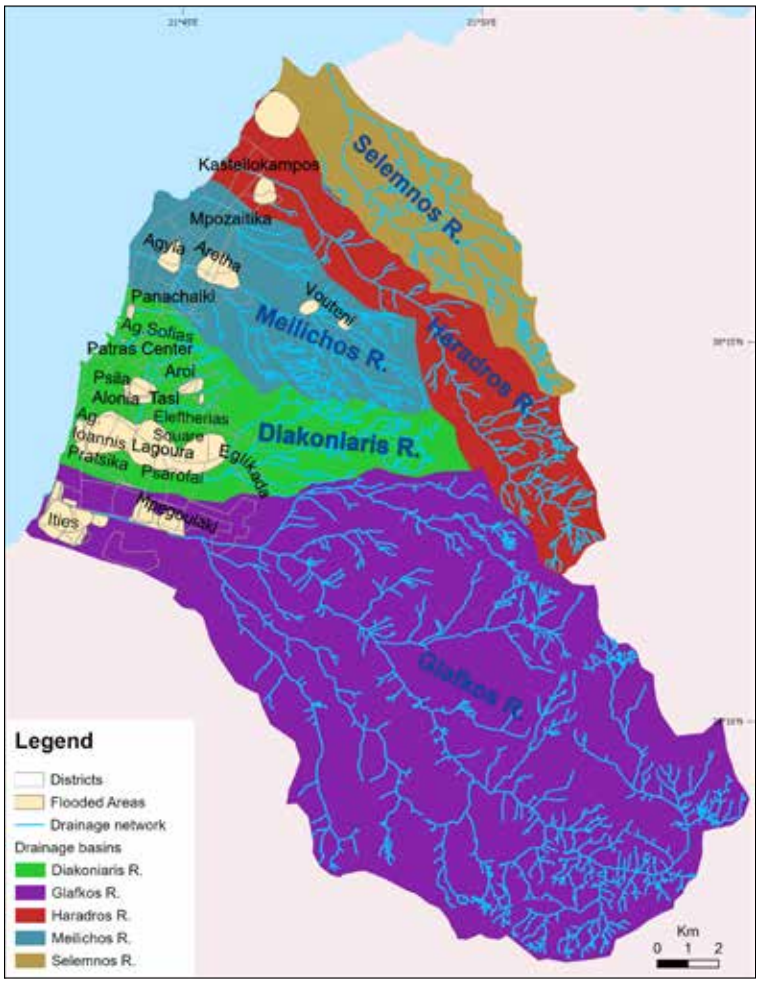

Figure 2. Map of Patras with districts, drainage basins and networks as well as flooded areas.

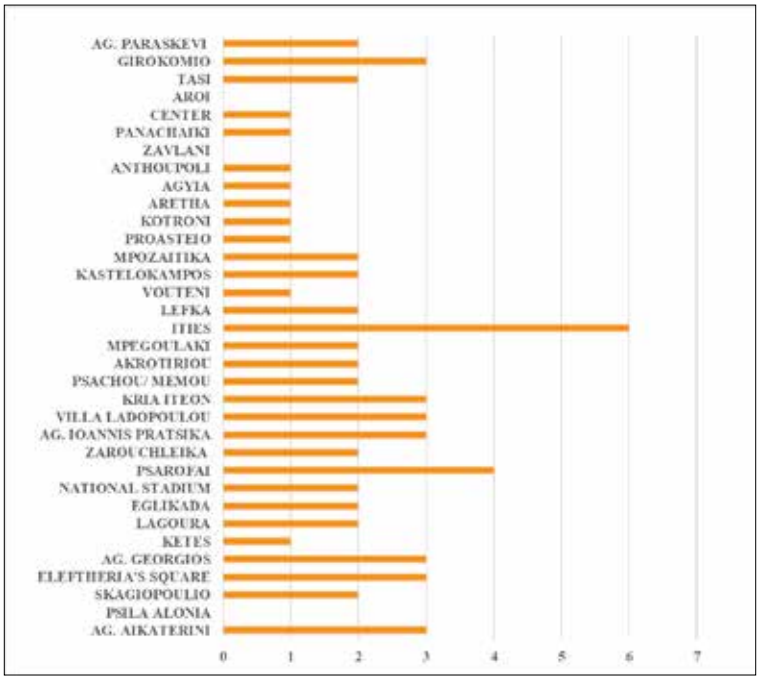

Figure 3. The number of flood events in the districts of Patras.

Figure 4 illustrates the impact of flooding on the Building Cover Ratio (BCR) over the past 115 years. When analyzed alongside the data in Table 1, a clear correlation emerges between the BCR, the extent of the flooded area, and the number of affected buildings in specific years.

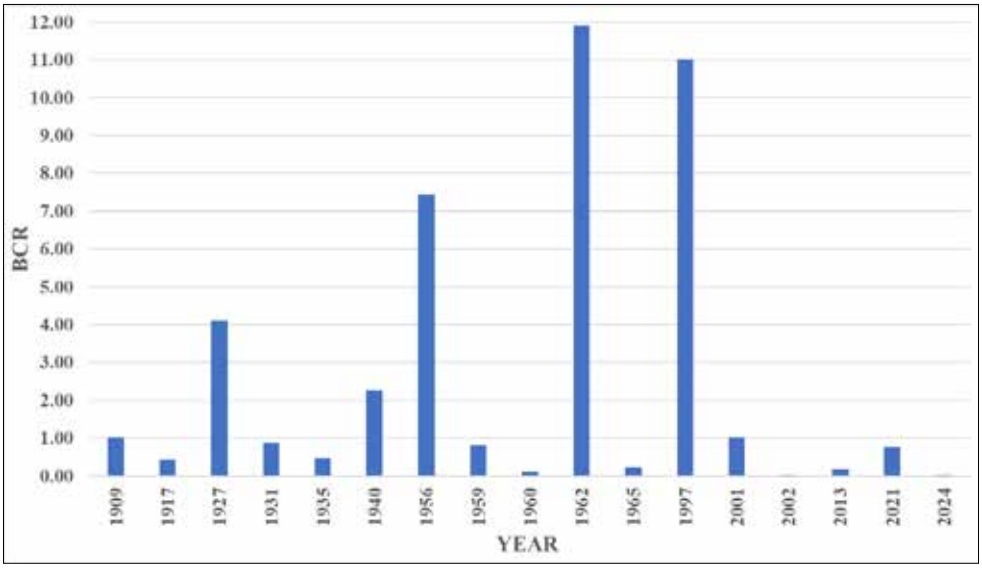

Figure 4. The Building Cover Ratio (BCR) affected by flood over the past 115 years.

Notably, in 1927, the BCR reached a high value of 4.1, which coincided with a significant flooded area of 1.12 km² and a large number of flooded buildings (80). Moreover, in 1956, the BCR was recorded at 7.43, indicating a significant flooding event, with the flooded area extending to 2.03 km² and the number of affected buildings reaching 250, both at considerable levels. In 1962, the BCR reached its peak value of 11.90, corresponding to the largest flooded area of 3.25 km² and the highest number of affected buildings (4,000), marking one of the most catastrophic floods recorded._Similarly, in 1997, the BCR (11.09) was nearly at its peak, corresponding to the flooded area of 3.01 km² and a significant number of affected buildings (1,500). The buildings affected by floods mainly involve basements and ground-floor structures.

Conclusions and discussion

The study of flood events in Patras reveals significant insights into the frequency, impact, and trends over the past 115 years. A total of 20 flooding events were recorded within the drainage basins of Glafkos, Diakoniaris, Meilichos, Haradros, and Selemnos rivers, affecting various districts of Patras.

The year 1962 stands out as the most catastrophic flooding event, followed by 1956 and 1997, with both the flooded area and the number of affected buildings reaching their highest levels. These years highlight the direct relationship between the extent of the flooded area and the resulting damage to infrastructure. While 2001 is the only recorded year with human casualties, emphasizing the severity of the event despite a subsequent reduction in flooded areas.

Ities is identified as the most flood-prone district in Patras, with six recorded flooding events, making it the most severely impacted area. It is worth mentioning, 40% of the regions have experienced flooding more than once, emphasizing the widespread and recurrent nature of the issue.

A distinct relationship is observed between the BCR, the size of the flooded area, and the number of flooded buildings in particular years. The peak BCR of 11.90 was recorded in 1962, coinciding with the largest flooded area of 3.25 km² and the highest number of flooded buildings (4,000).

Background

Natural phenomena such as earthquakes, floods, and landslides, which appear throughout geological history, are now classified as natural hazards. These events pose significant risk to human safety on a global scale (Bathrellos and Skilodimou, 2006). Effective planning is essential for minimizing loss of life and reducing the economic impact of these hazards (Bathrellos *et al.,* 2024). Accurate information on the spatial distribution of natural hazards serves as a crucial resource for environmental planners and engineers, helping them identify suitable sites for land use and development (Bathrellos and Skilodimou, 2019).

Natural hazards are complex phenomena, and most published studies have focused on in-depth analyses of individual hazard types (Bathrellos *et al.,* 2016, Karpouza *et al.,* 2021, Skilodimou *et al.,* 2021, Youssef *et al.,* 2024). However, a particular area is rarely affected by only one hazard; instead, multiple hazards may occur simultaneously or consecutively. In such cases, managing separate hazard zones for each type of disaster becomes impractical, especially when multiple hazards must be considered (Bathrellos *et al.,* 2021, Karpouza *et al.,* 2023). The solution to this challenge lies in adopting a multi-hazard analysis, which allows for a comprehensive assessment of various hazard types. Multi-hazard analysis is an essential tool for selecting appropriate land uses and evaluating the vulnerability and risk of urban areas. It plays a critical role in mitigating natural hazards and managing urban disasters (Karpouza *et al.,* 2024).

Objectives

In this context, the HOMEROS project focuses on enhancing multi-hazard assessment approaches within the fields of seismology, geodesy, geology, geomorphology and engineering geology. It utilizes technical solutions tailored to the big data era, marking a major step forward in standardizing research methodologies, fostering collaboration, and improving the understanding and forecasting of natural hazards through Open Science practices. HOMEROS concentrates on high-hazard regions in Greece, characterized by intense seismic activity, floods, and landslides. It consolidates earthquake, ground deformation, flood, and landslide data to offer a comprehensive assessment of these hazards.

This paper provides data and results from the program related to flood events and the production of flood hazard assessment maps in the northern Peloponnese. This work represents an early example of the findings from the HOMEROS project, stemming from the collaboration between the University of Patras, Lund University, Aristotle University of Thessaloniki, and the National and Kapodistrian University of Athens.

Study area

The study area includes the drainage basins of the Xerias, Phoenix, and Peneus rivers, located in the northern Peloponnese region of southern Greece (Fig. 1). The Xerias drainage basin spans 170 km² with a predominantly north-south elongated shape. Similarly, the Phoenix River basin covers around 94 km² and exhibits a southwest-to-northeast elongated orientation. Both river systems drain into the Gulf of Corinth. In contrast, the Peneus River drainage basin, occupying an area of approximately 900 km², extends in an east-west direction. It flows westward and discharges into the Ionian Sea (Fig. 1).

Methods

HOMEROS adopts an innovative approach by leveraging existing data and services from e-science gateways and platforms at multiple levels (national, research infrastructures, or scientific clusters), as well as external resources like Copernicus. It emphasizes the application of FAIR principles in research to deliver new open-access data products.

In this context, data from existing scientific publications were utilized to implement the project. Specifically, HOMEROS incorporated documented flood events that occurred for the period from 1920 to 2021, in the drainage basins of the Xerias, Phoenix, and Peneus rivers (Fig. 2), as reported by Bathrellos *et al.* (2017), Skilodimou *et al.* (2024) and Skilodimou *et al.* (2019), respectively. Additionally, it utilized information from these works concerning the applied methodologies and flood hazard assessment maps.

Figure 1. The study area comprises the drainage basins of the Xerias, Phoenix, and Peneus rivers.

Five key factors have been identified as the most significant in influencing flood events. These factors include slope, elevation, hydro-lithology, distance to streams, and land use. The Analytical Hierarchy Process (AHP) was integrated with Geographic Information System (GIS) to facilitate the assessment of the chosen factors employed in the production of the flood hazard assessment maps.

Figure 2. Flood events in the drainage basins of the Xerias, Phoenix, and Peneus rivers.

Results

The recorded number of past flood events for each drainage basin is as follows: ten for the Xerias River, eleven for the Phoenix River, and eight for the Peneus River.

The flood hazard assessment maps for the three drainage basins were categorized into five levels of flood hazard: very low, low, moderate, high, and very high (Bathrellos et al., 2016, Skilodimou et al., 2021). As stated by Bathrellos *et al.* (2017), the northern and central regions of the Xerias drainage basin have the most extensive coverage of very high and high flood hazard zones. The moderate hazard zone is primarily located in the northeastern and central parts of the basin, whereas the low and very low hazard zones are concentrated in the southern region (Fig. 3).

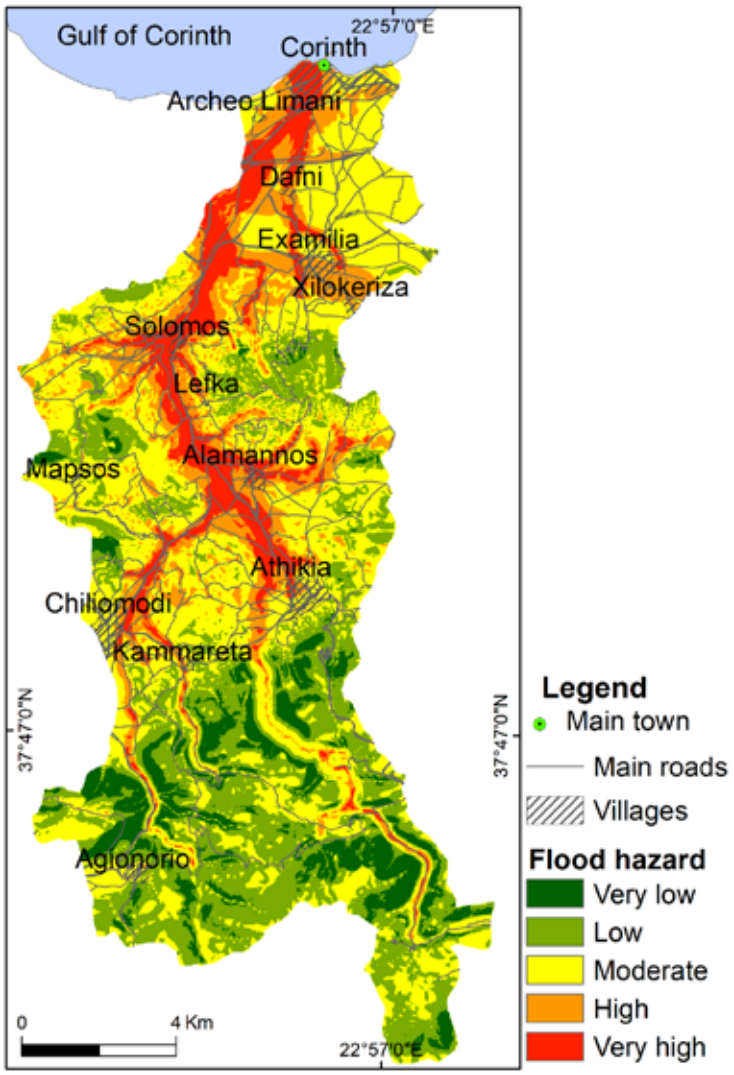

Figure 3. The flood hazard assessment map in the drainage basin of the Xerias River.

The high and very high hazard zones are mainly located along the mainstream of the Xerias drainage network and at the points where it intersects with major tributaries. Notably, most of the recorded flood events in the study area occur within the very high and high flood hazard zones. The lowland terrain, gentle slopes, presence of impermeable formations, and urbanization of these areas contribute to increased surface runoff, creating conditions that are more prone to flooding.

According to Skilodimou *et al.* (2024), the very high and high flood hazard zones are mainly found in the northern and central parts of the Phoenix drainage basin, along the mainstream channel of the drainage network. The moderate hazard zone is largely concentrated in the central area, extending into the northern, western, and southern areas. In contrast, the southern, western, and eastern parts of the study area include many locations within the low and very low hazard zones (Fig. 4).

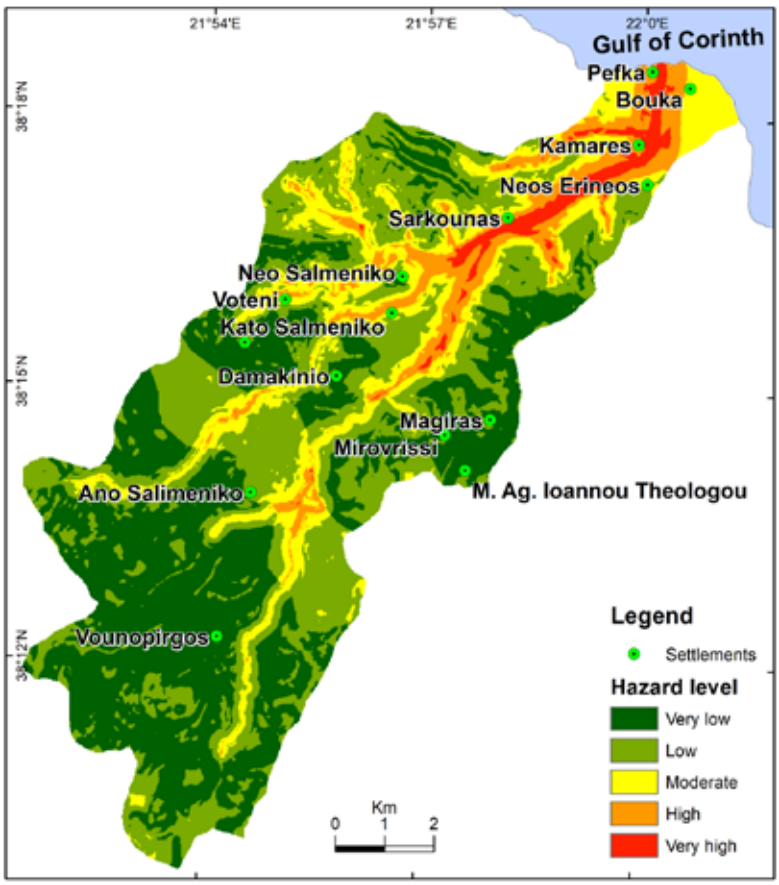

Figure 4. The flood hazard assessment map in the drainage basin of the Phoenix River.

The relatively small size of the Phoenix River drainage basin, along with its ephemeral streams, plays a key role in influencing flood events within the study area. Furthermore, the constricted artificial riverbed in the river's downstream sections, caused by agricultural and urban activities, disrupts the river's natural flow patterns and contributes to flooding incidents.

As reported by Skilodimou et al. (2019), the western, northern, and southwestern parts of the Peneus drainage basin include areas most susceptible to flooding, primarily along the mainstream of the Peneus drainage network. The moderate hazard zone is situated in the western and northern sections of the basin, while the low and very low hazard zones are found in the southern and eastern parts of the area (Fig. 5).

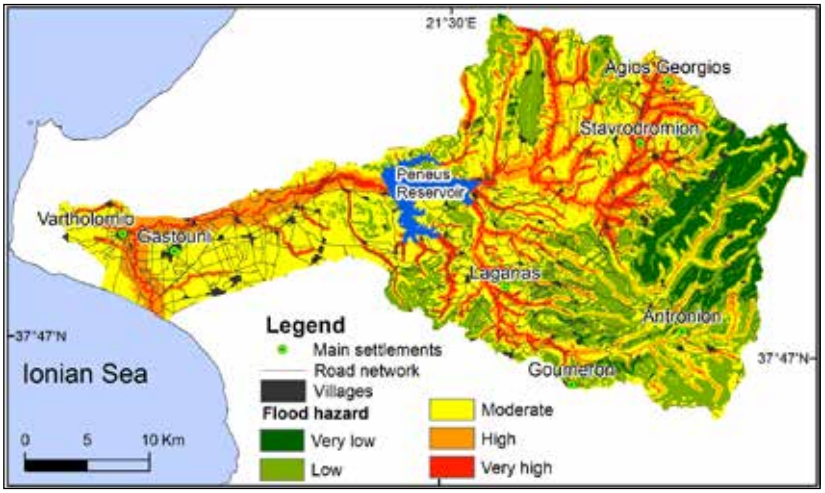

Figure 5. The flood hazard assessment map in the drainage basin of the Peneus River.

Land use changes in areas impacted by extensive fires have contributed to an increase in flood events. Additionally, the constricted artificial riverbed in the lower reaches of the Peneus River, resulting from agricultural land use and urban development, significantly disrupts the natural flow dynamics and exacerbates flooding.
Table 1 displays the percentage of area covered by each flood hazard zone for the Xerias, Phoenix, and Peneus drainage basins.

Table 1. The percentage of area for each flood hazard zone for the Xerias, Phoenix, and Peneus drainage basins.

	Xerias drainage basin	Phoenix drainage basin	Peneus drainage basin
Flood hazard zone	**Area (%)**		
Very low	9	38	8
Low	27	36	24
Moderate	40	16	39
High	15	8	20
Very high	9	2	9

In the Xerias drainage basin, the very high and high flood hazard zones cover a significant portion, making up about one-quarter of the basin. In comparison, the Phoenix drainage basin has a much smaller coverage, with these two zones spanning only 10% of the area. The Peneus drainage basin, however, has the largest extent, with the very high and high hazard zones covering approximately one-third of the basin.

Conclusions

The total number of past flood events across the drainage basins of the Xerias, Phoenix, and Peneus rivers amounts to twenty-nine. The northern and central areas of the Xerias and Phoenix drainage basins are the most flood-prone, while the western, northern, and southwestern regions of the Peneus drainage basin are particularly vulnerable to flooding. Among the three drainage basins, the Peneus drainage basin has the largest areas classified as very high and high flood hazard zones.

The gentle slopes and widespread urban development of the lowland areas in the Xerias drainage basin play a role in flooding. In the downstream sections of the Phoenix River drainage basin, the narrow artificial riverbed, shaped by agricultural and urban activities, also contributes to flooding. Changes in land use in regions affected by extensive fires have led to an increase in flooding events in the Peneus drainage basin.

EXTENDED ABSTRACT 007

Digital Visualization of Geological Heritage at Lesvos UNESCO Global Geopark: The Role of 3D Animations in Educational Experiences

Antonakis Emmanouil 1, Nicholas Zouros 2
(1) University of the Aegean, Mytilene, Greece, manolis.antonakis@rocketmail.com (2) University of the Aegean, Mytilene, Greece

Introduction / Background

In this paper, we use 3D animation technologies to visualize, interpret and communicate geological heritage in Lesvos UNESCO Global Geopark. Our objective is to make geological heritage more accessible to the general public. 3D animations have been utilized as a means to periodically monitor and document changes in geological sites over time, supporting conservation initiatives. Additionally, they can replicate geological events, describe the formation and evolution of landscapes, simulate how we believe paleoenvironments looked for a holistic learning experience. Their interactive and dynamic nature can boost engagement and facilitate learning in an educational context, while it can also engage tourists by offering previews, virtual tours of inaccessible or fragile sites. In this paper, we select 21 case studies of geosites or monuments of geological heritage to 3D geo-visualize. The selection method is based on three criteria: accessibility, supervision and relief of the geosite out of the total number of 151 designated geosites of the Geopark. The results were verified with a pilot study to participants of environment educational programs in the Natural History Museum of Lesvos Petrified Forest in 2024. . Overall, the approach promotes visitor democracy, as all groups have access to the visualized geosites and can be used to further improve the visibility of the geosites and that of the Geopark.

Objectives

In this paper, we use 3D animation technologies to visualize, interpret and communicate geological heritage of Lesvos UNESCO Global Geopark. Our objective is to make geological heritage more accessible to the general public.

Methodology

This research included the creation of 3D animation in Google Earth Studio to introduce the most important geosites within Lesvos UNESCO Global Geopark, it was divided into four topics: geosite selection, data collection and preparation, animation creation and visualizations evaluation. The main goal is to use these 3D animations in educational activities for students and non-experts.

Selection of Geosites:

The first phase involved identifying key geosites within the Lesvos UNESCO Global Geopark that would benefit from enhanced visual representation. Criteria for selection included accessibility of Geosite, Supervision of the location of the geosite,, and The topography of a geosite's location. Key sites, such as volcanic formations, petrified parks, and notable tectonic features, were chosen to highlight the geological diversity of the region.

Data Collection and Preparation:

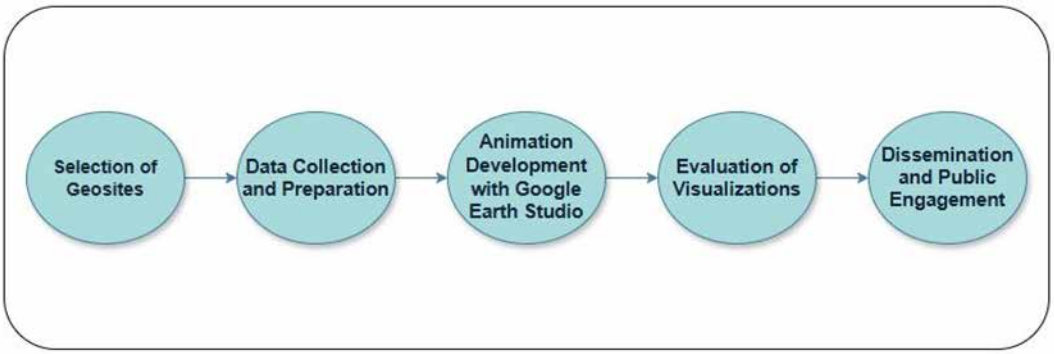
for each selected geosite, topographic and geological data were gathered to accurately represent the site in 3D animation. Sources included geological maps, high-resolution satellite imagery, and geospatial data accessible through Google Earth. Historical and interpretive information on each site was also collected to provide context for the animations.

Animation Development with Google Earth Studio:

Using Google Earth Studio, each geosite was visualized in a sequence of animations. The development process included defining camera paths to capture distinct perspectives, zooming into details of geological formations, and incorporating dynamic movements to simulate real-world exploration. Attention was given to camera angles and framing to ensure that animations were both engaging and informative.

For added educational value, labels, annotations, and shapes were embedded directly in the animations, highlighting significant geological features and processes relevant to each site. This interactive approach aimed to increase viewer comprehension of the complex geological structures and their historical importance.

Evaluation of Visualizations:



The educational activities focus on presenting complex geosites with one more easy and interactive way. After completing the educational activity, we made it for students and educators. The users give us feedback through questionaries. was collected to assess the animations' comprehensive, engaging, and educational impact, The responses guided further refinements, with adjustments made to optimize the balance between scientific accuracy and accessibility for a non-specialist audience.

Dissemination and Public Engagement:

The finalized 3d animation were presented to students and public due to guided tour in fieldtrips in Lesvos UNESCO Global Geopark and in educational trips at Natural History Museum of the Petrified Forrest of Lesvos, also were shared through the official Lesvos UNESCO Global Geopark website and social media platforms to reach a wider audience. By incorporating Google Earth Studio's animations, the project aimed to make complex geological phenomena more comprehensive and engaging for the public, fostering a broader appreciation of Lesvos's geological heritage.

This methodology demonstrates a structured approach to utilizing 3D animation as a powerful tool for geosite interpretation and education, highlighting the potential of Google Earth Studio to enhance public understanding of geological heritage sites.

Table 1 Methodology Flowchart

The study area

Lesvos UNESCO Global Geopark has a unique wealth of geological monuments and landscapes of natural beauty, habitats and cultural monuments which have contributed to its recognition and inclusion in the Global Geoparks Network of UNESCO.

In its western part, the Petrified Forest dominates, a unique piece of geological history, which has been declared a "Preservable Monument of Nature". Lesvos is scattered with a multitude of geological monuments and landforms of unique value and importance. Some of them are impressive volcanoes, hot springs, important fossil sites, large geological faults, waterfalls, coastal landforms that are important evidence of geological history that testify to the evolution of the Aegean basin.

The geosites: selection process

In this paper, we select 21 case studies of geosites or monuments of geological heritage to 3D geo-visualize. The selection method is based on three criteria: accessibility, supervision and relief of the geosite out of the total number of 151 designated geosites of the Geopark.

Geological Heritage, Education, and Geotourism

Geological heritage encompasses the unique geological formations, landscapes, and features that hold scientific, educational, and cultural significance. The integration of geological heritage into education fosters a deeper understanding of Earth's processes, history, and conservation needs. Geotourism, which focuses on showcasing geological attractions, bridges education and sustainable tourism by engaging visitors in immersive, place-based learning experiences. By blending science with storytelling, geotourism not only raises awareness about geological phenomena but also supports the local economy and conservation efforts, creating a holistic approach to promoting and preserving geosites like the Lesvos UNESCO Global Geopark.

3D Tools and Geoheritage

Digital tools, particularly 3D technologies, have revolutionized the way geological heritage is presented and understood. Otherwise, 3D animations, virtual reconstructions, and interactive visualizations, it is possible to bring to life geological features and processes that are otherwise inaccessible or difficult to comprehend. In the context of Lesvos UNESCO Global Geopark, these tools offer a dynamic platform for engaging educational experiences, allowing students and visitors to explore virtual landscapes, simulate volcanic activity, or visualize tectonic faults. This innovative approach not only enhances learning but also deepens appreciation for geoheritage by making abstract or hidden processes tangible and memorable.

Results

In this study, a total of 225 students and educators from Greece and other EU countries were surveyed during their visit to the Natural History Museum of the Lesvos Petrified Forest and various geosites within the Lesvos UNESCO Global Geopark. These participants were provided with scientific information regarding the geological heritage of the area, with the consideration of 3D geosite animations incorporated into the presentations to facilitate enhanced comprehension of the geosites. After the educational activity the users asked questionnaires, the findings of the study indicated the following:

To the question "On a scale of 1 to 5, how understandable was the concept of a geosite » 54% of respondents reported that the use of 3D animations made geosites highly comprehensive, while 33% found them very comprehensive.

Table 3 Methodology Flowchart

Discussion

The implementation of 3D animations through Google Earth Studio as educational tool for geosites within the Lesvos UNESCO Global Geopark has provided significant insights into the potential of digital tools for geoheritage promotion and education in other geoparks. This discussion addresses the benefits, challenges, and future implications of using this approach in geoscientific communication.

Enhanced Public Engagement and Education

Mixing geoeducation with the tours is an optimal way to keep tourism interesting. the tour guide and educational boards play an important role (Wang et al., 2023) The results demonstrate that 3D animations can serve as an effective tool for increasing public interest and comprehension of complex geological processes and formations. By offering an immersive, interactive view of geosites, animations make the scientific details of the landscape accessible to a broader audience, including those with limited geoscientific knowledge. Enhanced engagement aligns with findings in prior studies, where 3D visualization has been shown to effectively support educational initiatives in geoparks and geoscience education more generally.

Accessibility and Preservation of Geoheritage

The virtual nature of 3D animations also addresses key challenges in geoheritage conservation. By providing virtual access to sensitive or inaccessible areas, these animations help minimize the environmental impact of tourism, reduce the risk of physical degradation, and allow continuous public engagement without compromising the integrity of the geosites. This approach aligns with current geoheritage conservation goals, which advocate for minimal environmental impact while promoting public awareness and educational

outreach. Virtual flights over larger territories, supported by relevant commentaries highlighting relationships between nature and humans, may in turn be an attractive means to become acquainted with areas which lack singular spectacular sites (Migoń and Pijet-Migoń, 2024)

Technical and Methodological Limitations

Despite the successes observed, google earth is not perfect there exist several limitations, that is the inconsistent quality of images, insufficient capability for quantitative measurement (Yu and Gong, 2012),

lack of analytical functionalities, the study faced limitations in terms of data resolution and platform capabilities. Google Earth Studio, while powerful, has constraints regarding data detail and may not fully capture subtle geological features. Future studies could explore supplementary tools like high-resolution GIS mapping software or custom 3D modeling to complement Google Earth Studio, thus enhancing the accuracy of the representations. Additionally, labeling and annotation tools within Google Earth Studio could be expanded to improve the educational value of animations.

Future Research and Practical Applications

The use of 3D animation for geoheritage could be expanded in future research to include more comprehensive datasets, interdisciplinary collaborations. Also, it can be a useful tool for geoparks with hard accessible and fragile geosites.highlighting the role of 3D animations in geoheritage education and conservation.

However, it could further elaborate on the specific technical constraints of Google Earth Studio. For example, while the paper mentions data resolution issues, a deeper analysis of how these limitations affect the accuracy of geological feature representations such as fine-scale in different variations or subtle geomorphological changes—would be beneficial. Additionally, a comparison with alternative 3D modeling tools, such as GIS-integrated software or photogrammetry-based reconstructions, could provide a more comprehensive perspective on the advantages and trade-offs of the chosen methodology.

Furthermore, expanding the future research directions section to explore AI-driven enhancements, such as machine-learning-assisted geosite identification or automated annotation features, could significantly enhance the study's impact. Integrating AI could help refine data visualization, allowing for real-time user interaction and adaptive learning experiences tailored to different audiences. These aspects would not only strengthen the study's contribution to digital geoheritage visualization but also position it within the broader context of emerging technologies in geoscience education.

Conclusion

This study highlights the strong potential of using 3D animations as educational tools for geoheritage promotion, offering a way to communicate advanced geological science contents in an effective and enjoyable manner that can effectively engage the public in learning about culturally complex geological knowledge. Considering these benefits, while digital solutions will remain a powerful asset in the future of geoscience education and conservation, both technical innovations and methodological optimizations are necessary to enhance the impact of such visualizations. The combinations of Guided tour with 3D animation it can be an educational approach, and it can contribute to geological heritage management for fragile and inaccessible geosites.

Overall, the approach promotes visitor democracy, as all groups have access to the visualized geosites and can be used to further improve the visibility of the geosites and that of the Geopark

Land Subsidence and Flooding in the East Thessaly Plain: A Historical Overview

Antoniadis N.1, Loupasakis C.1

(1) School of Mining & Metallurgical Engineering, National Technical University of Athens, nikolaosantoniadis@metal.ntua.gr

Background

The East Thessaly Plain, a critical region for agricultural production in Greece, has a rich and complex geological and hydrological history that has shaped its current environmental and socio-economic landscape. Prehistorically, Lake Voivida, a vast body of water, covered the Plain and influenced early human settlements (Thermou, 2023). Over centuries, the lake experienced fluctuating water levels, with humans adapting to the changing environment. The region's evolution saw a transition from lake-based ecosystems to large-scale agricultural land use, particularly as drainage and flood management projects were implemented in the late 19th and early 20th centuries. In the 1960s and 1970s, rapid agricultural expansion, combined with intensive groundwater extraction for irrigation, led to significant hydrological changes. As a result, the East Thessaly Plain became one of the most important agricultural areas in Greece, contributing significantly to the country's grain production. However, this transformation came at a significant environmental cost, including land subsidence, water shortages, and vulnerability to flooding (Arapostathis et al., 2024). In recent decades, the Plain has experienced recurring land subsidence, particularly in areas that rely heavily on groundwater for irrigation. These subsidence phenomena, linked by the overexploitation of the aquifers, have been influenced by extreme weather events, including the 2023 Daniel storm, which caused widespread flooding and infrastructural damage. The interaction between land subsidence, flooding, and land use changes, compounded by climate change, has created a complex set of challenges for the region's future.

Objectives

This paper aims to provide a comprehensive historical overview of the evolution of the East Thessaly Plain emphasizing on the land subsidence, as well as explore its interaction with flooding events, land use changes, and extreme storms, particularly in the context of the intensification of agricultural practices over the past century. The study draws upon existing research, reports, satellite-based InSAR data, and historical accounts.

Methods

A detailed review of historical documents, archaeological excavations, and scientific literature has been conducted to track the region's evolution from prehistoric lake systems to modern agricultural landscapes. Key sources include studies of early human settlements in Thessaly, geological, geotechnical and geophysical surveys, and flood records. The study incorporates data from geological surveys, such as reports conducted by the Hellenic Survey of Geology and Mineral Exploration (HSGME), Central Laboratory Public Works (KEDE), as well as reports from the Ministry of Environment and Energy of Greece.

Open-access InSAR (Interferometric Synthetic Aperture Radar) products, such as Copernicus European Ground Motion Service have been used to track land subsidence over the last decade, providing a unique opportunity to assess the long-term impacts of groundwater extraction and flooding phenomena on the region's land stability.

Field surveys and ground-based observations have been combined with remote sensing data to assess the physical and hydrological changes in the East Thessaly Plain, focusing on key areas such as Larissa, Tyrnavos, and Velestino. This multi-method approach allows for a more comprehensive understanding of the historical and ongoing processes affecting the region.

Results

The results of the study reveal a clear relationship between land subsidence, changes in land use, and extreme weather events. Historical records suggest that the area has long been subject to fluctuating surface water levels, with periods of lake expansion and contraction. The draining of Lake Karla in 1962, which transformed large parts of the Thessaly Plain into cultivated land, marked a significant turning point in the region's hydrological history. This, along with the intensification of irrigation practices, created a situation where groundwater extraction reached unsustainable levels, leading to the onset of land subsidence.

Satellite-based InSAR data has shown that subsidence is most pronounced in areas that experienced intensive groundwater extraction, with significant subsidence recorded in the regions of Larissa and Tyrnavos. The rate of subsidence has increased since the 1990s, coinciding with the period of progressive intensification of agricultural practices in the region. InSAR data also highlights that the subsidence is not uniform, with certain areas showing localized shifts in the ground level that correspond with faults and tectonic zones (Fakhri & Kalliola, 2015; Parcharidis et al., 2011; Vassilopoulou et al., 2013). Land subsidence phenomena are still ongoing as shown by the European Ground Motion Service's products (Figure 1).

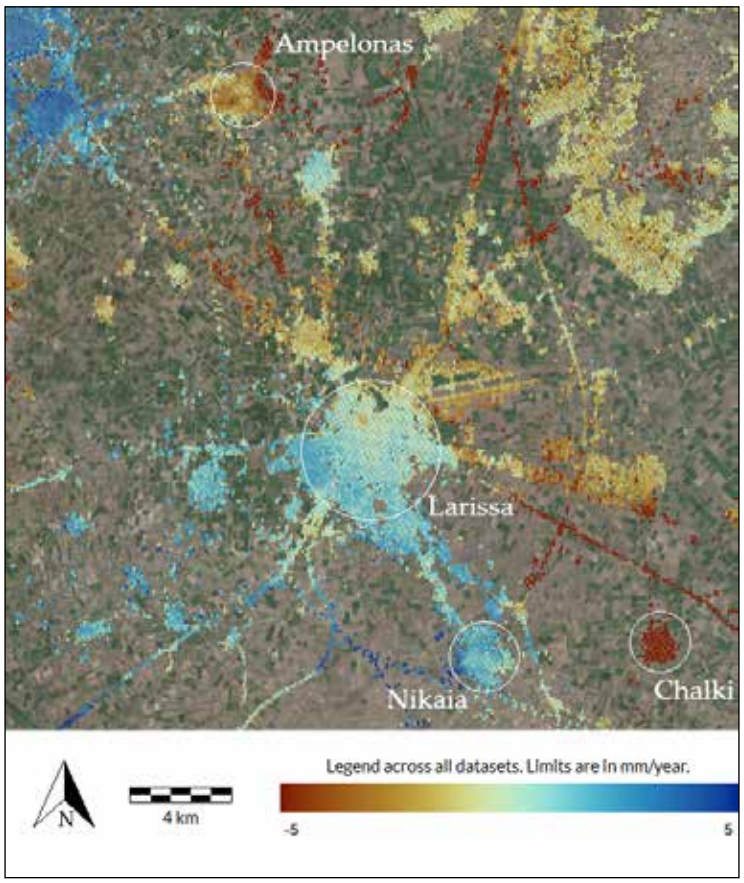

Figure 1. Ground deformation phenomena in the greater area around Larissa from EGMS Copernicus

Field surveys and studies reported land subsidence phenomena in several villages such as Rizomylos, Stefanovikeio, Kastrio, Melia, and Niki, where the drop in the water table reached up to 35 meters by the early 1990s (Soulios, 1997), while similar patterns have been identified in the villages of Halki and Magoula (Kaplanides A. & Fountoulis D., 1997). Land subsidence has also been observed in the Karla area, where excessive groundwater extraction took place. Marginal fractures appeared as the thickness of

the Quaternary sediments diminished (Rozos, 2007). These findings were aligned with tectonic patterns in the region, where subsidence appeared more pronounced along fault zones, suggesting a combination of natural tectonic activity and human-induced groundwater extraction as primary contributors to subsidence in the region.

On the other hand, flooding events, particularly those caused by extreme storms like the Daniel storm in 2023, have further affected the impact of subsidence on the region. These floods have caused widespread inundation, damaging infrastructure and agricultural land. The interaction between land subsidence and flooding is particularly problematic in areas with poor drainage systems, such as the Lake Karla area, where water remains stagnant for extended periods after heavy rainfall.

Conclusions

The East Thessaly Plain's evolution has been shaped by a complex interaction between geological processes, human activity, and climate change. The expansion of irrigation systems and exploitation of the underground water have transformed the Plain into one of the most productive agricultural regions in Greece. However, this transformation has come at the cost of land subsidence, which has been exacerbated by groundwater overexploitation. The review underscores the need for more sustainable water management practices to mitigate further subsidence and flooding risks. The integration of satellite-based monitoring techniques like InSAR offers a powerful tool for tracking ground deformation and assessing the long-term impacts of land use changes.

The findings highlight the importance of continued monitoring of groundwater levels and the implementation of flood control measures to protect the agricultural productivity of the East Thessaly Plain. Furthermore, the ongoing challenges posed by land subsidence and extreme weather events underscore the need for adaptive strategies to address the evolving risks associated with climate change and urbanization in the region. The study also calls for further research into the interactions between groundwater extraction, land subsidence, and storm-related flooding to develop more comprehensive and effective risk management strategies for the future.

EXTENDED ABSTRACT 009

Geological suitability in remote mountainous settlements using the AHP method. The case study of the settlement of Klepa in Greece

Antonopoulou A.[1], Depountis N.[1], Kokkalas S.[1]*

*(1) Department of Geology, University of Patras, 26504 Patras, Greece. *up1065387@ac.upatras.gr*

Research Highlights: **GIS-based Analytical Hierarchy Process (AHP) for geological suitability evaluation in remote mountainous settlements**

Introduction

The evaluation of geological suitability is crucial in managing and planning residential development in settlements, where geological conditions are harsh, and accessibility is limited. This becomes even more critical in areas affected by geohazards, such as landslides that primarily occur in remote mountainous regions due to their complex terrain, geological characteristics, and human activities. These studies are compulsory in every case of urban planning or demarcation of a settlement and aim to safeguard the built environment from natural hazards or hazards resulting from human intervention and activities (Depountis, 2023).

Focusing on mountainous remote settlements influenced by landslide events, this study employs a GIS-based multicriteria analysis using the Analytical Hierarchy Process (AHP) to evaluate geological suitability. This methodology incorporates various geological factors affecting the study area to produce a suitability map and categorize existing settlement conditions into safe or unsafe building zones. The Analytical Hierarchy Process (AHP) assigns certain weights to the chosen criteria and spatial datasets are produced within a GIS environment to create a geological suitability map that identifies optimal areas for development; thus, categorizing them as suitable, unsuitable, or suitable under specific conditions.

Background

The settlement of Klepa, located in the Central Western Greece, belongs to the regional unit of Aitoloakarnania. The geology of the study area is characterized by the presence of Alpine bedrock, specifically the Pindos unit. The formations in the study area are primarily comprised of flysch, limestone and cherts. In addition, Quaternary deposits are present, including fluvial deposits, scree and landslide materials.

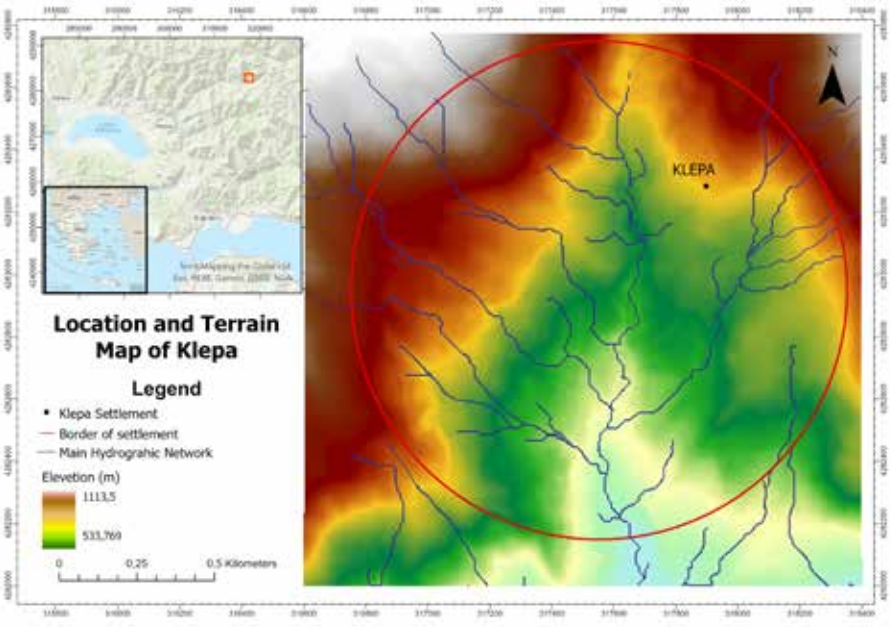

Figure 1. Location and terrain map of the study area.

The landslide problem in the wider area of Klepa is well-known and has been repeatedly examined by the Hellenic Survey of Geology and Mineral Exploration. In particular, the area has recorded activations of old or recent landslides at least four times in the last 35 years, with the most recent and severe occurred in 2015. The impact of landslides was severe, destroying several houses and a section of the provincial road about 120 meters long.

Methodology

The methodology of this study is divided into four key phases: a) criteria selection, b) AHP application, c) spatial analysis and standardization, and d) suitability assessment. The criteria were selected from the study by Depountis (2023), which proposes an outline for the application of various parameters for MCE suitability related to different land uses. The selected criteria are (1) Geohazards/Landslides, (2) Geomorphology/ Slope, (3) Geology/Lithology, (4) Hydrology/Rivers, (5) Ground Seismicity Hazard and (6) Tectonics/Faults. The current study employs the Analytic Hierarchy Process by Saaty (1980), a multicriteria decision method that uses eigenvalue theory to compute weights and maintain consistency in pairwise comparisons. The AHP is a comprehensive measurement theory, which allows the creation of ratio scales through comparison of discrete and continuous variables (Hajar, 2017) and is a globally recognized technique aiding in risk assessment and mitigation planning (Mokhtari et al., 2023).

The pairwise comparison of the chosen criteria was performed to assess their relative importance to a defined objective, using Saaty's weighting scale 1-9. After the process of the matrix's normalization to ensure logical consistency, the Consistency Ratio (CR) is calculated, which includes the following indices:

- Random Index (RI): A constant derived from Saaty's random index scale, based on the number of criteria.
- Maximum Eigenvalue (λmax): The mean obtained by multiplying elements of the normalized comparison matrix by the priority vector (weights).
- Consistency Index (CI): A measure of matrix consistency, using the number (n) of criteria and calculated as:

$$CI = \frac{\lambda_{max} - n}{n - 1} \quad (1)$$

The CR is computed by dividing the CI by the RI, with values ≤0.10 deemed acceptable; higher values suggest the need for revised comparisons (Saaty, 1980).

The main purpose of the application of the analytical hierarchy process is to determine the weight values of the criteria discussed to solve the problem and their place in the hierarchical structure at the solution stage (Topuz & Deniz, 2023).

The criteria (or factors) used in this study and their calculated weights are presented in Table 1. In Table 2 the criteria used are presented as data layers imported in the GIS framework and divided into four classes (1-4) for proper suitability assessment.

Table 1. Pairwise matrix of the criteria and produced weightage W_i.

Criteria	Geohazards/ Landslides	Geomorphology/ Slope	Geology/ Lithology	Hydrology/ Rivers	Ground Seismicity Hazard	Tectonics/ Faults	Weight W_i.
Geohazards/ Landslides	1	2	3	4	4	4	0.368
Geomorphology/ Slope		1	2	3	3	3	0.236
Geology/ Lithology			1	2	2	2	0.144
Hydrology/ Rivers				1	2	2	0.106
Ground Seismicity Hazard					1	1	0.073
Tectonics/Faults						1	0.073

Table 2. Division of criteria into classes and Suitability assessment.

Data Layer	Class	SC	Data Layer	Class	SC	Data Layer	Class	SC
Landslides	Active/ recent	4	Slope (%)	<10	1	Lithology	Recent loose Landslide materials	4
	Inactive/ older	3		10-20	2		Paleo & Older semi-compacted Landslide materials	3
	Absence	1		20-35	3			
				>35	4			
Distance from Streams (m)	<10	4	Ground Seismicity Hazard	A	1		River bed deposits	3
	10-50	3		B	2		River terrace	1
	50-100	2		C	3		Scree	3
	>100	1		D, X	4		Sandstone/ Flysch Pindos Unit	2
Distance from Faults (m)	0-20	4					Siltstone/ Flysch Pindos Unit	2
	>20	1					Limestone/ Pindos Unit	1
							Cherts/ Pindos Unit	2
CR= 0.0192 ≤ 0.10								

1: Suitability Class (SC) refer as; (1) Highly Suitable, (2) Moderately suitable, (3) Marginally suitable and (4) Unsuitable.

The spatial analysis was conducted in ArcGIS Pro 3.1 software. To illustrate the spatial distribution of the relevant criteria, six thematic maps were developed based on the data layers and classification categories specified in Table 2. These maps provide a detailed spatial representation, contributing to a more thorough understanding of the patterns and relationships within the study area (Figure 2, 3). The data necessary for the creation of the aforementioned layers were sourced from various references, which are detailed subsequently. Moreover, a modification and validation of vector data was performed, specifically for the limits of the area of active landslides. Figure 2A depicts the landslide inventory, classifying areas into three distinct classes: (i) absence, (ii) inactive/older landslides, and (iii) active/recent landslides. This classification is crucial for identifying regions with historical or ongoing instability. Slope plays a pivotal role in affecting the occurrence of landslide events. Steeper slopes are more prone to instability due to the greater gravitational force acting along the slope surface, which increases the probability of failure. A slope map was generated by processing the Digital Elevation Model (DEM) of the area, which has a grid size of 5x5m. The layer was classified into four distinctive categories that are: (i) less than 10, (ii) 10 to 20, (iii) 20 to 35 and (iv) greater than 35, each representing different slope percentages (Figure 2B).

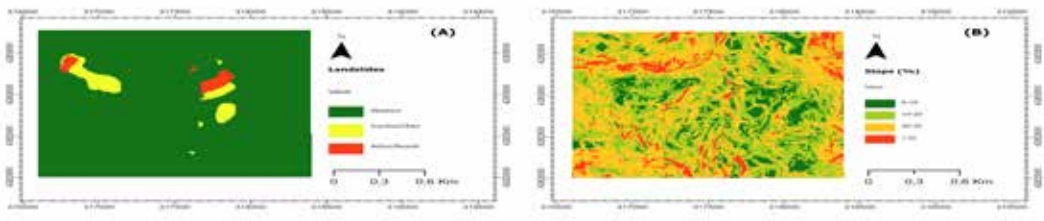

Figure 2. Thematic layer maps: (A) Landslides, (B) Slope.

Figure 3C presents the lithological classification, detailing various geological formations. The geological and lithology features were digitized from a large-scale (1:2.000) Engineering Geological map produced by the Hellenic Survey of Geological and Mineral Exploration (T-2855/2016) and an update was made after an on-site geological surveying.
The distance from streams portrays a critical hydrological factor influencing slope stability. The drainage network was derived from the Digital Elevation Model (DEM) and subsequently verified against the Engineering Geological map. The vector data was modified to define the boundaries of the river banks, and buffer zones were established around the streams, categorized as follows: (i) less than 10 meters, (ii) 10 to 50 meters, (iii) 50 to 100 meters, and (iv) greater than 100 meters. These buffer zones are represented as a layer in Figure 3D.
Furthermore, Figure 3E illustrates the proximity to fault lines, categorizing the study area into two classes: (i) areas within 0 to 20 meters from faults and (ii) areas beyond 20 meters, based on the provided data of the Engineering Geological map. Figure 3F represents the ground seismicity hazard of the geological formations, with the layer classified into four categories: (i) A, (ii) B, (iii) C, (iv) D, X, corresponding to the Engineering Geological map of the area and the Greek Code for Seismic Resistant Structures (EAK 2000). It is important to note that the third class is not represented in the thematic map, as no geological formations were classified within this category.

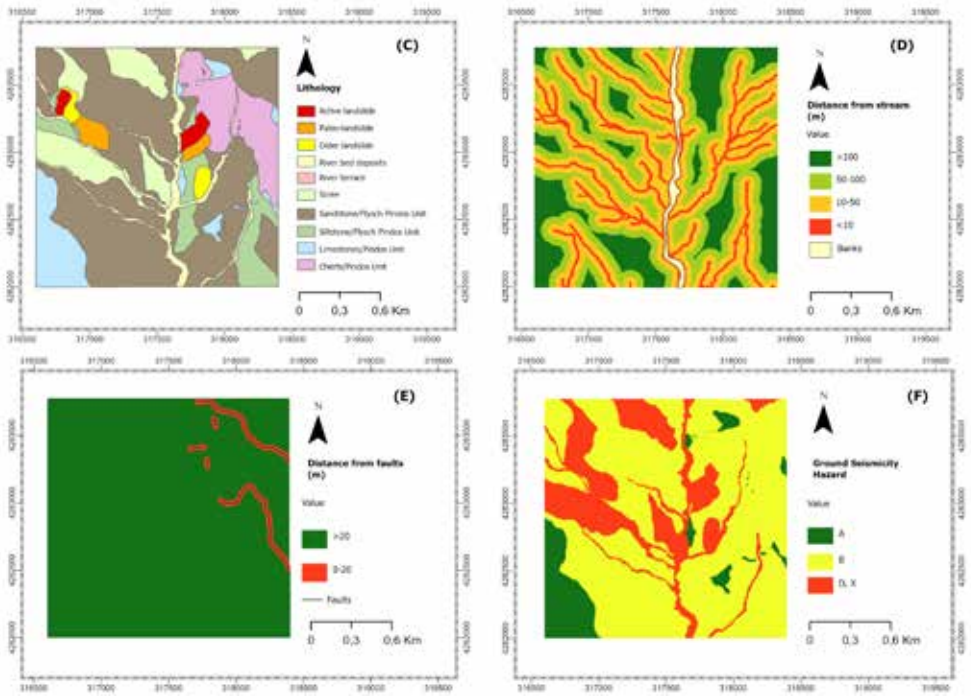

Figure 3. Thematic layer maps: (C) Lithology, (D) Distance from stream, (E) Distance from faults and (F) Ground Seismicity Hazard.

The raster layers were exported and then a scale of 1-4 was applied for the process of reclassification, following the scale of suitability values mentioned in Table 2. The levels of suitability were evaluated based on the relative significance of the contribution made by each criterion as has been suggested by Feizizadeh (2012). The reclassification of the spatial layers was made in order to eliminate the units of measurement and transform the data into a unitless format as has been suggested by Mansour et al. (2019). This process enhances compatibility, allowing for smoother integration with other datasets, regardless of their measurement system.
Following spatial analysis, a geological suitability map was obtained by the Weight Linear Combination

(WLC) method, then reclassified with Jenks natural break, categorizing the study area into four suitability categories (Figure 4). The WLC approach is one of the most frequently used in GIS-MCDA (Malczewski, 2000). The criteria and their individual weights are summed up in WLC, and the combined sum presents the final suitability map using the equation:

$$\sum_{i=1}^{n} = w_i \cdot c_{ij} \quad (2)$$

Where Wi: weights of selected criterion i, Cij: Reclassified criteria and n denotes total number of criteria.

Results

Each individual category of the final map corresponds to a unique geological suitability level with a specific color (Figure 4). For example, the lowest suitability level, represented by the highest weighted score, is highlighted in red. In this study, the suitability map shows four suitability categories as follows: (a) Unsuitable, (b) Marginally suitable, (c) Moderately suitable and (d) Highly suitable.

The analysis reveals that 38.58% of the total area is classified as highly suitable for residential development. The largest share of the land, 44.85%, falls under the “Moderately suitable” category, making it the most dominant classification in the analysis. While considering the land area that is not suitable, it is seen that a small area of the field consists of the Marginally suitable class 12.77%, whereas 3.80% of the study area is considered unsuitable for residential development.

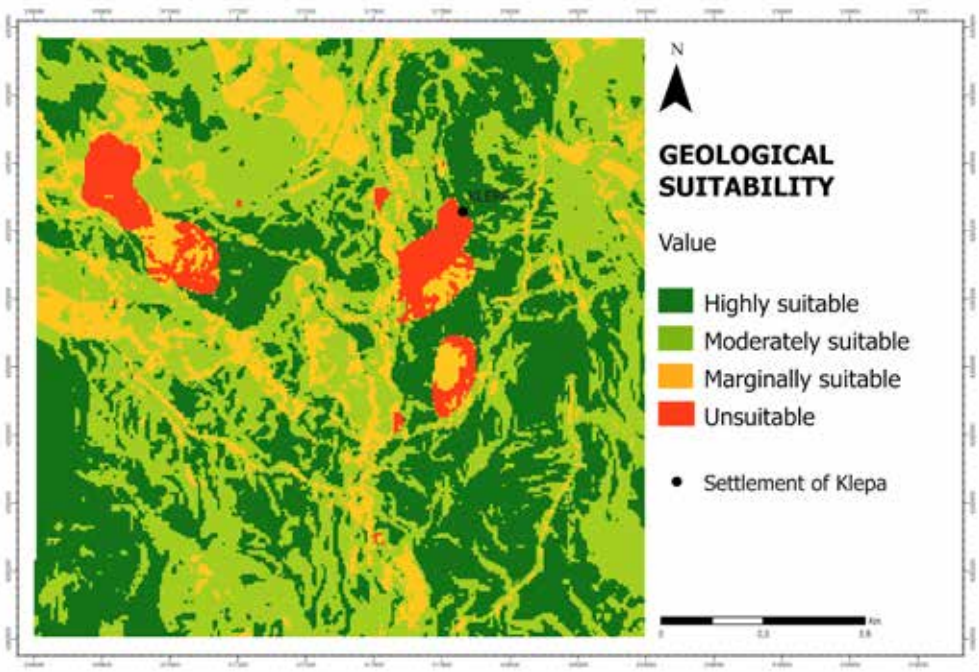

Figure 4. Geological Suitability map of the study area with color classification for each suitability category.

Conclusions

This study effectively combines Geographic Information Systems (GIS) and the Analytic Hierarchy Process (AHP) to assess geological suitability and residential development in mountainous settlements impacted by landslide events. By prioritizing key criteria through AHP and via GIS for spatial analysis, a geological suitability map is obtained. The produced map presents four levels of suitability: Unsuitable, Marginally Suitable, Moderately Suitable, and Highly Suitable. The analysis reveals that 38.58% of the investigated area is highly suitable for development, whereas 44.85%, of the total area falls under the Moderately

Suitable category. A smaller portion, 12.77%, is Marginally Suitable and 3.80% is classified as Unsuitable. This comprehensive approach provides a valuable decision-making tool for sustainable residential development and planning, particularly in remote settlements and geohazard-prone areas, that can be adapted to diverse cases and assess the influence of multiple factors in a region.

Introduction / Background

Geothermal source of energy has become a priority in the energy sector providing a precious transition from hydrocarbons. Geothermal energy has the great advantage to be used when it is needed especially in islands when there is a boost in consumption in the summer period. Public Power Corporation Renewables SA (PPCR) has sponsored geological and geophysical surveys for many years now for geothermal exploration leading to important results through geophysical surveys (Tzanis et al., 1991, Lagios et al., 1994, Lagios and Apostolopoulos, 1995, Apostolopoulos et al., 1997, Tzanis et al., 2018, Tzanis et al., 2020) in various sites of geothermal fields of interests. In the Lesvos Island, faults that may act as thermal circulation zones have been speculated through geothermal springs and through geophysical studies (Thanassoulas and Xanthopoulos, 1991, Apostolopoulos et al., 1997). A good correlation between geology, seismicity and geothermics has been found using remote sensing data and GIS in the island (Voulgaris et al., 2004)

Kontis et al. (1994) state that the active geothermal system in the Megala Therma (Northern Lesvos) is probably a late evolutionary stage in the formation of mineralization with different types of alterations from silicification, propylitization, argillic alteration and potassic to phyllic. This is important because in the gravity Bouguer anomaly map of Lesvos Island (Figure 1) this area is part of a low gravity anomaly trending in south-westwards towards Stipsi and extending to the south with relatively low gravity values where Kalloni and Polychnitos area are also of geothermal interest.

Figure 1. Northern Central part of the Bouguer gravity anomaly map (in mGals) of Lesvos Island over Google Earth map.

Geothermal exploration today involves geophysical method such as magnetotellurics (MT), a method of great detection depth, which is sensitive to zones of conductivity and possibly associated with geothermal circulation or reservoir but also with saline water presence. In the case of Lesvos, 3D interpretation of legacy magnetotelluric data (Tzanis, 2024) provide resistivity distributions at various depths with one particular at depth of approximately 1.25 km below mean sea level (Figure 2) showing great correlation between low resistivity values and low gravity regions previously inferred.

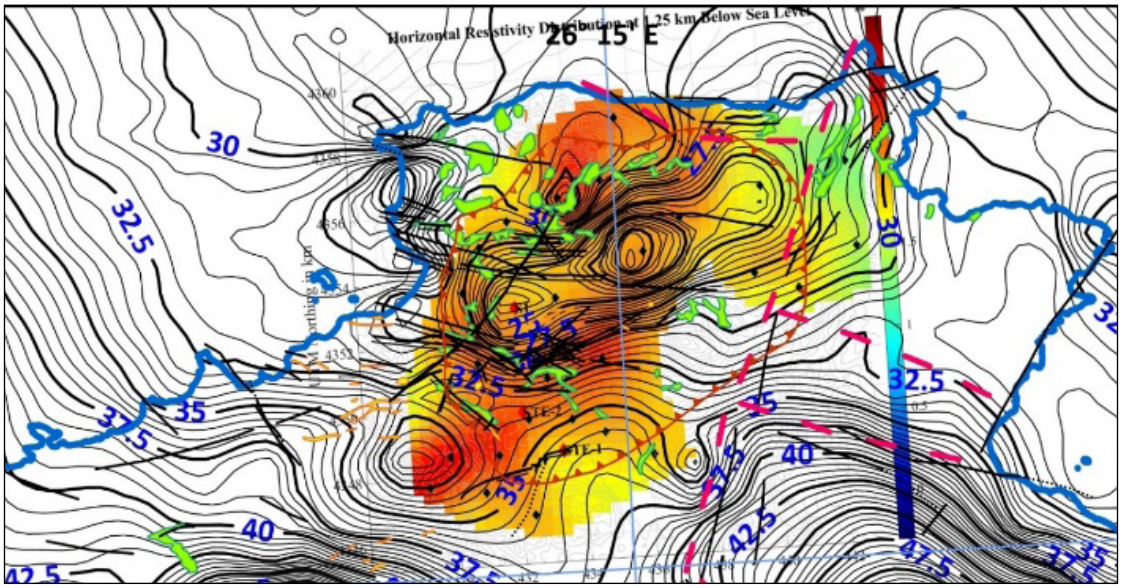

Figure 2. Northern Central part of Lesvos Island with horizontal electrical resistivity slice at the depth of 1.25km below mean sea level over the Bouguer gravity anomaly map (in mGals). The resistivity slice among others was extracted from the 3-D model elaborated by Tzanis (2024) on legacy magnetotelluric data.

PPCR has sponsored a renewed geothermal project under the coordination of National Technical University of Athens (NTUA, School of Mining and Metallurgical Engineering, Laboratory of Hydrocarbon's Exploitation & Applied Geophysics) in collaboration with Uppsala University (UU, Department of Earth Sciences) and National and Kapodistrian University of Athens (NKUA, Faculty of Geology and Geoenvironment) that consists a geological-tectonic and geophysical study in an integrated mode that will provide a better understanding of the geothermal field through the positioning of faults that act as geothermal circulation zones and areas of geothermal alteration. The project goal is to propose the best position for a new deep borehole in the area for geothermal exploration. The project involves the evaluation of all available geological and geophysical data, new geological field survey including the use of UAV imaging for remote sensing in areas of interest such as fault zones, new gravity, and magnetic data along with an active seismic survey.

Geology of the Petra area

The geological formations (Figure 3) presented in Mythimna and Ayia Paraskevi work (Hecht, 1973, 1974), were verified macroscopically in the field. The main lithological types are the following: i) entirely silicified lava, ii) Dykes (rhyodacitic or dacitic), iii) Upper lava unit (dacitic, latitic, latitandesitic and quartz-andesitic; minor rhyodacitic lavas), iv) Lowermost parts of the upper lava unit (mostly latitic to latitandesitic), v) Pyroclastic layer (lapilli tuff and tuff breccia containing increasing amounts of volcanic bombs towards the west region of Scalochori), vi) Lower lava unit of the Stipsi and Vatoussa areas (mostly latitandesitic, partly andesitic or latitic, lavas; kaolinized zones of the lower lava unit, locally silicified. Basic lapilli tuff, magmatic breccia, or agglomerate within the lower lava unit).

Figure 3. Geological map of Lesvos Island Northern Central part (geographical coordinates UTM 35N) (Hecht 1973, 1974).

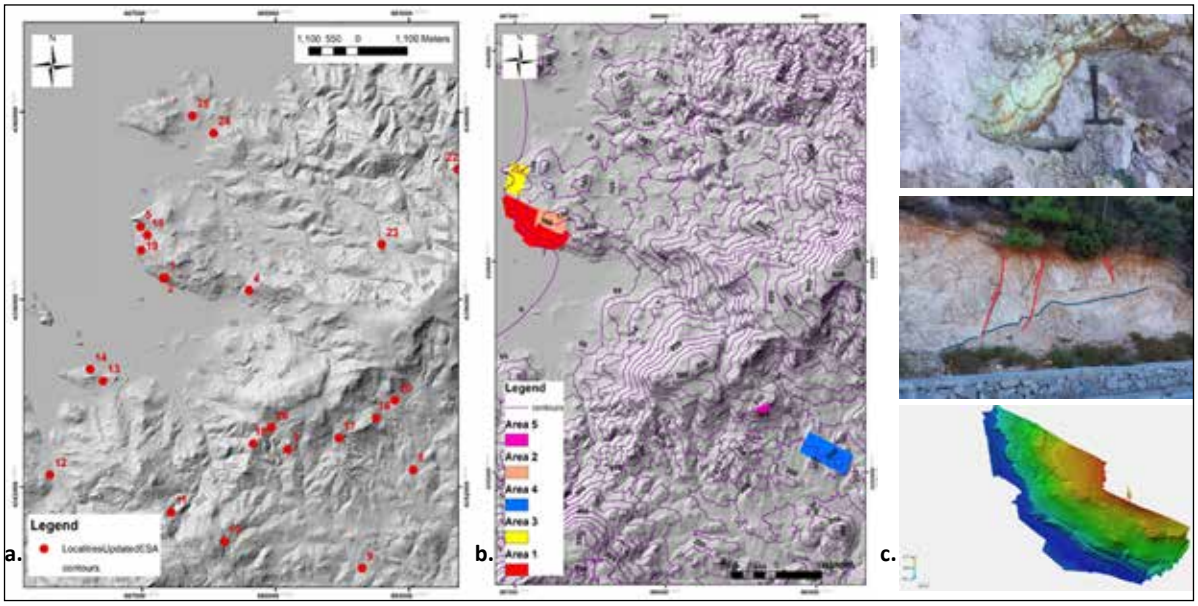

Figure 4. a) Geological data acquisition map in Petra study area, b) areas were drone surveyed (geographical coordinates Greek Grid), c) Hydrothermal alterations in the contact of pyroclastic sediments with the lower part of the Upper Lava Unit, faults affecting the silicified lavas (East of Stipsi), digital elevation model of Area 1.

The field geological survey (Figure 4a) focused on the following objectives:

- Identifying the rock units in the study area, using the geological map sheets of Mythimna and Ayia Paraskevi (HSGME, scale 1:50000) as reference.
- Conducting structural measurements, including faults and joints.

Additionally, in areas of interest, such as fault zones, data collection was enhanced using UAV imaging for remote sensing (Figure 4b).

Macroscopical identification of the lithological units in the study area, identification and measurement of potential fault zones and remote sensing data acquisition in 5 areas utilizing a set of 1373 aerial images were accomplished (Figure 4c) with the next step to be the construction of the structural model of the area in collaboration of the geophysical team.

Geophysical surveys

After considering all legacy data, geological and geophysical, in parallel with the geological survey, an integrated geophysical survey was designed in such a way to cover all interesting geological and tectonic features around the Petra area and the areas with low gravity and resistivity values the extended gravity map and magnetotelluric results.

The gravity and magnetic measurements designed and operated by NTUA-NKUA teams as well as the seismic profiles designed and operated by UU groups covered areas from Molyvos to Anaxos and Lafionas and from Petra to Petri and Stipsi (Figure 5). The gravity measurements were acquired from two groups with the Lacoste Romberg gravity meters and the magnetic measurements with the magnetometers Scintrex Envipro and Geometrics 852 (Figure 5). Differential RTK LEICA GPS instruments and Metrica Network were used for the positioning of the measurements. Four seismic profiles were positioned for a total of 24 km long across several suspected geological structures. UU subcontracted the Geological Survey of Denmark and Greenland (GEUS) in order to provide their new vibro-truck (Innova UV2 weighs approximately 17 tons, operates at a peak force equal to 115.6 kN and configured to produce a time-synchronised and phase-locked linear sweep signal from 10-140 Hz over 18 seconds) and its operation, while coordinated the survey and design with its own recording instrumentations (1000 wireless or nodal recorders connected with 10 Hz geophones for autonomous data recording). Receiver and shot points had a spacing of 10 m, except for P4 which was 20 m. At every shot point, 3 sweeps were generated to improve signal-to-noise ratio by vertical stacking of the repeated shot records. The recording time was set to 25 s with a sampling rate of 2 ms. Aiming for upper 2-3 km subsurface imaging and capitalizing from the large number of nodal recorders, long offset data were aimed for during the acquisition, reaching sometimes to up to 7.2 km.

Bouguer gravity and magnetic anomaly, reduced to the pole, maps show in the eastern region lower values something that was expected from the Bouguer gravity map of the Island (part of it in Figure 1). These lower values are very well associated with the Upper Lava Unit and possibly with geothermal alteration of the underground formations.

The unmigrated seismic section of P1 (Figure 6) shows an interesting cross-section of the subsurface with various characters appearing to suggest fault systems. Noteworthy the Bouguer gravity values show similar general behavior as the reflection seismic section (Figure 6). A gravity low correlates well with a seismic depression zone in the Petra area.

Figure 5. Gravity and magnetic measurements along with seismic profiles in the survey area on Google Earth map. Photos from gravity and magnetic measurements (left) and seismic survey (right).

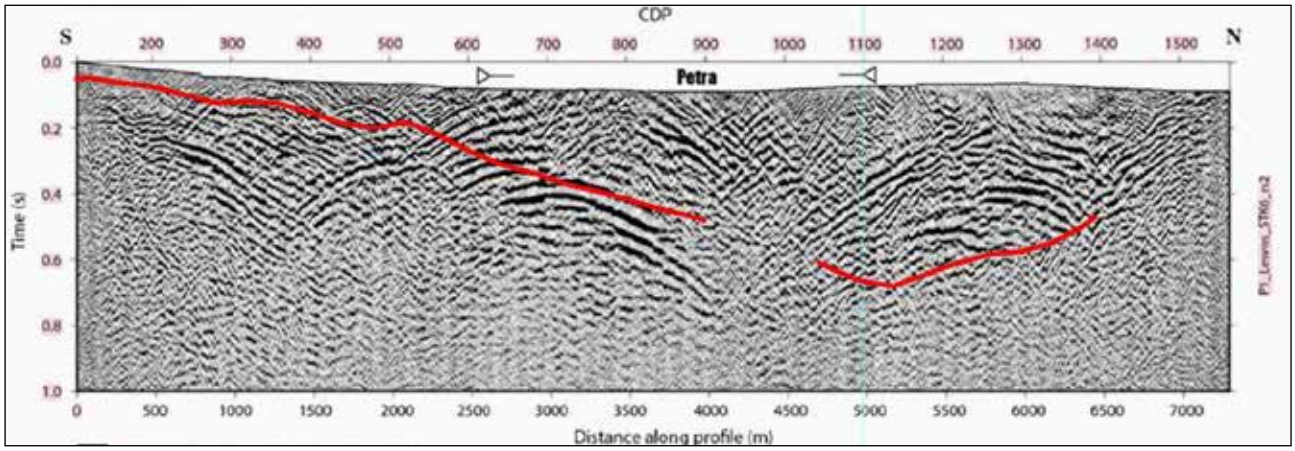

Figure 6. Unmigrated reflection seismic section of "P1" profile with the red line showing the of Bouguer gravity anomaly values extracted along the same profile.

First comments

According to the legacy data analysis, the geophysical and geological data coverage that was followed in the field with the final survey area extended as much to the east reaching Stipsi village to include in a substantial way the area of gravity low (Figure 1) as well as the resistivity low (Figure 2), the boreholes "S1" and "STE-2" (Figure 5) and most of the proposed faults. All data as expressed in maps or sections look of great quality and very good coincidence of what previous data were suggesting. The geophysical maps (Bouguer gravity anomaly map, magnetic anomaly reduced to the pole) which are considered reference map as uniquely represent the underground response already give interesting areas for geothermal activity. It is expected that further processing and data interpretation will lead to 3D models of the underground. The seismic shot gathers and unmigrated CDP sections show useful information of subsurface structures. This information will be useful both for density models as well as to refine the geological model suggested by surface geological observations. The fact that many of the features to be interpreted in the gravity maps as well as the surveyed geological and tectonic features are in seismic profiles gives the benefit of the integrated interpretation this project has as a target.

Acknowledgements

The authors wish to thank firstly Public Power Corporation Renewables for sponsoring the project. We also thank the Geological Survey of Denmark and Greenland (GEUS), which provided their new vibro-truck and their geoscientists Dr. G. Donoso and Mr. L. Solheim who operated it. EXTENDED ABSTRACT 011

Modelling Coastal Protection as an ecosystem service in the Greek coastal zone

Konstantina Apostolopoulou[1], Efthimios Karymbalis[1], Maria Salomidi[2], Evangelia G. Drakou[1]

(1) Department of Geography, Harokopio University, El. Venizelou 70, 176 76 Kallithea, Attica, Greece (2) Institute of Oceanography, Hellenic Centre for Marine Research, 46.7 km Athens Sounio Ave., 19013, Anavyssos, Greece

Research Highlights

Structural connectivity within seagrass meadows can enhance the ecosystem service of coastal protection capacity. This work provides an integrated modelling approach of biotic and abiotic seascape features while incorporating the role of structural connectivity to existing coastal protection ES models.

Background

Coastal areas are known to contribute to human well-being through the supply of ecosystem services (ES) (Liquete et al., 2013) or nature's contributions to people (NCP) (Díaz et al., 2018). Among these ES, coastal protection is of particular importance , especially in the face of increasing climate change impacts. Coastal protection is defined as the ecosystem service which provides natural defense of the coastal zone against inundation and erosion from waves, storms and sea level rise (Liquete et al., 2013). Coastal habitats, such as mangroves, saltmarshes, seagrasses, coral reefs and dunes, can act as natural defense against coastal flooding and erosion through wave attenuation, storm surge reduction and seabed elevation, thereby enhancing the resilience of coastal communities against these hazards (Trégarot et al., 2021). This is very timely, as climate change is expected to increase the frequency and magnitude of extreme weather events, such as storms and hurricanes, as well as lead to accelerated sea level rise. This increasing frequency and intensity of extreme events, along with anthropogenic activities such as coastal development, which degrade the coastal zone, pose a great threat to coastal populations and economies through increased erosion, flooding, and damage to infrastructure.

Greece has a diverse array of coastal habitats that are crucial for coastal protection. Sandy beaches act as dynamic buffers, absorbing wave energy and dissipating storm surge. Rocky shores provide refuge for marine life and offer resistance to erosion. Wetlands, such as salt marshes and lagoons, absorb floodwater. Seagrass meadows, stabilize sediments, and reduce wave energy. Among them, *Posidonia oceanica* meadows, endemic to the Mediterranean, as well as *Cymodocea nodosa*, are particularly important for coastal protection in Greece. *Posidonia oceanica* is identified as the most abundant seagrass species in Greece, being present in almost 70% of the Greek coastline (Panayotidis et al., 2022). In more shallow, brackish and sheltered areas, especially in the northern Aegean latitudes, *Cymodocea nodosa* also forms extensive meadows, playing a respective key role in coastal dynamics. Other seagrass species namely *Zostera noltei* and *Halophila stipulacea* also have a restricted presence in the Greek coastal zone (Panayotidis et al., 2022). Greece's complex coastal geomorphology with numerous bays, gulfs, peninsulas and islands, influences wave patterns, currents, and sediment transport, which in turn affect the distribution and resilience of coastal habitats. For instance, the steep slopes and narrow coastal plains characteristic of Greece's coastline, influence the vulnerability of coastal communities to sea-level rise and extreme weather events. Understanding the complex relationship between geomorphology, coastal habitats and their distribution, and biophysical processes is essential for developing effective coastal management strategies in Greece (Hasan et al., 2022).

In Greece, there have been many studies focusing on different aspects of coastal protection. Anastasiou and Sylaios (2016) investigated shoreline dynamics and evaluated coastal protection approaches in an erosion-vulnerable deltaic region of Northern Greece. Tragaki et al. (2018) assessed the physical and social vulnerability of Peloponnese to coastal hazards through variables like geomorphology, shoreline change rate, coastal slope, relative sea-level rise, mean wave height, and mean tide range. Hasan et al. (2022) adapted a regional coastal protection model proposed by Liquete et al. (2013) to Greece by mapping three

indicators, coastal protection capacity, exposure, and societal demand.

Objectives

The aim of this work is to assess and map the ecosystem service of coastal protection in Greece with a more holistic and integrated manner. The work presented uses existing knowledge and modelling approaches on coastal protection as an ES and enhances it with estimates of structural connectivity and fragmentation within coastal habitat types. The paper focuses on seagrass meadows, particularly *Posidonia oceanica* and *Cymodocea nodosa*, being the most abundant along the Greek coasts, and assess their distribution and connectivity patterns, in order to assess the role of seascape patterns in coastal protection.

Methods

The paper focuses on the role of the connectivity of seagrass meadows in enhancing coastal protection. The dataset developed by Panayotidis et al (2022) was used to account for the spatial distribution of seagrass meadows in the Greek coastal zone (Figure 1). Extra emphasis is given on *Posidonia oceanica*, a seagrass species endemic to the Mediterranean Sea, considered a priority habitat under the European Union's Habitats Directive (92/43/EEC). Seagrass beds form extensive underwater meadows up to 40 meters depth that provide essential ES, such as coastal protection. Coastal protection provided by seagrasses is based on their capacity to mitigate flooding and erosion, which are the primary natural threats to coastlines (Ondiviela et al., 2013). Seagrass beds and even more, *Posidonia oceanica* are well known for their ability to provide coastal protection through mechanisms such as wave attenuation and sediment stabilization (Campagne et al., 2015). They reduce wave energy, thereby mitigating the hydrodynamic force impacting the shoreline. The effectiveness of wave attenuation is influenced by factors such as meadow extent, density, blade length, and the overall health of the seagrass ecosystem. Beyond direct habitat effects, seagrass banquettes— formed on the shoreline by beach-cast dead leaves and rhizomes from the meadows— also absorb wave energy, acting as natural barriers that further enhance coastal resilience against erosion and storm surges. (Boudouresque et al., 2016; Ottero et al., 2018).

While there is little research on the contribution of *Cymodocea nodosa* on coastal protection, it has been shown that the species' meadows in combination with *Posidonia oceanica* meadows could significantly reduce the average annual wave height, reducing the amount of energy reaching the beach and enhancing the defense against flooding and erosion. Also, the largest wave damping can be observed in water depths between 1 and 5 meters, because of the greater submergence ratio (canopy height over water depth) (Sierra et al., 2023). In the Greek coastal zone, *C. nodosa* replaces *P. oceanica* at these depths in almost every semi-enclosed gulf where muddy-sand substrata prevail (Panayotidis et al., 2022).

Continuous and dense meadows provide a larger surface area for interaction with water flow, enhancing their capacity to reduce wave and current energy. Fragmented meadows, however, may not offer the same level of protection due to reduced biomass and connectivity. Also, fragmented meadows may lead to increased coastal erosion as the protective barrier they provide is compromised (Ondiviela et al., 2013). In addition, fragmentation can lead to increased sediment resuspension and transport, as the cohesive structure of the meadow is disrupted, reducing its ability to trap and stabilize sediments effectively (Montefalcone et al., 2010).

Incorporating this information within existing models of coastal protection is achieved through the identification and quantification of biophysical and socioeconomic variables. An adaptation of the model developed by Liquete et al. (2013) and downscaled by Hasan et al. (2022), is used. They assessed coastal protection through three indicators: coastal protection capacity, exposure and demand. Through these indicators they calculated the flow of the ES and eventually the benefit of coastal protection. Data on 20 biophysical and socio-economic variables were collected. For coastal protection capacity, slope, geomorphology, seabed and emerged habitat and sediment accretion rate were considered. Within the seabed and emerged habitat variables, an additional to the original model variable to capture the connectivity impact on coastal protection, was included. To assess the structural connectivity and fragmentation patterns

of the meadows, spatial pattern metrics using the FRAGSTATS software were calculated. Metrics and indicators that describe density and shape of the habitat patches, but also those which are dedicated connectivity measures, such as Splitting and Aggregation Indices were selected. For coastal protection exposure, wave height, storm surge height, sea level rise and tidal range, as well as wind speed and eastward and northward current were considered. Coastal protection demand was calculated based on population density, transportation network, artificial surface and cultural sites density, with the addition of port area density, ecologically important site density and mineral extraction site density.

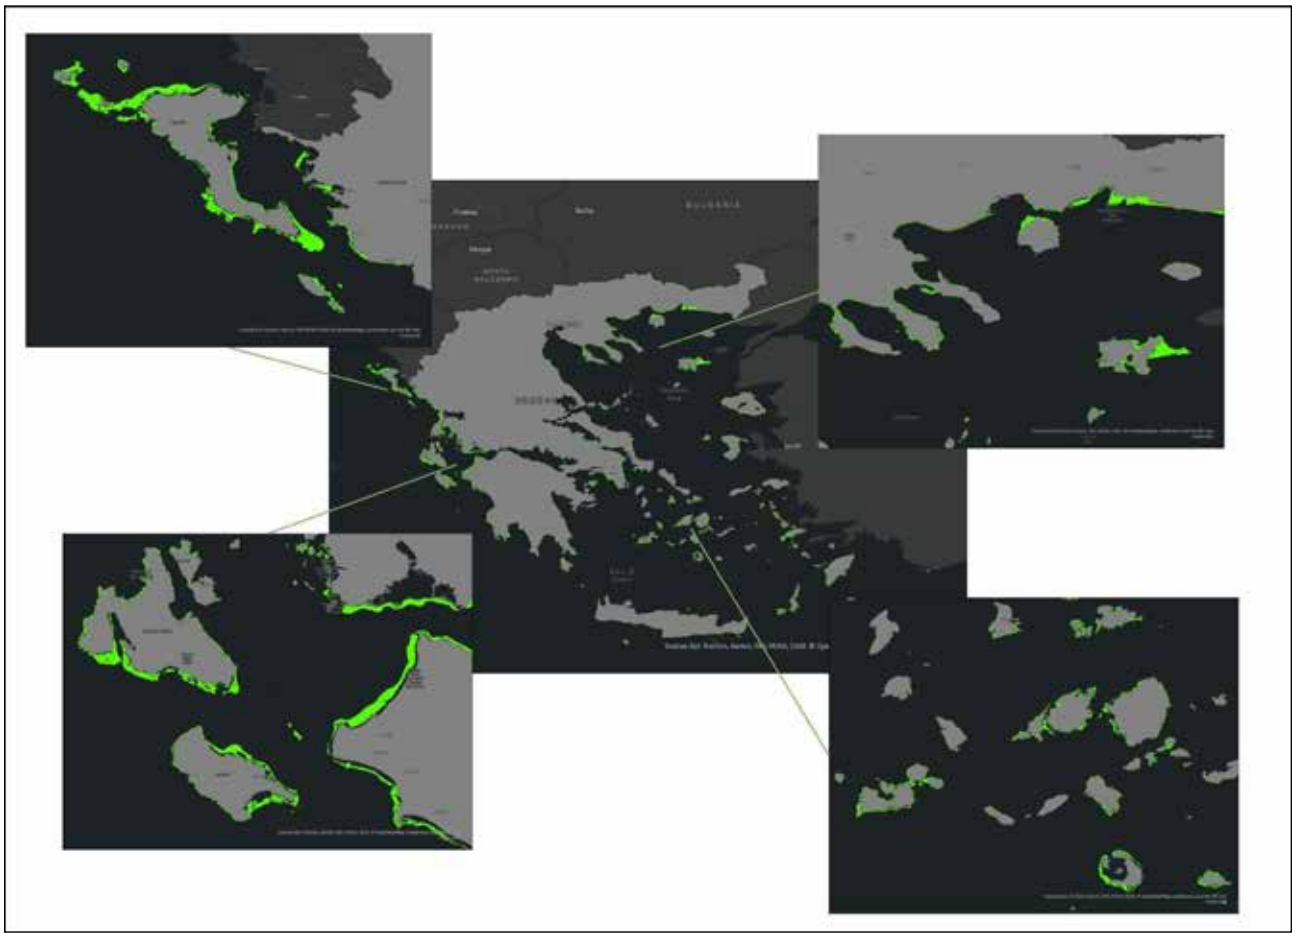

Figure 1. Seagrass meadows in the Greek coastal zone adapted from Panayotidis et al., 2022.

Results

The results are analyzed at two levels: i) the understanding of the spatial patterns emerging across the seascape and ii) the coastal protection ES across the coastal zone of Greece, and its linkage with the spatial patterns of seagrass meadows. For the connectivity assessment, a series of landscape metrics were applied on the locations of seagrass meadows across the coastal seascape. The indicators used were analyzed statistically to identify those that can better describe the variability in structure of submerged coastal vegetation. The results indicated that Shape and Aggregation metrics were able to reveal differences across locations. For instance, the islands of the north Aegean Sea such as Lemnos, or the Western part of the country such as Peloponnese and Corfu (in the Ionian Sea), had largely connected habitats, while the coastline of the mainland or Crete had a quite patchy and dispersed habitat.

Connectivity indicators were then included in the modelling of coastal protection and the results indicate

that there might be a shared pattern across the two. The largest cities in Greece, particularly Athens and Thessaloniki, seem to have low natural protection capacity since seagrass meadows are absent or at low density. Many of the islands show a pattern of high demand and exposure to coastal threats, yet only those with presence of seagrasses have medium natural capacity for protection. Also, certain regions within Peloponnese, particularly in the northern and eastern parts, experience high exposure and demand for coastal protection while simultaneously having low protection capacity. Only areas that have high density of seagrass meadows, such as the southern west and east part of Attica, coasts of Western Greece and north Aegean islands have a relatively high coastal protection capacity. The results indicate a positive correlation between well-connected seagrass vegetation with areas that show higher coastal protection capacity.

Conclusions

This research highlights the critical role of seagrass meadows and particularly *Posidonia oceanica* and *Cymodocea nodosa* in enhancing coastal protection within the Greek coastal zone, particularly in the context of increasing climate change impacts. By integrating biotic and abiotic factors to assess structural connectivity, the study underscores the importance of understanding the spatial dynamics of seagrass meadows and their contribution to mitigating coastal erosion and flooding. The findings indicate that while urban areas such as Athens and Thessaloniki face high demand for coastal protection, they simultaneously exhibit low natural protection capacity due to the natural absence or decline of seagrass meadows. Conversely, regions with dense seagrass coverage demonstrate a greater ability to withstand coastal threats. The research emphasizes the need for comprehensive coastal management strategies that prioritize the protection and restoration of these important ecosystems, particularly in areas most vulnerable to extreme weather events.

Introduction and scope

Rainwater harvesting (RWH) has long been an essential practice for ensuring water availability, especially in regions with limited freshwater resources. With increasing global concerns about climate change, the demand for sustainable water management systems has grown (EEA, 2009). Climate change is exacerbating existing water scarcity problems, contributing to prolonged droughts, extreme heat events, and shifting precipitation patterns (Eckstein, 2009). The Greek islands, particularly small islands like Fourni, face significant challenges in water security due to their limited natural water sources (Feloni and Nastos, 2024). This underscores the potential of rainwater harvesting systems to provide an efficient alternative for in-house water needs, such as toilet and laundry use, while enhancing the sustainability of both the island's water resources and the agricultural sector (Essendi, 2014; Koumoura et al., 2018; Londra et al., 2015, 2022).

Fourni Island, located in the Aegean Sea, is characterized by its small population, limited freshwater supply, and vulnerable water resources. This makes it an ideal case study for assessing the potential role of rainwater harvesting systems in addressing local water scarcity.

This study focuses on evaluating various domestic RWH scenarios to simulate the system's efficiency under both historical climatic conditions and projected future scenarios based on the Representative Concentration Pathways (RCP) 4.5 and 8.5 models. These scenarios allow for an exploration of how climate change might influence the feasibility of RWH systems for domestic use, with specific attention given to factors such as household size, tank volume, and rooftop collection area. In this work, we simulate a range of scenarios involving different household sizes (2, 3, and 4 residents), rooftop areas (40-140 m²), and tank volumes (5-30 m³) to assess their impact on the efficiency of RWH systems in achieving coverage targets of 30%, 40%, and 50% of daily water consumption needs. We also consider how these systems would perform under both current climate conditions and the future projections of the RCP 4.5 and RCP 8.5 models, using available timeseries of the EURO-CORDEX regional climate downscaling (Jacob et al., 2020) provided by the DEAR-Clima web application (DEAR-Clima, 2023). While rainwater harvesting systems have the potential to offer significant benefits in arid regions (e.g., Preka et al., 2017), this study highlights the challenges faced by Fourni Island in meeting the desired coverage targets, especially considering future climate projections.

Methods

To evaluate the performance of the rainwater harvesting (RWH) system and compare different scenarios, a water balance simulation model was employed (Tsihrintzis and Baltas, 2013). This model simulates the daily operation of the RWH system, focusing on the collection, storage, and utilization of rainwater. The system collects rainwater from rooftops and other available surfaces and stores it in tanks, which vary in material and size.

To implement the model, it is crucial to have accurate rainfall data for the region. This data serves as input to the simulation model, determining the volume of rainwater that can be captured. Additionally, the volume of rainfall influences the sizing of the storage tank and helps assess the percentage of demand that the system can meet.

The amount of stored water is calculated using a daily water balance equation:

$$St = St{-}1 + Rt - Dt \ , \ 0 \le St{-}1 \le Vtank$$

Where: St the volume of water that can be stored in the tank on t days (m^3), $St-1$ the volume of water that can be stored in the tank on the previous day (m^3), Rt the volume of the rainwater that runoff from the collection water and enters the tank on t days (m^3), Dt the demands on water on day t (m^3) και $Vtank$ the capacity of the water tank (m^3).

The efficiency of the rainwater harvesting system is determined for the simulation period using the efficiency factor Re. To calculate the efficiency factor Re, several equations are used in the simulation model (Rosas et al., 2024). These equations account for daily storage, runoff, and demand, and allow for the determination of the system's performance across different scenarios, including variations in household size, collection area, and tank volume. In this analysis, this factor is the ratio of the number of days in which the tank water meets the household's full water needs to the total number of days over which the rainfall data is recorded and used in the model.

$$Re = \frac{D_{eff}}{D_{total}}$$

Where: Re is the Efficiency factor, as the ratio of effective days (D_{eff}) to the total number of simulation days (D_{total}).

In this study, daily rainfall data for the area of Fourni were used to simulate the performance of the rainwater harvesting system. The data covered a period from 2012 to 2023, encompassing a total of 10 hydrological years. This data was used as input for the simulation model to determine the volume of rainwater that could be harvested over the specified period.

Several different scenarios were analyzed to assess the impact of various factors on the efficiency of the rainwater harvesting system. The scenarios considered the following parameters:

- Household Size: Two different household sizes were modeled: one with 2 members and another with 4 members. These values were represented as N_{cap}, reflecting the number of people in the household and their corresponding water demands.
- Rooftop Area: The area of the rooftop used for rainwater collection was varied between 40 m² and 140 m². This range covers typical household roof sizes, affecting the volume of rainwater that can be harvested each day.
- Rainwater Tank Volume: The capacity of the rainwater storage tank was varied between 5 m³ and 30 m³. Larger tank volumes allow for more significant storage and provide greater flexibility to manage periods of lower rainfall.
- Coverage Target: The primary objective of the study was to meet a coverage target of 30% of the household's total daily water demand that is about the water amount required for toilet demand (Domènech and Saurí, 2011, after Domene et al., 2004). Further analysis also provided regarding the target of meeting the 40% and 50% of the total daily water demand. The daily water demand was set at 180 L per person, a standard value based on typical household usage for non-potable needs, such as toilet flushing and laundry. Each of these factors was simulated across a range of possible configurations, with the efficiency of the system being evaluated based on the ability to meet the target coverage. The simulations allowed for the comparison of different scenarios and helped to identify which combinations of household size, collection area, and tank volume provide the most efficient solutions for rainwater harvesting on Fourni Island.

The efficiency of the rainwater harvesting system was further examined under future climate change scenarios. To simulate the potential impacts of climate change on the system's performance, EURO-CORDEX climate projections were used, focusing on two representative concentration pathways (RCPs): RCP4.5 (moderate scenario) and RCP8.5 (adverse scenario). These climate scenarios provide projections of future climate conditions, offering insights into how temperature, precipitation, and other climate variables may evolve over time. The time series for future estimates was set to cover 30 hydrological years, from October 1st, 2030 to September 30th, 2060. It is important to note that these projections are not forecasts but tools used to simulate potential climate conditions based on current climate models.

For the future climate scenarios, the following parameters were considered:

- Household Size: The simulations included household sizes of 2 and 3 members (N_{cap} =2,3), reflecting

different household configurations and their corresponding water needs.

- Rooftop Area: The rainwater collection area was adjusted to a range of 60 m² to 100 m². This represents a slightly larger minimum collection area compared to the historical scenarios, accommodating potential increases in demand or larger household sizes in the future.
- Rainwater Tank Volume: The tank volume was limited to a smaller range, between 5 m³ and 10 m³, reflecting the more conservative storage capacity designed for future needs, potentially due to anticipated changes in rainfall patterns and storage efficiency under climate change. These sizes are also available in the market.
- Coverage Target: As with the historical scenarios, the coverage target was set at 30% of the household's total daily water demand. This target was chosen to match non-potable water usage such as toilet flushing, with the daily demand still set at 180 L per person.

The climate scenarios were used to simulate the effect of changing precipitation patterns and other climate variables on the efficiency of the rainwater harvesting system. The simulations aimed to determine how the system's ability to meet the daily water demand would be affected under the moderate scenario (RCP4.5) and high emissions scenario (RCP8.5). This analysis helps to assess the potential future performance of the system and identify how climate change may influence the viability and effectiveness of rainwater harvesting as a sustainable water supply solution for Fourni Island.

To better illustrate the system's performance under varying scenarios, the daily fluctuation of water storage in the domestic tank is presented for cases involving two (2) household members and tank volumes ranging from 5 to 20 m³ (Figure 1). Calculations are based on the daily water balance method. Additionally, for the smallest tank volume, changes in water storage are shown for several rooftop areas (60–100 m²). As observed, rooftop area is the most critical parameter influencing model efficiency. Under the first scenario, overall performance reaches 89%; when rooftop area increases, the system fully satisfies the target demand coverage.

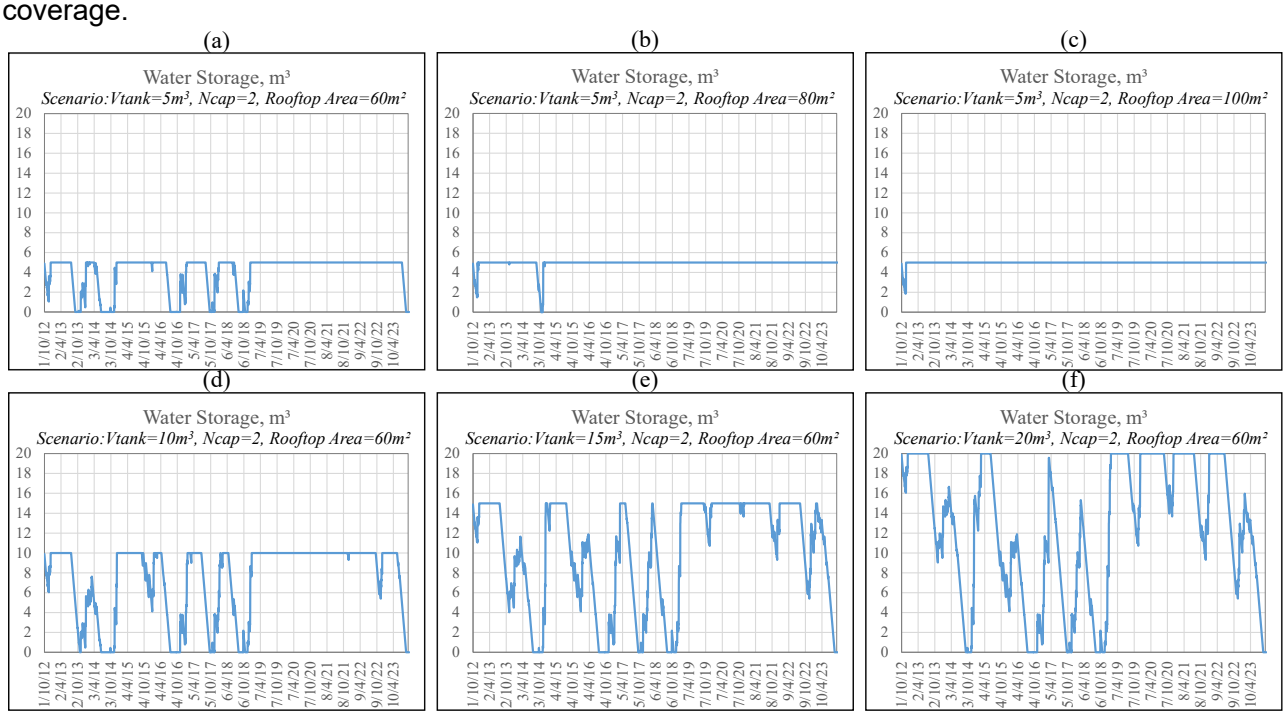

Figure 1. Daily water storage fluctuation in the domestic tank under different combinations of tank volume and rooftop area for two household members, using the water balance method. Sub-figures represent: (a) V = 5 m³, rooftop area = 60 m²; (b) V = 5 m³, rooftop area = 80 m²; (c) V = 5 m³, rooftop area = 100 m²; (d) V = 10 m³, rooftop area = 60 m²; (e) V = 15 m³, rooftop area = 60 m²; (f) V = 20 m³, rooftop area = 60 m².

Results

Initial simulations (historic timeseries of a ten-year period)

The results of the rainwater harvesting system simulation highlight the impact of rooftop collection area and tank volume on system efficiency, expressed through the reliability factor Re. The system's performance was assessed for different household sizes and water demand coverage targets.

- Household with 2 Members (N_{cap}=2): As shown in Figure 2, for a rooftop area of 80 m² or larger, the system meets the 30% water demand coverage target. The efficiency of the system increases with larger rooftop areas, reaching near 100% for collection areas of 120 m² regardless of the size of the tank. In other words, tank volume has a lesser impact on efficiency compared to the rooftop area, as even smaller tanks (5-10 m³) provide sufficient storage when combined with a large collection surface.
- Household with 3 Members (N_{cap}=3): As seen in Figure 2 (right panel), when the household size increases, the system struggles to meet the 30% coverage target for most scenarios. The target is only achieved for collection areas of 140 m² with large tank volumes. For smaller rooftop areas (≤100 m²), the system remains inefficient, indicating that a larger roof area is essential for sustaining a 3-member household.
- Higher Coverage Targets (40% and 50%): When the target coverage is increased to 40% and 50% of total water demand, the system's reliability significantly drops for smaller collection areas. The system is only effective ($Re \geq 90\%$) when the collection area is at least 100 m². Tank volume remains a less sensitive parameter, meaning that increasing storage capacity does not significantly improve efficiency unless the collection area is also sufficiently large.

The graphical results provide valuable insights into selecting the optimal tank size based on individual household conditions. By examining the figures, it becomes evident that the coverage target is more frequently achieved in the 2-member household compared to larger households.

- For 2-member households , the system successfully meets the 30% coverage target for collection areas starting from 80 m².
- For 3-member households, achieving the 30% target is significantly more challenging and is only possible for the largest rooftop area (140 m²) with maximum tank volumes.
- For 4-member households, the system fails to meet the 30% coverage target in all cases, indicating that rainwater harvesting alone cannot be a reliable solution for larger families under current conditions.

When the coverage target increases beyond 30%, the system's performance declines, as seen in Figure 3.

The key observations are:

- Only collection areas of 100 m² or larger provide acceptable efficiency ($Re \geq 90\%$) for 40% and 50% demand coverage.
- Tank size has a limited impact compared to rooftop area, reinforcing the importance of maximizing the collection surface rather than solely increasing storage capacity.
- The system's reliability remains low overall, as it rarely meets higher demand coverage targets, emphasizing the need for supplementary water sources on Fourni Island.

These findings underline the limitations of RWH systems in semi-arid environments and suggest that their effectiveness is highly dependent on household size, available rooftop area, and target water demand levels.

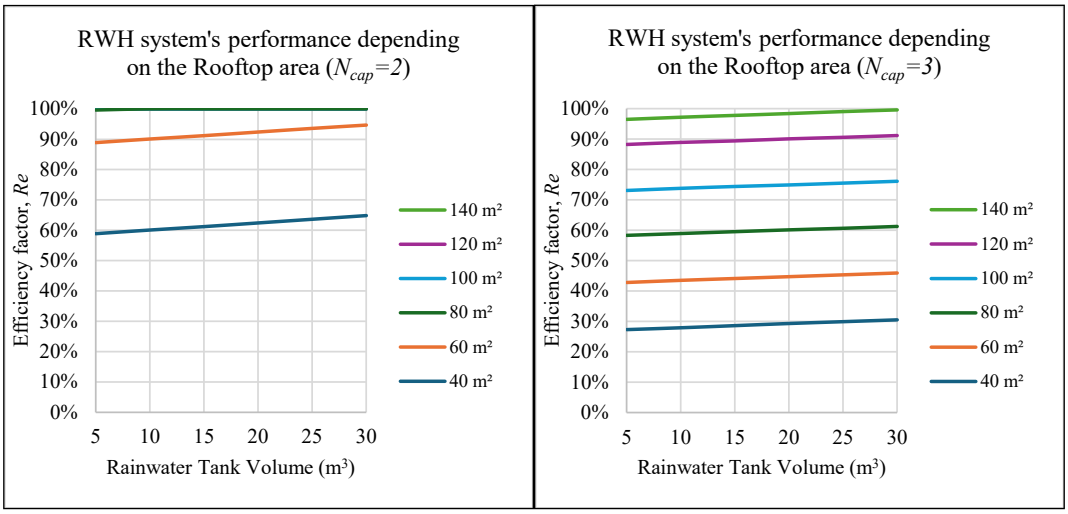

Figure 2. RWHS' performance for two-member (left panel) and three-member household (right panel), and for a 30% coverage target, using the historic timeseries.

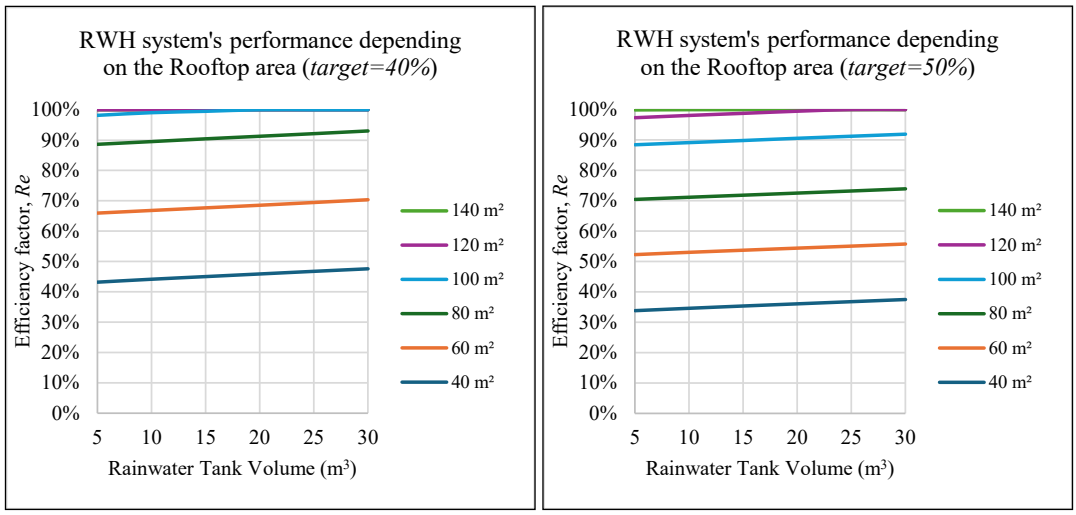

Figure 3. RWHS' performance for a two-member household, and for a coverage target of 40% and 50% (historic period).

B. Impact of Climate Change on System Performance

The results of the rainwater harvesting system simulations (Table 1; codes 1-8) under climate change conditions (RCP 4.5 and RCP 8.5) reveal notable variations compared to the historical timeseries (Table 1; code = 0). The system's efficiency, represented by the reliability factor, Re, is particularly affected for the cases of smaller collection areas, demonstrating the potential impact of altered precipitation patterns in future scenarios.

Key observations from Climate Change (CC) simulations and for a two-member household are presented in Figures 4-5, for RCP4.5 and RCP8.5, respectively. The performance of the rainwater harvesting system under climate change scenarios exhibits significant variability across models. The CC6 scenario (SMHI-RCA4_IPSL-IPSL-CM5A-MR) consistently results in the lowest system performance for both RCP 4.5 and RCP 8.5, irrespective of tank size (5 m³ or 10 m³), indicating that rainfall projections under this model predict less favorable conditions for rainwater harvesting efficiency. In contrast, CC3 and CC4 slightly overestimate system efficiency, yielding performance levels marginally higher than those observed in the historical period; however, these improvements are negligible and do not significantly alter the overall conclusions regarding RWH feasibility. A general decline in system reliability is evident, as most climate

change simulations indicate a decrease in the *Re* factor, with system effectiveness projected to deteriorate under future climate conditions. On average, the *Re* factor under climate change scenarios is approximately 15% lower than in the historical period for a rooftop area of 60 m², suggesting that reduced precipitation and increased variability may challenge the reliability of RWH systems on Fourni Island. These findings underscore the vulnerability of rainwater harvesting systems to climate change, particularly for smaller collection areas, with potential consequences for households reliant on rainwater as a primary source of water. To ensure long-term water security, additional water management strategies may be necessary. Meanwhile, larger collection areas (≥100 m²) remain the most effective approach to maintaining system efficiency despite changing climatic conditions. Overall, the results highlight the need for adaptive planning in water resource management to mitigate the adverse effects of climate change on domestic rainwater harvesting, especially in small island environments.

Conclusions

This study assessed the efficiency of domestic rainwater harvesting (RWH) systems on Fourni Island, Greece, under various household and climate change scenarios. The findings highlight the potential and limitations of RWH as a supplementary water source in an arid island environment with limited freshwater resources.

The results demonstrated that rooftop collection area is the most significant factor influencing the system's performance. Larger collection surfaces (≥100 m²) improve system efficiency, ensuring higher rainwater availability. Tank volume plays a secondary role; once a sufficient storage capacity is reached (10-30 m³), additional increases in volume provide diminishing returns in performance.

For two-member households, the system achieved the 30% coverage target in several scenarios, particularly when collection areas exceeded 80 m². However, for three- and four-member households, meeting the coverage target proved significantly more challenging. The four-member household scenario failed to reach the target under any conditions, highlighting the system's limitations in larger households. Higher coverage targets (40% and 50%) further reduced the system's efficiency, requiring rooftop areas of at least 100 m² to maintain reliability (Re ≥ 90%).

When assessing the impact of climate change (RCP 4.5 & RCP 8.5) on system reliability, most scenarios projected a decline in efficiency. Most climate models indicated an average 15% reduction in Re compared to historical conditions, particularly for smaller collection areas (60 m²). The CC6 scenario (SMHI-RCA4_IPSL-IPSL-CM5A-MR) consistently showed the lowest efficiency across both climate pathways, indicating that future rainfall projections under this model predict less favorable conditions for RWH. In contrast, CC3 and CC4 models slightly overestimated system performance but did not significantly alter overall conclusions.

Despite these challenges, RWH remains a viable water management strategy, particularly during peak demand periods such as the tourist season, when water needs increase sharply. While it may not fully replace conventional water sources, RWH can serve as a reliable supplementary resource, reducing dependence on external water supply systems.

Future research should focus on cost-benefit analysis, assessing whether the implementation of RWH systems is economically viable for households in the short and long term. Additionally, exploring hybrid solutions, such as integrating RWH with desalination or greywater reuse, could enhance water security on small islands like Fourni.

In conclusion, while RWH offers potential benefits, its effectiveness depends on site-specific factors such as rooftop area, storage capacity, and climate conditions. Policymakers and local authorities should consider

adaptive planning strategies, including financial incentives for larger collection areas and optimized tank sizing, to improve the feasibility and long-term sustainability of RWH in water-scarce island regions.

(2) Department of Structural, Historical & Applied Geology, School of Geology, Aristotle University of Thessaloniki, 54124 Thessaloniki, Greece

Introduction

The area of the Varnous plutonite is located in northwestern Macedonia, Greece. It lies west of the town of Florina, east of Mikri Prespa Lake, and extends northward across the border between Greece and North Macedonia. The southern boundary extends to the foothills of Mount Vernon (Fig. 1). The plutonite is differentiated, comprising various petrological types ranging from leucogranite to monzodiorite (Katerinopoulos, 1983; Koroneos & Christofides, 1990; Koroneos, 1991; Koroneos et al., 1991; Koroneos 1993, Koroneos et al., 1994). It intruded the basement of the Pelagonian Nappe in 297 Ma (Koroneos et al., 1993).

Although several studies have mentioned the existence of thermally metamorphosed rocks in contact with plutonite, this aspect has not been thoroughly investigated (Kilias, 1980; Katerinopoulos, 1983; Kilias & Mountrakis 1989; Koroneos, 1991). There is ongoing debate regarding whether these rocks are thermally or regionally metamorphosed (Mposkos et al., 2001). The aim of this study is to identify the different metamorphic assemblages and clarify the presence or absence of a thermal aureole.

With cyan sampling locations

Materials and Methods

Seventy-eight polished-thin sections of the rocks surrounding the plutonite were studied by optical and scanning electron microscope for the determination of their mineralogical composition and their textures (see Figure 1 for sampling locations). The scanning electron microscope used was a JEOL JSM-6390LV type equipped with an energy dispersive spectrometer INCA 300, at the Laboratory of Scanning Electron Microscopy at Aristotle

University of Thessaloniki. Analytical conditions were 20 kV operating voltage, 0.4 mA beam current, 80 s analysis time and ≈1 μm beam diameter.

Results

For better data management, the study area has been subdivided into three regions: the eastern part, parallel to the Florina-Agia Paraskevi Road; the western part, parallel to the Andartiko-Mileonas road; and the southern part, parallel to the Florina-Pissoderi-Andartiko road. The southern and eastern parts exhibit the most similarities, while the western part is considerably different.

The eastern part contains the most complex assemblages within the study area. In the same thin section, minerals from a wide range of temperatures and pressures can be observed. The samples can be divided into those that contain sillimanite and those that do not. The main assemblages are as follows (abbreviations after Whitney and Evans 2010)

- Qtz + Mica (Ms-Ph+Pg) + Bt + Grt + St + Sil ± Chl ± Ilm ± Pl ± Ap, and
- Qtz + Mica (Ms-Ph+Pg) + Chl + Grt + Cld ± Bt ± Ilm

Analyses of the minerals are presented in Table 1.

Similar assemblages are found in the southern part; however, in some cases, St occurs alongside Cld. Evidence of overprinting in the samples (Figs. 2 and 3) suggests that the minerals formed as a result of polymetamorphism. Large garnet crystals contain inclusions of sillimanite and appear broken and deformed. A new generation of garnet is observed, characterized by small euhedral crystals. Staurolite and chloritoid occur in some locations, forming euhedral crystals that do not conform to the rock's overall texture. In some samples, sillimanite appears broken and/or replaced by mica, while in other cases, it occurs in the form of fibrolite.

In contrast, the main assemblage in the western part is Qtz + Mica (Ph + Par + Mrg) + And + Crd + Bt ± Pl ± Kfs ± Chl ± Ilm ± Rt ± Sil ± Cld. Crd is, in some cases, almost completely replaced by Ms, Mrg, Bt, and Chl (Fig a,b). In other cases, Crd rim is altered to pinite (Fig. 2 c,d).

All minerals that form solid-solution series with Fe-Mg are iron rich. Chl is classified as brunsvigite, a type of chamosite, with Fe/Fe+Mg ratio of 0.62, while in Bt the same ratio is 0.63. In Cld the ratio Fe/Fe+Mg ratio is 0.8, whereas in Crd it is 0.53. As shown by the representative analyses, micas exhibit a wide range of compositions. The underlying causes of these variations in mica composition are still under investigation. Garnet, where present, is almost always represented by the following composition: $Alm_{66}Sps_{14}Py_{9}Grs_{4}Adr_{2}$. Plagioclase is classified as albite in some samples, while in others it is identified as oligoclase.

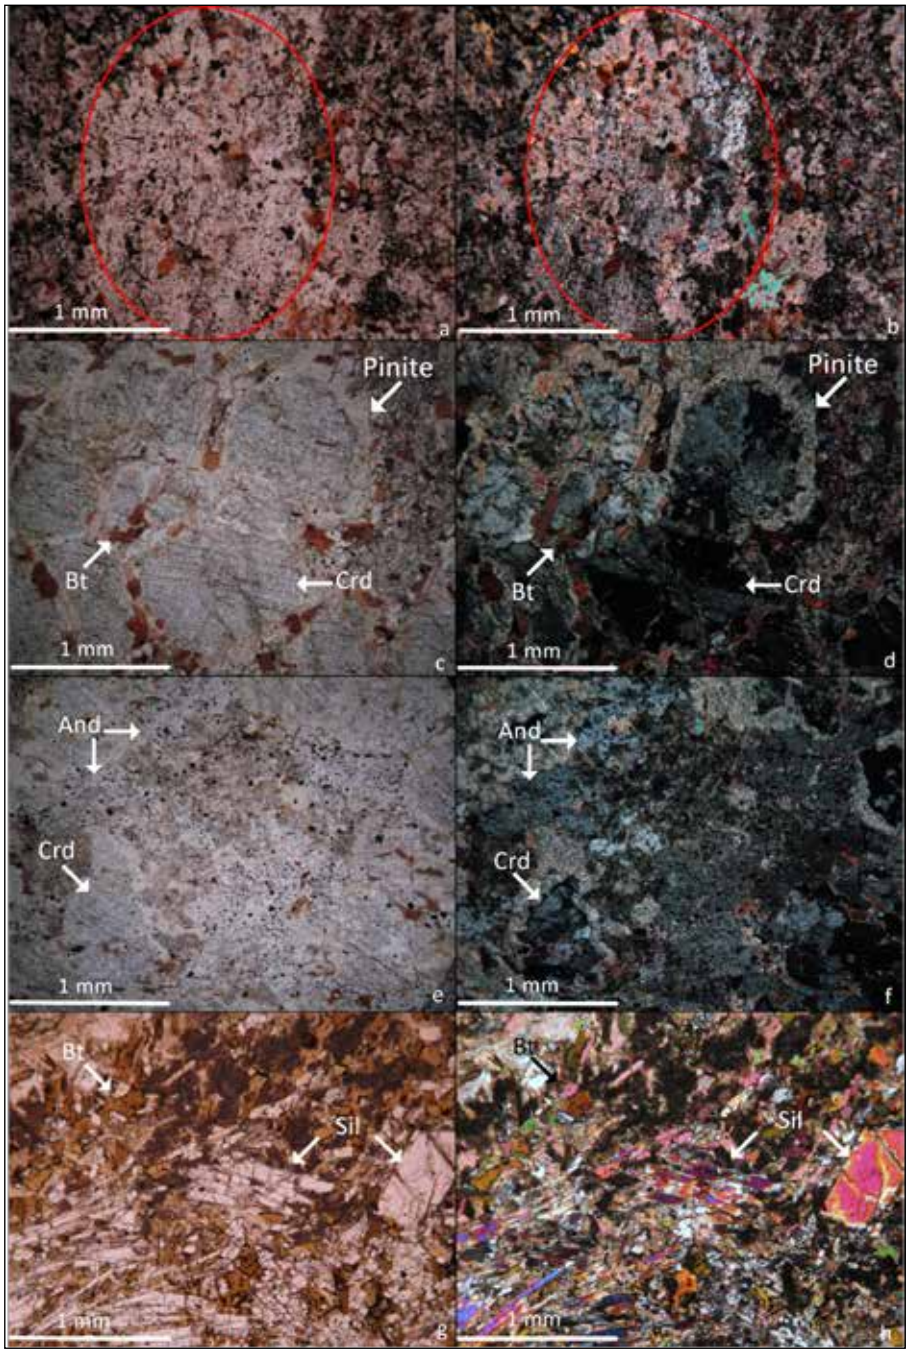

Figure 2. Microscopic images of metapelitic samples of the area. On the left are images with //N and on the right images with +N. Pictures a) and b) show pseudomorphs of mica, biotite and chlorite after cordierite from the western part. Pictures c) and d) show cordierite crystals with pinitic alteration and biotite from the western part. Pictures e) and f) show andalusite and cordierite from the western part. Pictures g) and h) show prismatic sillimanite and biotite with diablastic texture from the eastern part.

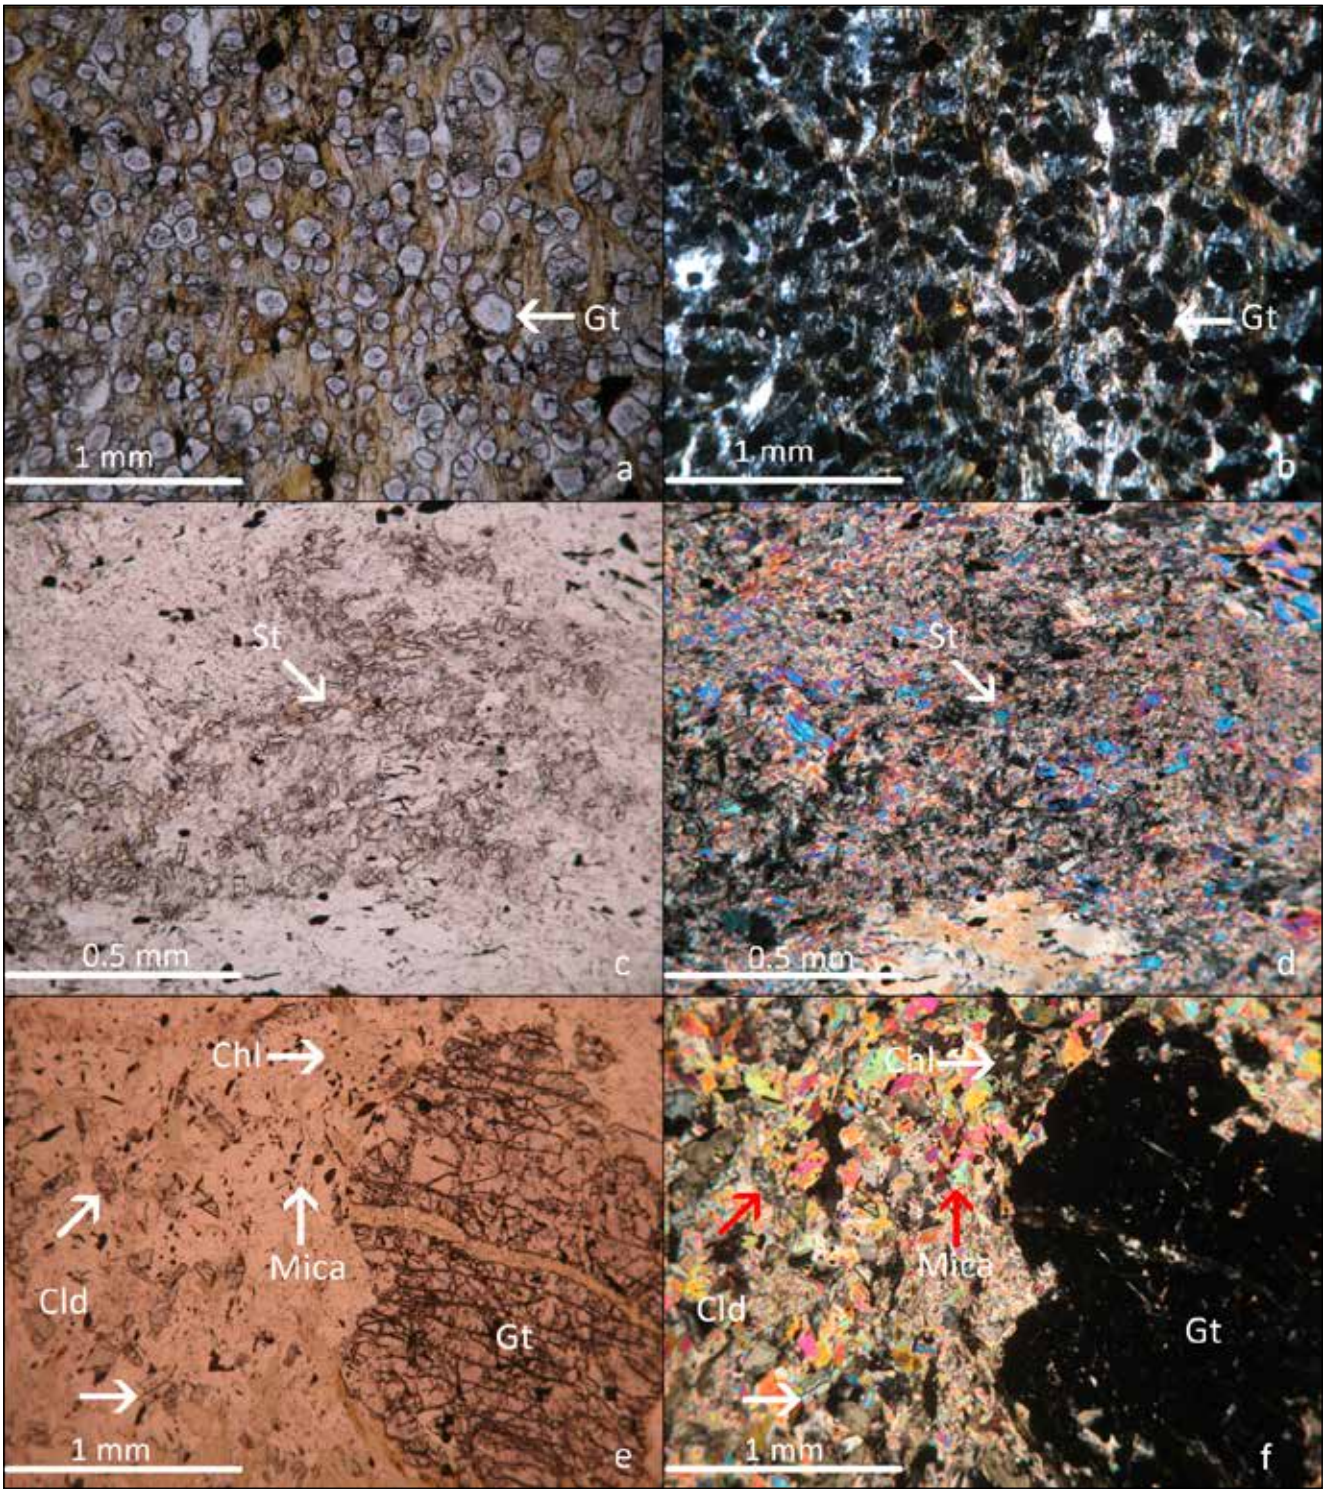

Figure 3. Microscopic images of Alpine metamorphosed rocks of the area. On the left are images with //N and on the right images with +N. Pictures a) and b) show newly formed small garnets in a biotite, chlorite, mica lepidoblastic mass from the eastern part. Pictures c) and d) show staurolite crystals with sericite mass from the eastern part. Pictures e) and f) show prismatic crystals of chloritoid with chlorite and mica and an old garnet with sillimanite inclusions, partially altered to chlorite

Discussion and Conclusions

The eastern and southern parts of the study area exhibit significant similarities, whereas the western part is distinctly different. It is important to note that the basement of the Pelagonian Nappe is considered to represent a continental fragment of Gondwana. Having been formed before the Alpine orogenesis, it has undergone all the tectonic and metamorphic stages associated with this event. Since the plutonite intruded the basement, the surrounding rocks must predate the intrusive rock, with some studies estimating their age at approximately 700 Ma (Anders, 2005; Zlatkin et al., 2014). Consequently, the tectonic history of the area supports the evidence of polymetamorphism observed in the samples.

The Alpine metamorphism in the study area has been well-documented (Avgerinas, 2014; Kilias et al., 2010). According to these studies, a metamorphic event occurred between 150 and 130 Ma, resulting in the formation of an assemblage comprising Cld + Mica + Chl + Kfs + Pl + Qtz + Grt. Another metamorphic event, dated to 110–90 Ma, overprinted the previous assemblage, as evidenced by the alteration of mica to sericite and garnet to chlorite, along with quartz and plagioclase. Finally, a mylonitic event occurred between 90 and 70 Ma.

Based on these studies, it can be inferred that the samples collected from the eastern and southern parts demonstrate these Alpine assemblages, as well as older ones. The older assemblages include Sil-Bt-Grt, characterized by a diablastic texture with large prismatic crystals of sillimanite (Fig. 2 g, h). In some samples, sillimanite occurs as small fibrolite crystals forming an ino-lepidoblastic texture together with chlorite and chloritoid. Samples from the western part also exhibit a diablastic texture, which strongly suggests that these rocks formed under low-pressure/high-temperature conditions.

The assemblages Sil-Bt-Grt in the eastern part and And-Crd-Bt-Ms in the western part are older than the Alpine metamorphic events. These assemblages are attributed to thermal contact metamorphism associated with the intrusion of the Varnous plutonite. This conclusion is further supported by the overprinting of Alpine metamorphic events onto these earlier assemblages.

The sequence of metamorphic events in the area can be summarized as follows:

1. Formation of Sil + Bt + Grt and And + Crd + Bt + Ms at approximately 297 Ma.
2. Development of Cld + Mica + Chl + Kfs + Pl + Qtz + Grt ± St during the Alpine event at 150–130 Ma.
3. Alteration of these assemblages by sericite, chlorite, and margarite at 110–90 Ma.
4. Mylonitization of all previous assemblages at 90–70 Ma.

Further research is ongoing to determine the factors responsible for the formation of different assemblages in the eastern and western parts of the contact aureole.

EXTENDED ABSTRACT 014

Balancing Precision and Resources: The Effect of Sampling Density in Regional Soil Geochemical Mapping

Argyraki A.[1], Kontomichalou A.[1], Kypritidou, Z.[1], Liakopoulos, A.[2]
(1) Department of Geology and Geoenvironment, National and Kapodistrian University of Athens, Athens, Greece, argyraki@geol.uoa.gr (2) Hellenic Survey for Geology and Mineral Exploration, Athens, Greece

Research Highlights

This study investigates the impact of field sampling density on the quality and reliability of regional geochemical maps using chromium (Cr) and lead (Pb) as case studies due to their contrasting geochemical behaviour within the mapped area. Two data sets, comprising 117 and 24 evenly distributed sampling locations within the same study area of 2500 km^2, were used to produce geochemical maps for each element. Key statistical metrics, including the mean, median, and standard deviation were compared to assess the impact of varying sampling densities. The Inverse Distance Weighting (IDW) interpolation method was then applied to generate maps, enabling visualisation of spatial variability.

Introduction

Geochemical mapping is a method of "revealing the invisible", initially involving systematic sampling, followed by sample preparation, chemical analysis, interpretation of the results, and the plotting of geochemical maps. This valuable tool is used today in various fields, including mineral resource exploration, development planning, contaminated site inventory, epidemiology, agriculture, and forestry.

The work presented here is part of a preliminary study on establishing the soil geochemical baselines of a pilot area (Attiki-Voiotia region), with the ultimate aim of publishing the first Soil Geochemical Atlas of Hellas. The project is implemented by the Hellenic Survey for Geology and Mineral Exploration, Department of Geochemistry and Environment, through the National Funds Programme in collaboration with the Laboratory of Economic Geology and Geochemistry of the University of Athens. The dominant lithological types identified across the entire extent of the pilot area can be categorised into three groups: (a) Carbonate rocks of the Alpine orogeny (limestones, dolomites, and marbles), (b) Argillaceous-siliceous rocks of the Alpine orogeny (schists and schist-chert sequences) in stratigraphic or tectonic contact with the carbonates, and (c) Post-Alpine sedimentary rocks (marls, conglomerates, sandstones, etc.) and looser sediments (colluvium, alluvial clastic material), which occupy the lower topographic areas and plains. Mineralogical analysis by semi-quantitative powder X-Ray Diffraction of selected soil samples from the study area assisted in their classification into two major groups depending on the proportion of carbonate minerals, related to the underlying lithology. Specifically, samples of significantly lower carbonate mineral content are associated with the alpine rocks (Kypritidou et al., 2024).

The objective of the present study is to investigate the impact of field sampling density on the quality and reliability of regional geochemical maps using chromium (Cr) and lead (Pb); they are used as case studies due to their contrasting geochemical behaviour within the mapped area. Chromium is a primarily lithogenic element enriched in mafic-ultramafic rocks and their weathering products, and Pb is an element typically associated with diffuse anthropogenic contamination as well as areas of enrichment, related to massive sulphide ore bodies.

Methods

Top-soil (0-20 cm) samples were collected from 117 locations on a 5 x 5 km grid within an area of about 2500 km^2 by following and appropriately adjusting the guidance of the International Union of Geological Sciences Manual of Standard Methods for Establishing the Global Geochemical Reference Network (Demetriades et al., 2022). Dried and sieved (<2 mm) soil samples were analysed by ICP-AES / ICP-MS following hot aqua regia dissolution. The present study is focused on the analytical results of Cr and Pb.

To prepare the geospatial database for the pilot project, which incorporated the results of laboratory determinations and chemical analyses, a corresponding file was compiled in ArcGIS Pro. Sampling locations were integrated into the file by importing the complete KML format file exported from the GPS. The eastern coastline boundary, along with the

boundaries of HNHS (Hellenic National Mapping Agency) maps, or the municipal and community boundaries of the pilot area, were used to isolate and clip thematic layers to the extent of the pilot project area from broader national data sets. For the purposes of this study, a subset of 24 sampling points out of the total 117 locations, was used, i.e., by reducing the number of samples by 80%. The selection of the samples was based on their uniform spatial distribution, the different land uses, and litho-geological types of the area. It is noted that since the overall objective of the project is to establish the geochemical baselines, this thinned-out sample distribution did not include any samples within the urban area of Athens, in line with the prescribed methodology by the Manual of Standard Methods for Establishing the Global Geochemical Reference Network to "sample natural residual soil, meaning soil that is not affected by any anthropogenic activities" (Batista et al., 2022). The resulted sampling scheme is equivalent to a sampling density of approximately 1 sample per 10 x 10 km grid. This thinning-out of the grid would correspond to saving a great deal of resources during sampling, sample preparation and analysis.

The statistical treatment of the concentrations of Cr and Pb at the two sampling densities included the calculation of the basic statistical parameters, and the plotting of probability curves in order to test normality and calculate appropriate percentiles for defining the concentration classes in the produced colour-surface geochemical maps. Notched box-and-whisker plots were constructed to allow pairwise comparison of the medians to be performed at the 95% confidence level by examining whether the two notches overlap. One-way analysis of variance (ANOVA) was used to indicate the statistical significance of the differences between results by the two sampling densities. The subsequent geochemical mapping procedure followed the typical steps of spatial data posting and interpolation by using the deterministic IDW technique with output cell size set at 200, power of 2 and search radius variable with 12 points in ArcGIS Pro. Error analysis, by applying exploratory interpolation in ArcGIS Pro, was used to calculate mean error enabling comparison of interpolated results between the datasets.

Results and discussion

The descriptive statistics for the two elements at the two sampling densities, and their probability plots are presented in Table 1 and Figure 1, respectively.

Table 1. Summary statistics for Cr and Pb (mg/kg) in soil for the two sampling densities.

Element	N	Mean	Median	Standard Deviation	Minimum	Maximum
Cr	117	134	86	190	2	1273
Cr	24	185	89	225	2	990
Pb	117	213	29	969	5	10000
Pb	24	238	31	558	8	2138

The statistical parameters of the raw data (Table 1) indicate that both elements display non-normal, right skewed statistical distributions with mean values significantly higher than their corresponding medians and several outlying values. A comparison of the median values for the two sampling densities demonstrates nearly similar results for both elements. One-way ANOVA (95% confidence level) on log-transformed data indicated no statistically significant differences in mean Cr and Pb concentrations between the two sampling densities. Particularly for Pb, the median values of 29 mg/kg for the dense and 31 mg/kg for the sparse sampling locations are comparable with the values of 26 and 45 mg/kg measured for rural and suburban soil within the area in a previous study by Argyraki et al. (2018).

Although Cr data approach a log-normal distribution, Pb data after log-transformation are not normalised, probably due to the presence of multiple populations within the study area. Indeed, the effect of elevated Pb concentrations in soil samples from the sulphide-ore bearing Lavreotiki peninsula is profound as a separate geochemical domain within the study area. Following these observations, and the number of samples classified in each interval, concentrations corresponding to the 25^{th}, 50^{th}, 75^{th}, 90^{th}, and 95^{th} percentiles of the data were selected to define the class limits for mapping both elements at the two sampling densities.

The boxplot comparison (Figure 1) shows that the notches at the 95%-confidence interval about the medians overlap, indicating that there is no significant difference between the median values of Cr and Pb at the two sampling

densities. However, the folding-in behaviour of the Cr low sampling density boxplot is caused by the notch extending beyond the first quartile, suggesting that more samples are needed to define the background population.

For plotting the interpolated surfaces, the deterministic IDW technique was used. The resulting maps are displayed in Figure 2. Graduated size symbol layers are superimposed on the colour surface maps to provide the exact concentration measured at each sampling site. Visual inspection of the maps indicates that although the spatial variability is better captured by the dense sampling data set, anomalous areas can still be delineated even when using the 24 sampling locations. This observation highlights that careful selection of sampling sites in conjunction with a thorough study of the underlying lithology plays a crucial role in regional geochemical mapping, and that a 10 x 10 km sampling grid would still be fit-for-purpose for the delineation of regional geochemical trends.

Within the study area, elevated Cr concentrations correspond to areas of laterite occurrences in the north-west part of the map, serpentinised rocks in Hymettus Mt., and greenstones in the south-east part of the map. A gradual increase in Pb concentration is observed from north-west towards south-east areas on the map, peaking in the Lavreotiki area, which hosts the well-known galena ore deposits. These trends are captured by both the dense and the sparse sampling data sets. However, error analysis on the interpolated results indicated a 6-fold and a 3-fold increase of mean error for Pb and Cr respectively when the number of samples is reduced to 24.

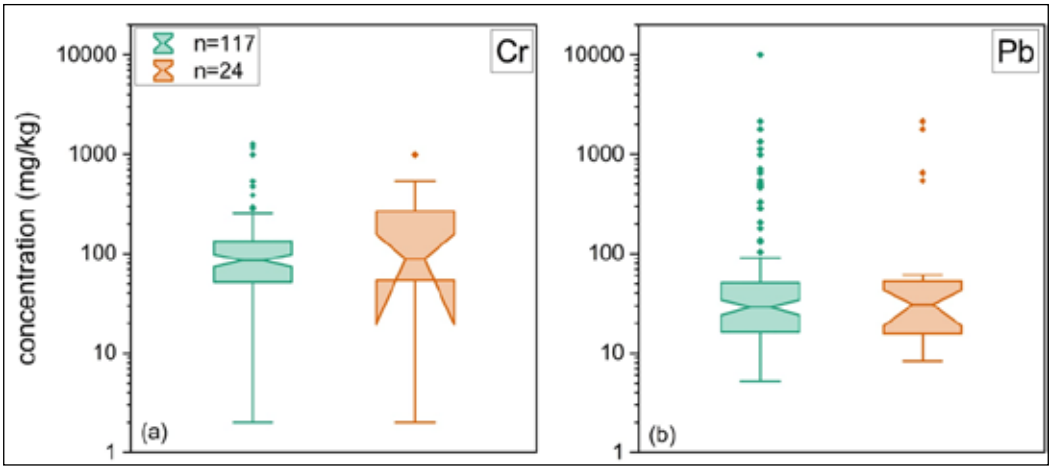

Figure 1. Notched box-and-whisker plots of Cr (a) and Pb (b) for comparison at different sampling densities.

Conclusions

The main findings of the comparison presented between the two sampling densities and the Cr and Pb spatial distribution are as follows:

- The geochemical patterns of both elements in soil are explained by bedrock lithology.
- No significant differences were identified between the descriptive statistics for both elements and sampling densities; the overall trend of the statistical distribution was captured with sufficient precision by the lower sampling density data set.
- The interpolated surfaces in the geochemical maps show anomalous concentrations in the same areas. The lower sampling density captured most of the anomalous areas. However, the spatial variability is better attained by the dense sampling data set for both elements.

Overall, the results of this study suggest that soil sampling locations for mapping the geochemical baseline of chemical elements at the regional scale should be selected by adopting a combination of statistical and judgmental approaches with careful consideration of the local conditions at each sampling site. In this way the balance between effort and final map precision can be achieved.

Further work should focus on testing the results for additional elements of interest and for different sampling densities. The current sampling data set on the 5 x 5 km sampling grid provides the opportunity for such trials, which

could be of paramount importance for optimising available resources for sampling, sample preparation and analysis when expanding the project to the national scale.

BULLETIN OF THE GEOLOGICAL SOCIETY OF GREECE, SP. PUBL.

EXTENDED ABSTRACT 015

Seismic resilience of primary water transfer network at Lagadas municipality, North Greece

Arnaouti, S.[1], Ktenidou O.-J.[2]

(1) Civil Engineer at Municipal Water Supply and Sewerage Company of Lagadas, Greece

(2) Senior Researcher at National Observatory of Athens, Greece

Introduction

Among natural disasters, earthquakes have the most destructive potential to water pipe networks. The induced damages to the water supply can be the main reason for post seismic economical disruptions. Thus, it is of utmost importance to recognize the most vulnerable elements of the water pipe network under seismic load, in order to manage effectively prevention and post seismic actions.

At the present work, we estimate the seismic resilience of the external water network - based on Balaei et al (2020) methodology - at Lagadas municipality, one of the ten largest area municipality in Greece, as a measure of the system's ability to absord a shock when occurs and to recover quickly after that (Bruneau, 2003). The results can be used to rank the prevention actions necessary to reduce earthquake consequences to water network performance.

Background

The term 'resilience' was first introduced by Holling (1973) at ecology field, as a measure of the system capacity to absorb parameter changes. The term was imported to engineering by Klein et al. (2003), that study the characteristics of mega-cities resilience to natural hazards. The conceptual work of Bruneau et al. (2003) defines seismic resilience as 'the ability of social units to mitigate hazards, contain the effects of disasters when they occur and carry out recovery activities in ways that minimize social disruption and mitigate the effects of future earthquakes.' As such, a resilient system entails the properties of robustness, redundancy, resourcefulness and rapidity to recovery.

Focusing at the water pipe networks, the works of Menoni et al. (2002) and Borzi (2023) estimate the network's vulnerability. In respect of the 'resilience' term, Arcadis company (2016) ranks fifty cities worldwide regarding their ability to secure constant water supply. Cimellaro et al. (2015) propose a resilience index for the water distribution network (WDN) as a product of three parameters: the number of users that lose their access to water, the water level in the tank and the water quality. The same year, Matthews analyses the water and sewage network resilience during natural hazards. In his study, the key parameters of the water infrastructure are quantified, based on Katrina and Rita hurricane events. Farahmandfar et al. (2016) propose a metric for seismic resilience of WDNs dependent on hazard intensity, estimated pipeline response and network topology in order to prioritise pipeline replacement works. Makropoulos et al. (2018) recognize three failure states for the WDNs, namely insufficient water quantity, insufficient water quality and infrastructure failure and suggest a toolbox to assess network resilience. Mo'Tamad et al. (2022) applied 27 different earthquake senarios to the WDN of an M-city in Ontario and examined how the expected failures affect its hydraulic resilience, in terms of pressure, water serviceability and population impacted. The analysis showed that for medium to large earthquakes, water supply can be lost for days and affect more than 90% of the city population.

Balaei et al. (2020) propose an index-based methodology to estimate WDN resilience under seismic load; the technical factors that affect WDN resilience are established through literature review and expert interviews and then quantified through expert judgement. The study showed that vulnerability, redundancy and criticality are the major technical factors affecting system resilience.

Methodology

The methodology used to estimate water system resilience is based on the work of Balaei et al. (2020) and is described in detail at Arnaouti, 2020. Balaei et al. (2020) initially state that system resilience consists of two principal terms: the residual functionality of the system after shock (robustness) and the swiftness of the system to return to its initial functionality (recovery rapidity). For the first part, the authors consider

that it mainly depends on the physical characteristics of the system rather than in social, economic and organizational parameters. For the latter part, the authors assume that the recovery time depends on the same parameters as the robustness, in the sense that an organization that creates a robust system usually develops quick time responses as well. By taking those simplified assumptions under consideration, Balaet et al. (2020) convert the resilience estimation problem to a robustness estimation problem. Literature review and field expert interviews resulted in the selection of three technical factors that define water system robustness under seismic load: vulnerability, redundancy and criticality. The authors suggest index values for those three factors through provided tables. For the vulnerability index assessment, the authors take account of the three main seismic hazards to the water network, namely fault rupture, slope failure and liquefaction. Once the vulnerability index (V_i), the redundancy index (ρ_i) and the criticality index (C_i) are determined for each pipeline section i, the robustness index R_i is given by the following equation:

$$R_i = 1 - \frac{V_i \cdot C_i}{\rho_i} \quad (1)$$

If L_i is the length of pipe section i and N is the number of the network pipe sections of the settlement water network, then the total robustness of the network is:

$$R = \frac{\sum_i^N L_i \cdot R_i}{\sum_i^N L_i} \quad (2)$$

Study area

The Municipality of Lagadas is located about 20 klm northeast of Thessaloniki and is the 10th larger municipality in Greece in terms of area (1220.3 km^2). It consists of seven municipality units, namely Assiros, Vertiskos, Kallindia, Koronia, Lagadas, Lahanas and Sohos) and its total population is 37.022 inhabitants (ELSTAT data, 2021).

The present study focuses on to the primary transfer water network of the total 37 housing areas/ settlements of Lagadas municipality, since there are scarce data for their water distribution network.

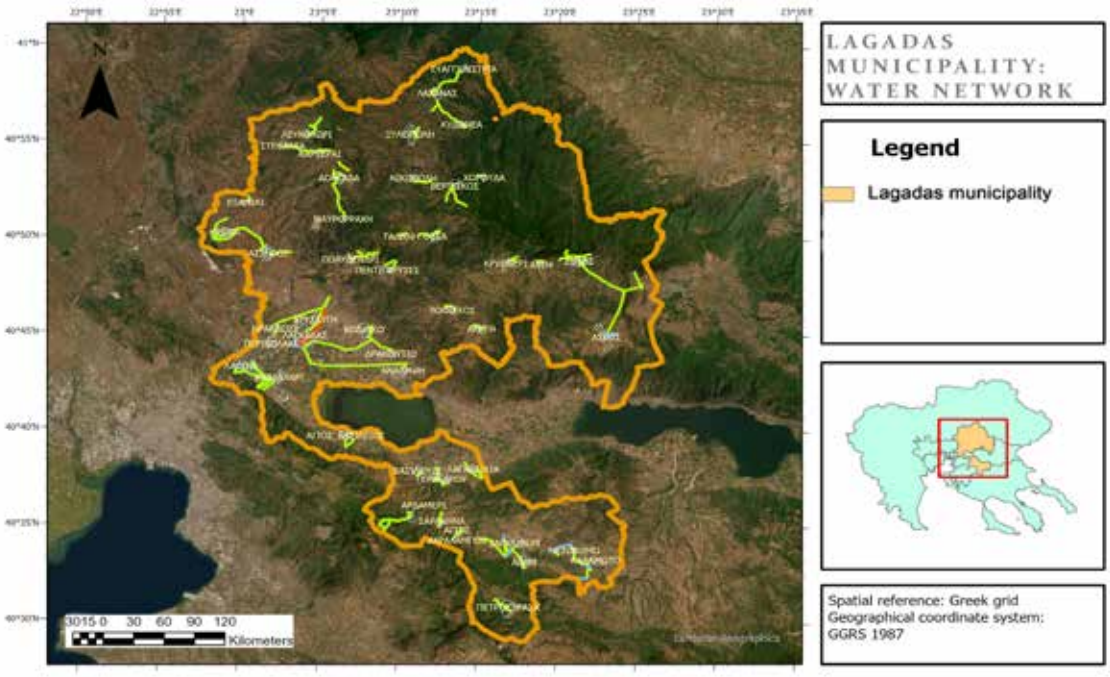

Figure 1: Primary water transfer network of the 37 settlements of Lagadas municipality

- **Fault ruptures at Lagadas**

Caputo et al. (2012) report two main fault ruptures in Lagadas area, the Sohos-Mavrouda fault and the Mygdonia fault. The Sohos-Mavrouda fault has a W-E direction, its length is about 41 km and it is an antithetic fault, since it is the only one with south-dipping structure. The Mygdonia fault with a total length of 69 km, is divided in three parts, that follow the borders of the homonymous basin: from west to east, there is Lagadas segment, Gerakarou segment and Apollonia segment. The Gerakarou segment with a W-E direction dips to the North and was the causative fault of the 1978 Mw=6.5 Thessaloniki earthquake, while the Lagadas segment strikes NW-SE and caused the M6.5 Assiros earthquake in 1902. The authors state that some researchers consider that Lagadas segment is not related to the current stress field, though oblique-slip kinematics show evidence of reactivation. On the other hand, some researchers believe that the seismic activity has abandoned Lagadas segment and been transferred to the south, towards Asvestohori fault. In addition, Chatzipetros et al. (2006) have detected a fault in Lagyna region with a NW-SE strike that was not included to the IGME geological map. This fault is parallel to the rest of the active faults of the area and is considered to be caused by recent over pumping activity. The map with the aforementioned fault ruptures available at Chatzipetros et al. (2006) was digitized through ArcGIS Pro program.

- **Landslides at Lagadas**

Koukis et al. (2005) recorded landslide occurrences in Greece for the time period 1950-2004 and provide a landslide hazard zonation map of Greece. According to this map, the Lagadas area exhibit a number of 0-1 landslides per 100 km^2 area. In addition, Wilde et al. (2018) and Günther et al. (2014) created a landslide susceptibility map of Europe with a 200x200m resolution based on a semi-quantitative method that relates the number of landslide occurrences to slope angle, lithology and land cover. The map was received in a raster form through the ESDAC Dataset Access service, after digital request.

- **Liquefaction at Lagadas**

As stated by Papathanassiou (2006), the 1902 Assiros earthquake caused liquefaction phenomena in Assiros and at the Thermal Springs of Lagadas, as written descriptions of mud puddles in dry tributary reveal. Papathanassiou et al. (2010) created a liquefaction susceptibility map of Greece by correlating liquefaction occurrences with geological, geomorphological and seismological data. Though a susceptibility map in a regional scale instead of national scale would have been more appropriate for the present study, the lack of such data led to the use of the data available.

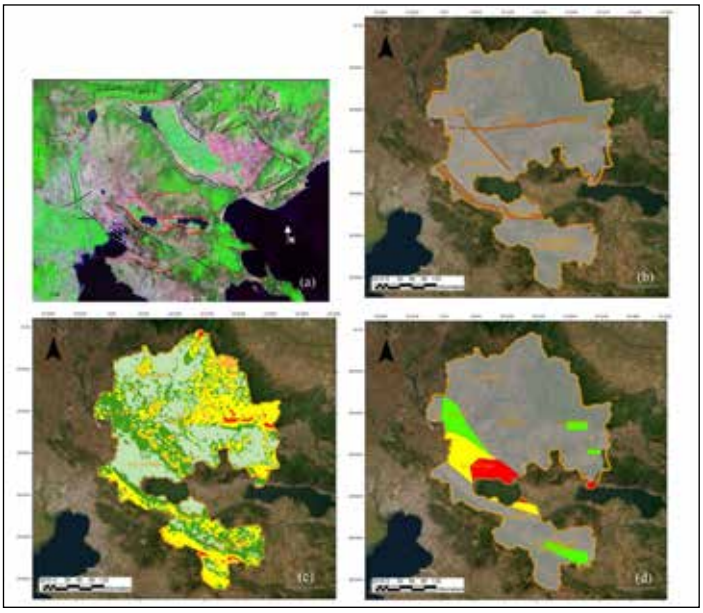

Figure 2: (a) Fault rupture maps at Lagadas area, taken from Chatzipetros et al. (2006), (b) Active faults of Lagadas municipality used for the present study, based on Chatzipetros et al. (2006) map, (c) Landslide susceptibility map of Lagadas municipality used for the present study (based on ESDAC data) and (d) Liquefaction susceptibility map of Lagadas municipality used for the present study (based on Papathanassiou et. Al, 2010 susceptibility map)

Calculations

- **Vulnerability index Vi**

According to the literature, vulnerability index Vi of the pipelines can be estimated based on their technical characteristics. For example, Menoni et al. (2002) propose a method for estimating Vi based on pipe age, pipe depth, construction material and pipe diameter. However, Menoni's methodology results in an almost uniform vulnerability index throughout Lagadas municipality, since the primary water transfer network share common characteristics (their diameter is usually below 300 mm, their material is PVC besides a few cases made of asbestos and the majority of the networks was constructed at the decade 1999-2009, just before the beginning of economic crisis in Greece).

According to the technicians of Municipal Water Supply and Sewerage Company of Lagadas, this is not the case in practice; transfer water pipe networks exhibit a considerable different performance under regular conditions, with damages ranging from almost none to too many damages per year. This different performance is attributed to three main reasons: (a) the asbestos pipelines that haven't been replaced yet (as Commission Directive 1999/77/EC defines), exhibit leaks at their joints, because the rubber joints have been worn with time. In addition, their repair is demanding due to the lack of special joints for large diameters, (b) inadequate initial design, since in practice the need to serve houses outside the settlement boundaries (in greater elevations and/or great distances from the settlement) lead to water pressures greater than initially designed and (c) inadequate compliance with technical specifications during construction; for example, non-appropriate pipe depth, no use of pipe sand-enacased or concrete-encased techniques when appropriate.

In order to import our technical staff knowledge about pipe actual vulnerability into our analysis, we have introduced five vulnerability categories (categories 0 to 4, where category 0 is for a pipe that is not in use, and categories 1 to 4 for pipes that exhibit damages 0, 1-2, 3-4 and more than 4 per year respectively) and set the vulnerability index according to the actual pipe performance under standard conditions. The most vulnerable sections of the transfer water pipe network are located at the municipal unit of Lagadas and more specifically at Lagadas, at Lagynas and at Irakleion – Perivolaki asbestos networks. At the rest of the municipal units, vulnerable sections can be found where elongated pipelines are used to transfer water to adjacent settlements, like in Stefania and Ossa.

- **Criticality index C_i**

Following Balaei et al. (2020) study, we used five categories for the criticality index (categories 1 to 5, when the population served was 0-50, 51-200, 201-500, 501-1000 and more than 1000 inhabitants respectively).

- **Redundancy index ρ_i**

Balaei et al. (2020) set five categories for the redundancy index (categories 1 to 5, for very high, high, some, low and no redundancy respectively). Since the redundancy description of Di Nardo et al (2016) is applied to water distribution networks and not to transfer water networks, we defined new categories and definitions for the redundancy index, shown at Table 1 below:

Table 1. Redundancy index categories for standpipes and downpipes, used in the present study

Redundancy index (ρ)	Standpipe (water transfer from drilling to the tank)	Downpipe (water transfer from tank to the settlement)
1	-	>2 downpipes
2	>5 functioning standpipes OR >2 standpipes with at least one spare	-
3	4-5 functioning standpipes OR 2 standpipes with at least one spare	2 downpipes
4	2-3 functioning standpipes	-
5	one functioning standpipes	One downpipe

- Rupture impact index $I_{RP,i}$, landslide impact index $I_{LD,i}$ and liquefaction impact index $I_{LQ,i}$

The impact indexes are estimated based on the tables provided by Balaei et al. (2020).

- **Robustness index**

The robustness index of pipe section i for seismic hazard j is:

$$R_{j,i} = \frac{1}{(V_i \cdot C_i \cdot \rho_i \cdot I_{j,i})}$$

Five categories were selected for the robustness index (index values: 1 for high robustness to 5 for very limited robustness), when robustness is 15-100%, 5-15%, 1-5%, 0.5-1% and 0-0.5% respectively. The robustness index in total, by taking account all three seismic hazards, is considerer to be the robustness of the worst-case scenario, thus it is the max robustness index: . $R_i = \max_{j=1\ldots3} R_{j,i}$. Through Eq.2, the robustness category per settlement network can be estimated.

All the calculations and maps of the present study were performed using ArcGIS Pro software, v.3.3.0, @ ESRI Inc 2024 (free license was available to MSc students of University of Aegean).

Results

Figure 4 shows the robustness of the water transfer network per pipeline section and per settlement.

The study reveals the very limited robustness of the water transfer pipelines at Lagadas, Lagyna, Perivolaki, Gerakarou and Lagadikia due to its proximity to faults. Liquefaction phenomena affect the water network at Lagadas, Xrisavgi and Irakleion. Regarding landslides, pipelines at Lagadas, Xrisavgi and Lagyna exhibit very limited robustness.

In terms of settlement networks, the only settlement with high robustness is Galini. Indeed, Galini is relatively protected by the seismic hazards and it has small population. Settlements at Lagadas municipality unit show very limited robustness due to the network's high vulnerability, the large population relative to the other municipality units, the proximity to fault ruptures and the liquefaction susceptibility. Very limited robustness can also be met at settlements of Koronia municipality unit, mostly because these networks lack redundancy and they are close to fault ruptures.

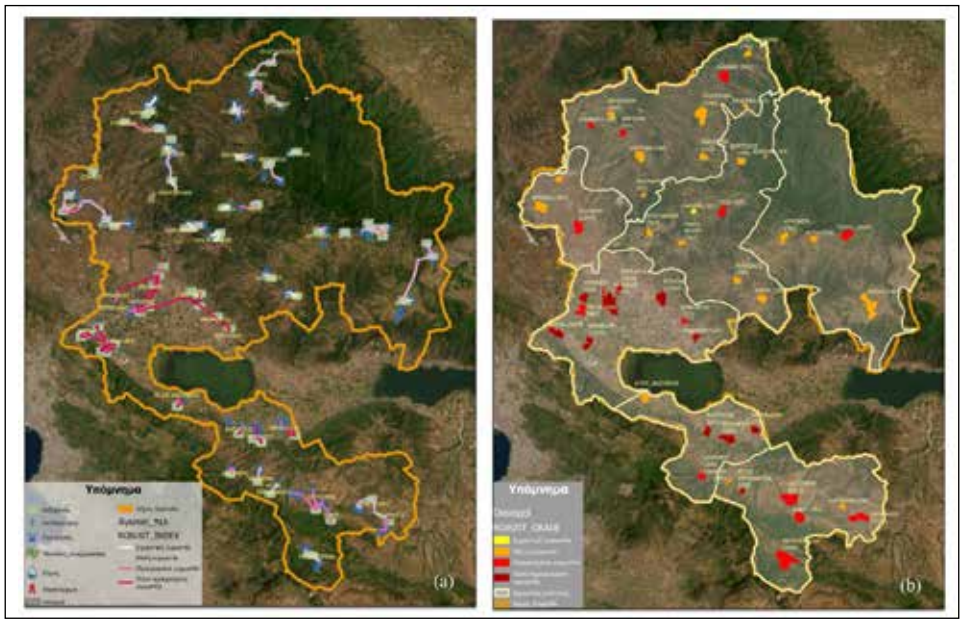

Figure 4: Water transfer network robustness. (a) Robustness per pipeline (white: high robustness, light pink: medium robustness, pink: limited robustness, magenta: very limited robustness. (b) Robustness per settlement of Lagadas municipality (yellow: high robustness, orange: medium robustness, red: limited robustness, brown: very limited robustness)

Conclusions

According to literature, the basic reason of failure of the water pipelines after earthquake is soil displacement, that can be caused by fault rupture displacements, landslide effects and liquefaction phenomena. The methodology proposed by Balaeti et al. (2020) takes account of all three seismic hazards.

Although literature review offers many approaches for estimating pipe vulnerability based on their physical characteristics, the use of our technical staff knowledge seems more appropriate, since it integrates critical aspects of the network, like inadequate initial design and not compliance with technical specifications during construction.

The results reveal that the majority of settlements in Lagadas municipality are not that robust and severe disruptions to water supply is expected after earthquake. Increasing pipeline vulnerability and enhancing network's redundance are prevention works for the least robust systems. Settlement robustness offers a valuable indicator to prioritize the prevention measures.

Acknowledgements

I would like to express my sincere appreciation to Municipal Water Supply and Sewerage Company of Lagadas and to its technical staff for providing all the necessary data for the water network providing and sharing their experience on its performance.

EXTENDED ABSTRACT 016

Implementing the Critical Raw Materials Act to explore strategic minerals potential in Greece

Arvanitidis N.[1], Laskaridis K.[2], Christidis C.[2]

(1) President of the Mineral Raw Materials Committee of the Association of Greek Geologists, nikolaos.arvanitidis@gmail.com (2) Hellenic Survey of Geology and Mineral Exploration, Greece, klaskaridis@eagme.gr, christidisc@hotmail.com

Introduction / Background

Vast amounts of raw materials from minerals will be needed to meet the demand for a global economy free of hydrocarbons. Some are categorised as Critical and Strategic Minerals (CSMs) due to their high economic significance and supply risk. Of the 34 minerals and metals on the current EU list of CSMs, established in 2023, 16—such as copper, nickel, and aluminium—are strategically significant (Grohol et al., 2023). The CSMs are the foundation on which modern technology is built. From photovoltaics to semiconductors, wind turbines, and lithium batteries, to transport and store the produced renewable energy. In addition to lithium, battery value chains need cobalt, graphite, nickel, and manganese (Rachovides, et al., 2024). The electrification of cars requires permanent magnets, whose value chains use rare earth elements (REE) such as neodymium, dysprosium, and praseodymium, but also increase the use of nickel, copper, zinc, and lead. The CSMs are also essential in digital technology. Without CSMs, there cannot be an energy and digital shift. As a result, the resilience and sustainability of the CSM value chains that deal with technology facilitating the energy transition are highly valued by the EU. The EU would need up to 18 times more lithium and 5 times more cobalt by 2030 and almost 60 times more lithium and 15 times more cobalt by 2050 to cope with the increase in the production of electric vehicle batteries. By 2030, the demand for graphite is expected to reach 4 million tons per year, with 75% going to lithium battery anodes (Rachovides, et al., 2024). A shortfall of around 780,000 tons per year is estimated by 2030. Given that several of the Green Deal's goals, such as reducing greenhouse gas emissions by at least 55%, must be addressed and achieved by 2030, the growing need for CSMs becomes even more urgent.

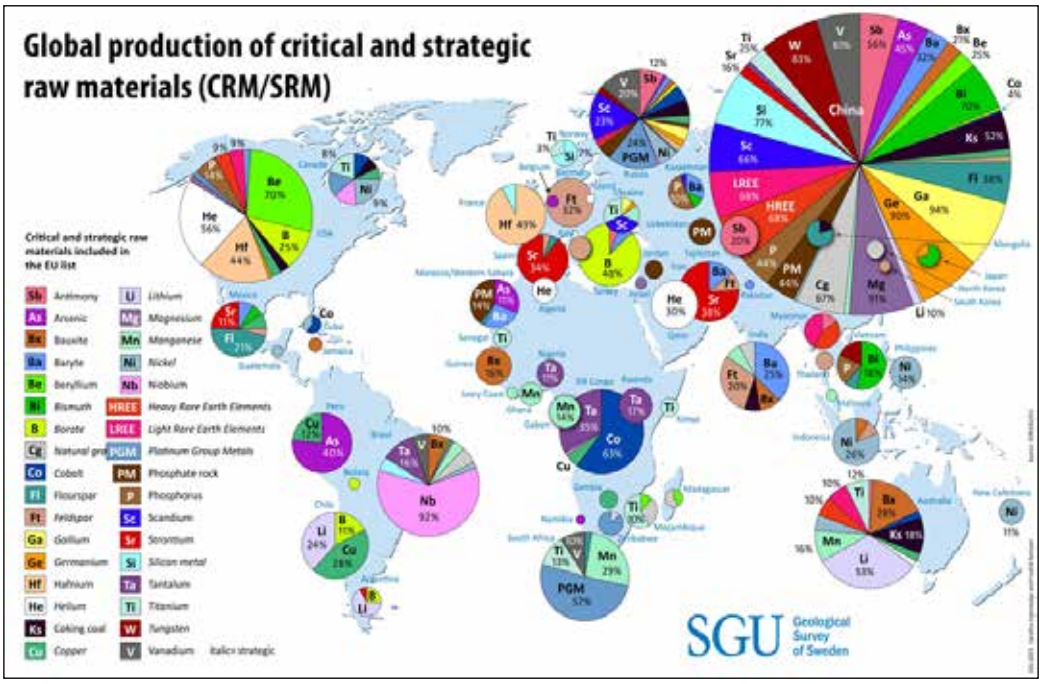

Figure 1. Map of world production of CSMs according to the current European list. Source: Geological Survey of Sweden.

The above forecasts seem "scary" considering that the EU depends on 75 to 100% of imports for most CSMs. It also happens that the production and processing of many CSMs are geographically controlled, making their geopolitical access and disposal vulnerable, accompanied by a series of social, economic, environmental, and other risks. So, some CSMs, but also their related value chains, tend to a large extent to be productively monopolized by specific regions of the planet, sometimes by essentially one country. For example, about 60% of the world's cobalt comes from the Democratic Republic of Congo (Fig. 1). China mines around 60% of the world's REE production, produces 85% of associated processed and metallurgical products, and consumes 70% (Arvanitidis, 2024). The urgent need for a global hydrocarbon-free economy will require therefore increasing quantities of raw materials. Therefore, it is important to know which and how many raw materials are needed to understand and assess the implications of their scarce access or scarcity for the European, and hence the Greek, economy. This article views why and how strategic and criticality in mineral resources arises, the geopolitical dominance of China, the European Regulation on Strategic and Critical Mineral Resources Act(CRMA), the key deposit of strategic and critical mineral raw materials resources, the need for increased investment in mineral exploration, new methodological approaches to mineral exploration, dynamic CRM systems in Europe and Greece and proposals for projects in mineral bearing areas of Greece.

The European Critical Raw Materials Act (CRMA)

The CRMA (European Commission, 2024) has become the political and strategic tool, but also the operational platform seeking to promote the implementation of the Green Deal, the new industrial strategy, the European partnership for innovation, the circular economy, and the integrated intra-European mining production, with the primary objective of making Europe climate neutral. This regulatory initiative is timely and necessary in formulating a policy for exploiting the European CSMs.

The main targets of the CRMA are until 2030

- At least 10% of CSM's annual consumption comes from European mineral deposits.

Europe's geology and metallogenetic evolution considerably favour its capability to capitalise on domestic CSM resources and become self-sufficient, resilient, and sustainable. Mineral exploration technologies for CSM deposits must be further developed to provide reliable resource estimates and feasibility studies. The national Geological Surveys of the member states must review the economic geology of their potential CSM systems, with the aim of a more documented and systematic assessment, to identify any exploitable targets.

- At least 40% of processed minerals are produced within the EU.

The integrated operation of resilient strategic value chains for the energy transition requires developing sustainable processing and refining technologies.

- At least 25% of the annual need in CSMs should come from recycling.

Most CSMs are mainly found as minor components in sulfide and oxide deposits of base metals (e.g. copper, lead, zinc, nickel, iron, aluminum). With mining and processing focused on base metal minerals, any accompanying CSM concentrations end up in various mining wastes, such as waste rocks and beneficiation tailings. Historical mining waste makes up the secondary resources that through their recycling and reuse, can potentially lead to the recovery of the CSMs they contain.

- Less than 65% dependence of each CSM on one country.

Minerals have been the missing link in the climate debate for many years. It is now clear that the EU's climate targets cannot be achieved without them. More specifically, any disruptions to the access and adequacy of CSMs, have implications for ensuring the energy transition and achieving the climate goals.

- Strengthening the resilience of strategic value chains for more effective implementation of energy and digital transition.

The value chains for CSMs include upstream mineral exploration and extraction, midstream processing (concentration, metallurgy), and downstream industrial processing and recycling. Unfortunately, in Europe today there are limited possibilities for the sustainable and integrated operation of CSM-based technology value chains

- Simplifying and speeding up licensing procedures.

The rapidly growing demand for mineral raw materials has also increased the need to update mining policy and research and innovation projects. The CRMA aims to reduce licensing time, and Member States will ensure that the overall permitting process related to such projects becomes faster. The governments of the EU Member States

agreed, in cooperation with the European Commission, the European Council, and the European Parliament, to highlight and implement strategic projects that would benefit from shorter and more efficient authorization procedures and easier access to finance.

- Development of environmentally friendly mining and production methods.

A common European understanding of best practices in the responsible mining of mineral resources, concerning social, environmental, and economic commitments and applications, set a trajectory toward the UN Sustainable Development Goals (SDGs).

- Channeling strategic partnerships between the EU and third countries to ensure sustainable and resilient CSM supply chains.

The CRMA aims to pave the way for long-term partnerships, with knowledge and technology transfer, training, and skills development for new jobs with better working conditions and income, as well as sustainable/ESG compliant extraction and processing in the partner countries from where Europe will be able to access and import some of the CSMs.

Metallogenetic settings sourcing CSMs

Most of the CSMs are minor accompanying components of important sulfides, oxides, and other metallic mineral systems. In nickel ore exploration, cobalt should also be a complementary target. Examples of CSMs found in subordinate concentrations along with known metallogenetic systems are,

- cobalt (Co) with nickel (Ni) and copper (Cu) deposits
- gallium (Ga), germanium (Ge), indium (In), antimony (Sb) with mixed sulfides
- gallium (Ga), rare earths (REE), scandium (Sc) with aluminum (Al) deposits
- platinum-based (PGM) with chromium (Cr), nickel (Ni) and copper (Cu)
- tungsten (W), niobium (Nb), indium (In), tantalum (Ta) with tin (Sn) deposits
- rare earth (REE) with phosphate (P) deposits.

"Critical" need for increased investment in mineral exploration.

Increasing the degree of self-sufficiency from 2-3% to 10% in 2030 means a 300-400% increase in intra-European production in 7 years. Huge efforts are therefore required for an increase in investment in mineral exploration to at least an equivalent degree to make the 10% degree of self-sufficiency possible. In this direction, innovative and sustainable approaches must be applied, using innovative prospecting technologies, thus improving economic performance and obtaining information that could not be obtained with conventional methods. The CRMA requests the member states to implement national CSM exploration projects through systematic economic geology approaches.

CSM potential mineral systems in Greece

Europe's geological environment and metallogenetic evolution substantially favour its ability to become self-sufficient, resilient, and sustainable in CSMs from domestic deposits.

In Greece (Fig. 2), potential CSM systems (Melfos and Voudouris, 2012; Stergiou, et al., 2023) relate to:

- active areas of mining base metal, magnesite, laterite, and aluminum bauxite mineral deposits (Fig. 2). Elevated geochemical values to higher grades of arsenic and antimony have been determined in the polymetallic ores in northern Greece. Along with nickel, the potential of exploitable cobalt contents in the laterites is a challenging target. A current project addresses the recovery of gallium, scandium, and REE with bauxite extraction and aluminium production.
- systems of metallic minerals in mainly Northern Greece (Figure 2, where mining activity (brownfields) or various scales (regional scale, deposit scale) of mineral exploration have been conducted in the past. The epithermal gold system in the Thrace region is connected to Tertiary volcanic basins and rocks with typical examples being the exploitable deposits of Sappes (Shaw and Constantinides, 2001; Border et al., 1999; Bridges et al., 1998; Cheliotis et al., 1999; Voudouris et al. 2006, Voudouris 1993), Agios Dimitrios (Michael, 1993; 2004; 2005; Michael et al., 1988), and Perama (Voudouris and Skarpelis, 1998; Lescuyer et al., 2003; McAlister et al., 1999; Michael C., 2002; Voudouris et al., 2011). In the case of this system, bismuth might be a potential target, as well as the challenging

target of locating deeper-seated copper mineralisation (Melfos et al., 2002). In the metamorphic basement of the Thrace region, there is a CSM exploration potential for antimony, with typical examples of mineralisation in Kallintiri (Michael, et al., 2012; Michael, et al., 2013; Kanellopoulos, et al., 2014), A prominent antimony prospect is found in Chios (Tsamantouridis and Chorianopoulou, 1977; Dimou et al., 1986).

- potential CSM exploration targets in central Macedonia are associated with the carbonate-replacement polymetallic mineral systems in the Serbo-Macedonian and Rhodope zones. In the lead-zinc-silver-gold ore deposits of Olympias and Mavres Petres in NE of Halkidiki arsenic and antimony, are mineralogically and geochemically also determined. The mineralisation in Thermes belongs to the same system (Arvanitidis et al., 1987) and the volcanogenic massive base-metal sulfide deposit (VMS) in Polykastro, where germanium and indium could also be of potential exploration interest. The VMS Molai base metal deposit in Peloponnese having a similar mineralogical composition, shows feasible germanium exploration results. While exploitable resources are mostly associated with the palladium-containing porphyry copper-gold mineral systems in the central Macedonian regions of Skouries and Kilkis, copper is the focus of exploration attention in the Kimmeria skarn mineralisation. The pyrolusitic manganese ores of the Varvara area in NE Halkidiki, which was explored in the past, probably needs a new review. Regarding antimony, the historical mining in the central Macedonia Lahanas area should not be ignored.
- to the mineral system of magmatic mineralisations, which is largely genetically linked to the ophiolite zones in mainly western Macedonia, with the predominant occurrence of Vourinos chromite deposits and the hydrothermally formed and ultrabasic rock-hosted magnesite in Halkidiki and Evia. Bauxites and laterites, formed by alteration, weathering and re-working of ophiolite-related ultramafic rocks and associated rocks (Valeton, et al, 1987), are exploratory placed in this system, with particularly increased contents of CSMs of gallium, scandium, REE, and cobalt, as mentioned with the respective active bauxite and laterite mines (Fig. 2). As far as nickel and cobalt are concerned, the mineral deposits in the western and eastern Vermio (e.g., Flamouria area), an exploration project previously implemented, concluded that an economic geology re-evaluation is highly recommended.
- the resource dimension and perspective of historical mining waste (mining tailings, beneficiation tailings, metallurgical residues), as part of the circular economy practices promoted and recommended by the CRMA, with exploring the potential of contained CSM resources, based on the UNFC classification system.

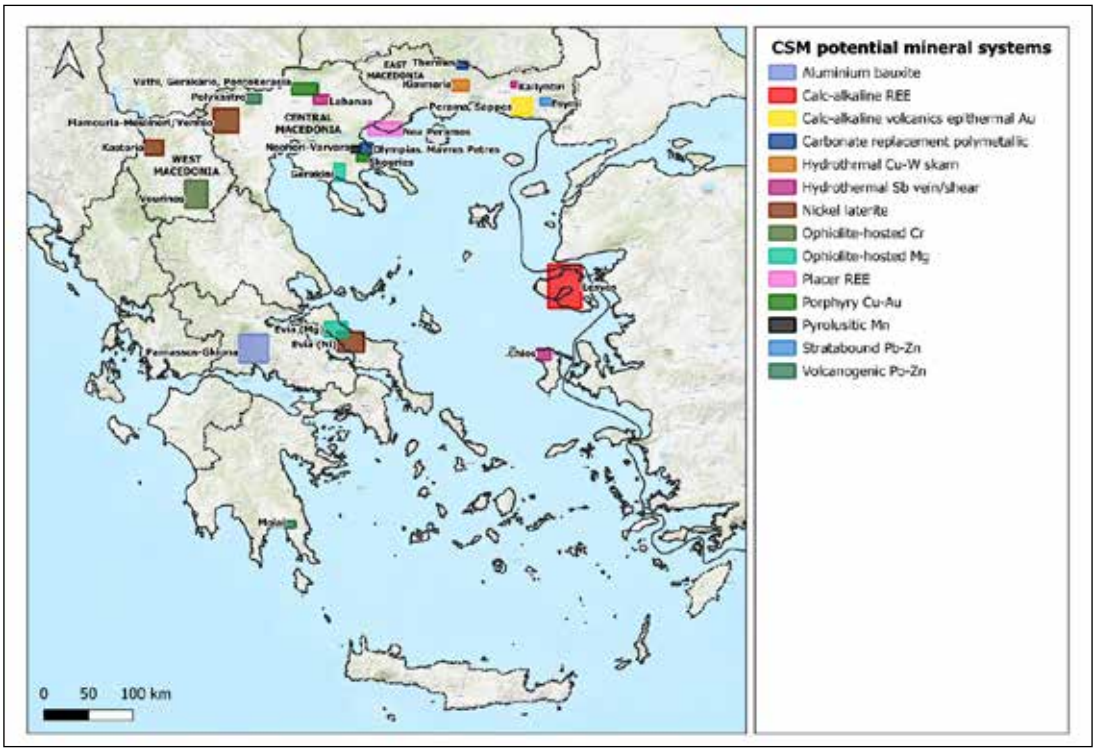

Figure 2. Map showing CSM potential mineral systems in Greece.

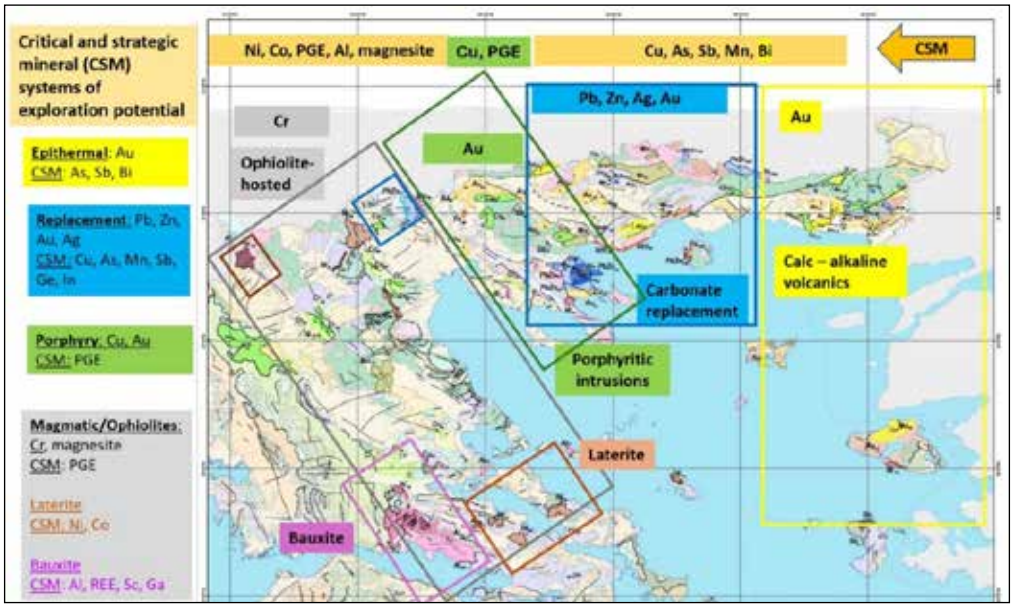

Figure 3. Mineral systems of CSM exploration potential in central and northern Greece.

- greenfields where the regional geology and lithological features justify conducting further economic geology approaches and exploration to target CSMs. For example, monazitic concentrations of REE have been identified in the coastal area of Nea Peramos. Exploring the granitic country rocks is necessary since they may be the sources of the REE found in the monazitic sands. The volcanic rocks in the NW part of Lesvos are found in the western extension of the Mesozoic-Cenozoic REE belt (Goodenough, et al., 2016) where a Turkish REE mineralisation was also made known. The REE geochemistry of these alkaline volcanics needs to be further explored. As far as lithium is concerned, several European Geological Surveys are exploring its potential in pegmatites. That could also be the case for the Greek pegmatites, particularly the ones of magmatic origin.

High-priority CSM exploration projects in Greece

Porphyry copper mineral systems. The project aims to explore economic geology and the feasibility of exploiting the porphyry copper mineralisations in Kilkis County's Pontokerasia, Vathi, Gerakario, and Mylohori areas (Apostolou and Stefanidis, 1987; Tsamadouridis, 1982; Drougas et al., 1981; Arvanitidis, 2010; Kelepertsis et al., 1986). The demand for strategic copper will increase rapidly and its price will follow the same upward trend, due to its use in energy transition technologies. Important copper resources can be found in Greece, such as Skouries, where mining is about to start. These developments are a motivation and an opportunity to highlight the CSM value of other porphyry copper-gold mineral systems, as they are in Pontokerasia, Vathi, Gerakario, and Mylohori. The resource potential is estimated at over 80 million tons, with typical grades of 0.30% copper and 0.8 grams/ton of gold. Porphyry copper systems typically develop a cylindrical structure, sometimes in the form of an inverted cone, and extend to an average depth of 2000 meters, with 1000 meters being a feasible exploration target.

Carbonate-replacement and VMS polymetallic sulfide minerals systems. The project addresses the economic geology and ore feasibility of Polykastro, Mavro Dendro, and Thermes base metal deposits, focused on the CSMs of copper, tungsten, germanium, and indium. The Polykastro mineral deposit, in Kilkis County, has an estimated resource of 4.7 million tons with about 6 % zinc and lead together, while the corresponding potential resources were estimated at 12 million tons. New exploration efforts will target deeper-seated copper mineralisation. In the neighboring area, the porphyry style Mavro Dendro deposit, amounts 4.8 million tons with 0.25% molybdenum and increased contents of copper and tungsten were

identified. In Thermes, in the County of Xanthi, there are confirmed 5.1 million tons with 6.9% zinc and lead, and 28 grams/ton of silver. In the same area, a graphite reserve of 400,000 tons with a content of 6% is found.

Manganese mineral systems. Previous exploration in Neohori and Varvara, including drilling, resulted in an estimated 1.5 million tons with 25-30% of pyrolusitic manganese, suitable for batteries. These mineralisations are found in the western part of the Stratoni fault, a regional structure known for its polymetallic sulfide minerals underlying iron-manganese oxidations. Characteristic examples of the Stratoni fault-controlled structural link between manganese oxides and base metal sulfides, as they move from shallower to deeper levels, are the Mavres Petres sulfide ore deposit in the eastern part of the fault and the Piavitsa sulfide mineralisation in the middle part.

Base and precious mineral sulfide systems. This project will target further exploration of several prospects of the County of Evros, in the Thrace region, which have been studied for lead, zinc, molybdenum, silver, and gold, including beneficiation testing. The potential occurrence of the CSMs of copper and bismuth will be in focus. Characteristic examples are the Esymi base metal deposit with 14 million tons of 6% zinc, and the adjacent Myli copper mineralisation. Excellent examples of feasible epithermal gold mineral systems are the ore deposits at Perama and Sappes.

Lateritic nickel mineral systems. The project will address the economic geology and exploitation potential of the lateritic nickel mineralisation in the Flamouria and Mesimeri areas of the prefecture of Pella. According to recent estimates (Source: Raw Materials Group, Future Mine & Mineral), global demand for stainless steel will continue to grow, with a projected increase of over 90% during the period 2021-2050. This is predicted to increase demand for nickel over the same period, by over 115%. Electric vehicles, which weren't on investors' radars in the early 2000s, are the new price engine for the anticipated nickel booms this time. Greece has a long-standing relationship with nickel mining production in LARCO's mining centers in Evia, Viotia, and Kastoria. Strategic nickel exploration was carried out in the Flamouria and Mesimeri areas, estimating a resource potential of over 1.5 million tons with approximately 0.9% Ni and 0.04% Co. Since cobalt and nickel are both now CSMs and the mineralisations are open downward geologically, more exploration is required. It should be noted that the need for deposits with high nickel grades has been greatly lowered by using hydrometallurgy rather than pyrometallurgy.

These selected exploration projects will contribute to access to increase the CSMs resource potential in Greece and the EU, as the CRMA targets, and to enable shortening the current timelines, to take no more than 27 months for mining licenses and 15 months for processing and recycling licenses.

EXTENDED ABSTRACT 017

Assessing the effect of 2023 Evros Wildfire: a new Post-Fire Rockfall Hazard System

Asteriou P.[1], Sotiriadis D.[1], Petala E.[1], Kazelis L.[1], Klimis N.[1]

(1) Democritus University of Thrace, Civil Engineering Dpt. Xanthi, Greece, pasterio@civil.duth.gr

This paper proposes a risk and hazard assessment system for rockfalls in fire-affected areas. The system has the ability to efficiently prioritize hazardous sites and evaluate post-fire rockfall risks, supporting rapid decision-making for mitigation actions.

Introduction

The Evros forest fire in August 2023 burned more than 90,000 hectares, making it the largest wildfire ever recorded on European soil since 2000. During the two-day period of August 21–23, the fire spread at an explosive rate, growing from approximately 8,500 hectares on August 21 to over 65,000 hectares by August 23, accounting for 60% of the total burned area. The explosive growth of the wildfire was driven by extremely dry atmospheric conditions during the incident and the prolonged drought that had affected the broader region in the preceding months. These factors led to exceptionally low moisture levels in the forest material, significantly facilitating the rapid spread of the fire.

Wildfires cause significant economic and social impacts, as they result in severe damage to infrastructure, area evacuations, livestock and wild animals, crops, farmlands, human lives and are associated with serious ecological consequences (Cunningham et al., 2024). Beyond the immediate effects of a wildfire, other natural phenomena and extreme events may arise. Wildfires can increase the susceptibility, frequency, magnitude, and area of influence of geohazards such as shallow landslides, rockfalls, debris flows, and soil erosion, triggering a destructive chain reaction with adverse consequences (Vahedifard et al., 2024). The occurrence of rockfalls depends on various factors related both to the slope, such as its gradient, geology, weathering, and vegetation, as well as, external factors, including climate, seismic activity, and exposure to human activities (Scheidl et al., 2020).

When a block detaches above a forested area, its movement will be constrained due to the impacts with the tree trunks. However, the destruction of vegetation, following a wildfire, cancels out this benefit. As a result, the block's travel distance is extended, and the severity of the impact increases. Consequently, the effects of a rockfall become more pronounced, posing a hidden threat to the safety of the exposed activities. The presence of vegetation makes the implementation of protective measures more cost-effective or even unnecessary (Scheidl et al., 2020). According to Moos et al. (2017), it has been found that protective forests can reduce the occurrence of rockfalls by up to 90% and their intensity by up to 70%, depending on variations in parameters such as the forest coverage, tree density and diameter, trunk arrangement, and the volume of the falling blocks. An overview of the current scientific knowledge and practical methods for addressing rockfall hazards in forested slopes can be found in Stoffel et al. (2006), Dorren et al. (2007), and others.

Recent studies report an increase in rockfall activity during and after wildfires (e.g., DeGraff et al., 2015; Perez-Rey et al., 2023). A combination of factors affects both the detachment areas and the propagation zones. Such factors include changes in the mechanical properties of the rocks and their fragmentation due to the high temperatures, the loss of vegetation's protective capacity, the impact of firefighting activities, and/or the destruction of existing protective measures (Sarro et al., 2021; Perez-Rey et al., 2023).

Objectives

The impacts of climate change, including rising temperatures and severe droughts, have intensified the occurrence of wildfires globally, leading to increased frequency, severity, and extent (Liu et al., 2010). Consequently, higher rockfall activity in burnt areas is expected, even in locations previously deemed safe due to vegetation. Thus, the objectives of this study are:

- Develop a user-friendly rockfall risk assessment system that accounts for the effects of wildfires. The system is designed to serve as a quick and efficient decision-support tool for identifying vulnerable locations.
- Apply the system to the area affected by the 2023 Evros wildfire, with the goal of identifying prone areas

and prioritizing them to facilitate decision-making regarding the restoration strategy, contributing to the area's restoration process.

Rockfall risk-hazard rating system

Ferrari et al. (2016) highlight the need for effective risk management by conducting a comprehensive review of existing methodologies for rockfall hazard and risk assessment. These methodologies are categorized into two main types: qualitative and quantitative. Qualitative methods rely on descriptive or classified criteria, requiring fewer data and allowing for quicker application, making them suitable for preliminary assessments or areas with limited data. In contrast, quantitative approaches involve numerical calculations and probability estimates, offering higher accuracy but demanding extensive data, complex models, and higher costs. When sufficient data are available, quantitative methods are preferred for detailed analyses of specific locations.

Classification Systems are widely used qualitative methods, that classify slopes based on their characteristic parameters. They have proven particularly effective for road networks, where slopes are evaluated to prioritize mitigation measures. The primary advantages of qualitative methods over quantitative ones are their cost-effectiveness and flexibility, enabling rapid hazard assessments across large areas. Their value lies in identifying high-risk zones that require further analysis. However, their main drawbacks are subjectivity and lack of precision.

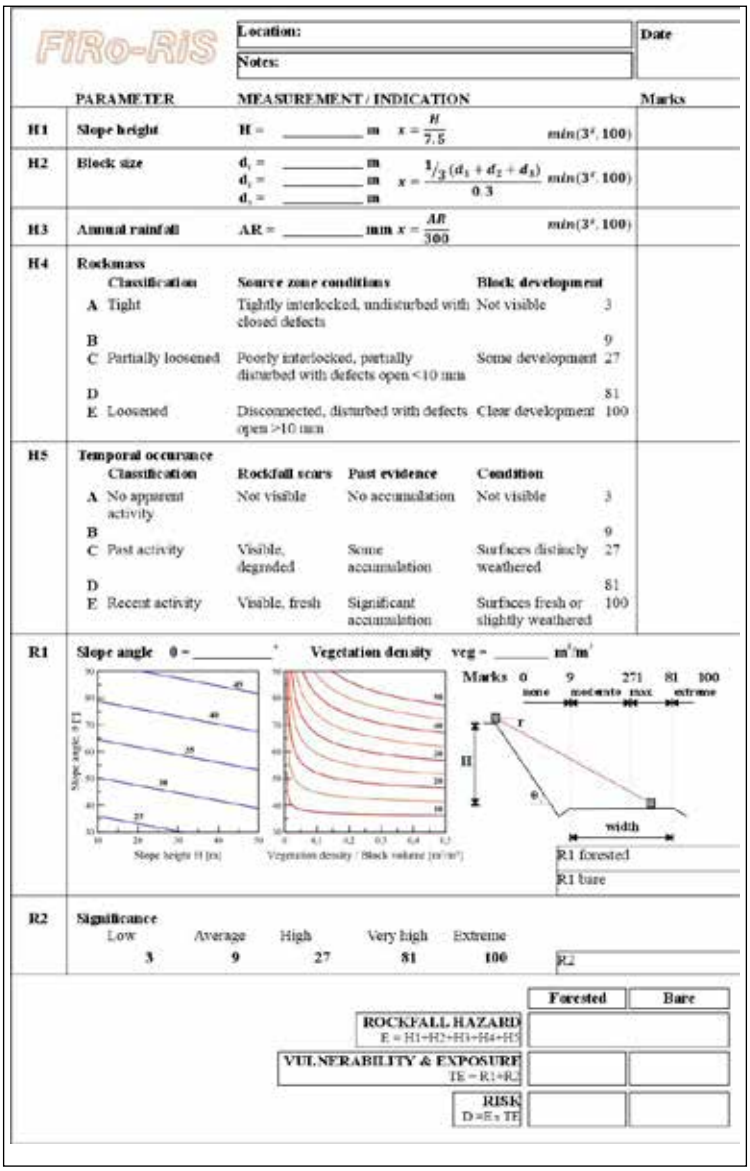
The most popular hazard assessment system is the Rockfall Hazard Rating System (RHRS), developed in the late 1980s by the Oregon Department of Transportation (Pierson, 1992) as a standardized tool for assessing and prioritizing rockfall risks along roadways. Each slope section is rated based on factors influencing rockfall risk, such as slope height, ditch effectiveness, average traffic exposure, sight distance, road width, geological conditions, and rock fragment size. These parameters are rated on an exponential scale ranging from 3 to 81 points, depending on the severity of the risk. The original RHRS has been adapted to various regions to address local geological, climatic conditions, and infrastructure needs. These adaptations often involve modifications to rating criteria and the inclusion of additional parameters to enhance accuracy under specific site conditions. Examples include customized systems tailored to regional requirements, such as mRHRs (Budetta, 2004), the proposition of Saroglou et al. (2012) for Monemvasia, Greece, and others.

The precise assessment of rockfall hazard involves evaluating: a) susceptibility; b) magnitude; c) intensity; d) potential runout area; and e) frequency of rockfalls. Susceptibility is determined by the rock mass properties and possible factors that may weaken it. Magnitude refers to the size (volume) of the detached rock blocks, while intensity relates to the kinetic energy of the trajectory. Although precise intensity is typically calculated through simulations, it can be estimated indirectly in a hazard-risk assessment system by considering the maximum height from which a block can detach. Similarly, the potential runout area is often determined via trajectory simulation, but simpler parameters such as slope height and angle can also be used for estimation. Finally, frequency is rarely based on detailed data; instead, it is typically inferred from general information and field observations that indicate recent activity, such as rock block at the slope base, impact marks on the slope face, or damage to the roadway.

For the development of the rockfall hazard-risk assessment system (Figure 1) for the area affected by 2023 Evros wildfire, the aim was to include the essential parameters without requiring time-consuming procedures during field surveys. Following this approach and after reviewing existing systems in the literature, seven parameters were selected, all of which can be measured or estimated through on-site observations. Five of these parameters are related to the hazard (H) of the slope, while the remaining two are related to exposure and vulnerability (R).

Rating for all parameters follows an exponential scale, consistent with the original system proposed by Pierson (1992), but have been modified to have a maximum value of 100. The parameters H1 (slope height), H2 (block size), and H3 (rainfall height) are derived from the original RHRS, while the parameters H4 (rock mass condition) and H5 (rockfall frequency) are based on the proposal by Eggers et al. (2021). To calculate the total rockfall hazard (E), the scores of each H parameter are summed.

To assess risk, in addition to hazard, it is essential to determine and rate exposure and vulnerability. Parameter R1 is determined from measurements made during the field survey along with a correlation of reach angle that considers the influencing parameters and was developed for this study. It is worth noting that for calculating the score of the R1 parameter, vulnerability factors of the infrastructure are considered, such as road width, and exposure is also assessed using the reach angle concept. Therefore, the R1 parameter is a combination of both vulnerability and



exposure.

Reach angle (r) is defined as the angle formed by the horizon and the line that connects the detachment position and the furthest trajectory endpoint. As demonstrated from a detailed site-specific study in Avantas settlement, that was severely affected by the 2023 Evros wildfire (Asteriou et al., 2024), the parameters influencing reach angle are: a) slope height; b) slope angle; c) vegetation density; and d) block size. To estimate the potential area affected by rockfalls, parametric analyses were conducted using RocFall2 by varying those parameters within their typical range for the broader study area. Table 1 presents the values used in the analyses, which combined result to a total of 216 analyses.

Table 1. Parameters and their discrete values used in parametric analysis.

Parameter	Discrete values
Slope height, H [m]	15, 30, 45
Slope angle, θ [°]	45, 60, 75
Vegetation density, ρ [m²/m²]	0, 0.01, 0.03, 0.05
Block volume, V [m³]	0.01, 0.05, 0.1, 0.25, 0.5, 1.0

Figure 1. The proposed Post-fire Rockfall Hazard-Risk Assessment System, FiRo-RiS.

Reach angle (r) was divided into two components: a) the basic reach angle (r_{bas}), which depends on the slope height and slope angle (without vegetation), and b) the surplus reach angle (r_{sur}), which depends on the block size and vegetation density. This allows for directly identifying the impact of vegetation loss due to a wildfire on the trajectory length, which affects the exposure. Before a wildfire, the reach angle (r) is the sum of these components. After the wildfire, the reach angle equals the basic reach angle, since the vegetation has been destroyed.

Utilizing the results of the parametric analyses conducted without the vegetation (bare slope), the basic reach angle (r_{bas}) is correlated with the slope height (H) and the slope angle (θ). The additional effect of vegetation on reach angle is correlated with the vegetation density (ρ), expressed as the total area of stems at breast height per square meter, the block volume (V), and the slope angle (θ). These correlations are embedded in the developed hazard-risk system (Figure 1) as nomographs.

Through the reach angle and the slope height, the runout distance or exposure is calculated. Parameter R1 is rated depending on the position that is influenced by the incident. In case that a road is affected, the following cases are discerned: a) the falling block does not reach the road, so no consequences are expected (R1 = 0); b) the falling block reaches the road but leaves a free width of 3 m width, allowing vehicle movement, thus the road maintains serviceability (R= 9 to 27, depending on the unaffected width); c) the falling block affects the entire road cross-section, resulting in maximum consequences (R1 = 81); and d) .the falling block exceeds the road area and threatens additional infrastructure, having extreme consequences (R1 = 100). The consequences are considered extreme (R1=100) when a resident or a facility is located within the rockfall propagation zone.

The R2 parameter refers to the significance of the potential impacts. It has a subjective nature and is based on the importance of exposed elements from a socio-economic perspective. For example, when the main infrastructure affected is the road network, criteria for assessing its importance could include daily traffic volume, the presence of alternative routes, or others.

The sum of the individual scores for the R1 and R2 parameters gives the total score for the combination of vulnerability and exposure, according to TE = R1 + R2. The final risk score is calculated as the product of the total hazard score and the total vulnerability-exposure score, according to $D = E \times TE$. To avoid excessively large values, the total scores of E and TE are normalized by dividing them to their maximum possible scores, which are 500 and 200, respectively. The proposed system is named FiRo-RiS, derived from the initials of the words Fire Rockfall Risk System.

Application to the area affected by the 2023 Evros Wildfire

The developed Rockfall Hazard-Risk System FiRo-RiS was applied to the area of Evros that was severely affected by the devastating wildfire (see Figures 2 to 4), during an on-site inspection carried out between September 16–18, 2024. The surveyed routes included the mountainous road network and settlements that were impacted by the wildfire. Along these routes, 36 slopes were identified and examined.

Figure 2 presents the hazard map of the examined locations, as derived from the normalized score, E_{norm}. The five classes of the E_{norm} were obtained by applying the Jenks algorithm (Jenks, 1968), according to which the classes are designed to minimize the standard deviation of the scores within the same class, while maximizing the distances between the central values of the classes. Since the system has a comparative character between the slopes examined, each class is given a qualitative description as follows: a) Low; b) Moderate; c) High; d) Very High; and e) Extreme, respectively.

The impact of vegetation loss is highlighted through the comparison of the maps in Figures 3 and 4, which show the distribution of the total risk score before and after the wildfire. It is noteworthy that before the fire, the majority of the locations (61%) were characterized by ‘Low’ risk, with the remaining classes occupying 6%, 14%, 5%, and 14% of the examined slopes, respectively. After the loss of vegetation, there is a significant decrease in the number of locations classified as ‘Low’ risk (19%), and a notable increase in the number of locations categorized as ‘Moderate’ risk (39%). For the ‘High’, ‘Very High’, and ‘Extreme’ risk classes, there is a slight increase, reaching percentages of 17%, 8%, and 17%, respectively.

Figure 2. Normalized hazard map of the investigated area.

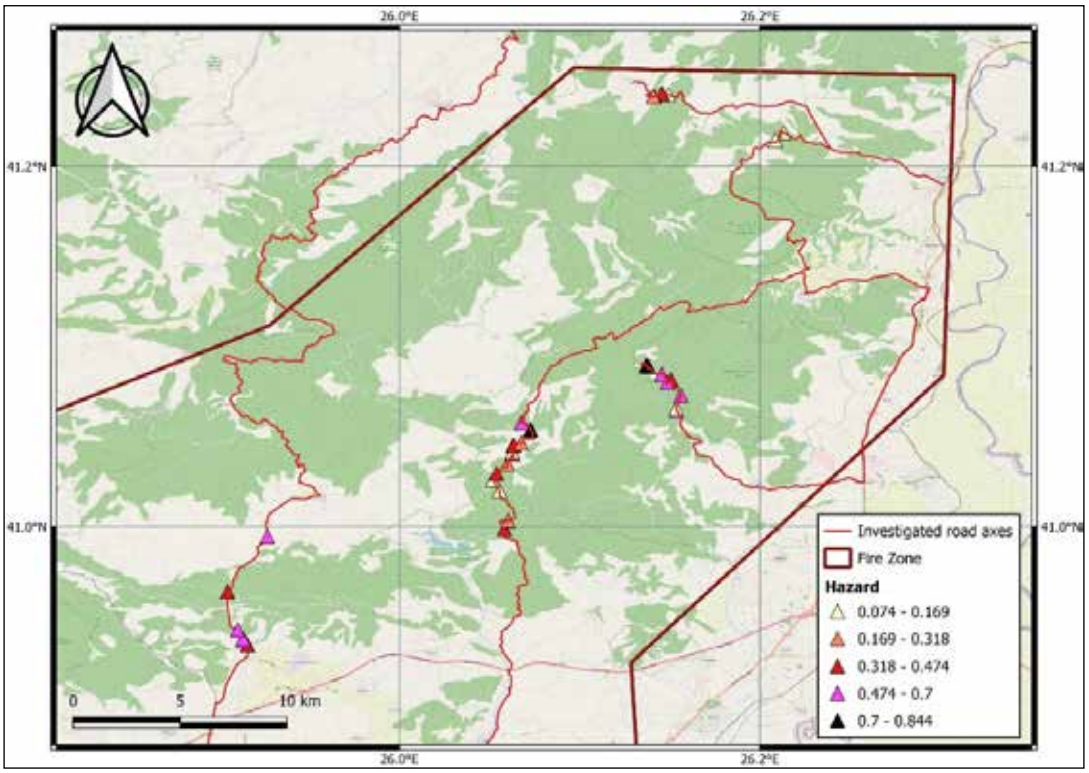


Figure 3. Normalized risk map before the wildfire of the investigated area.

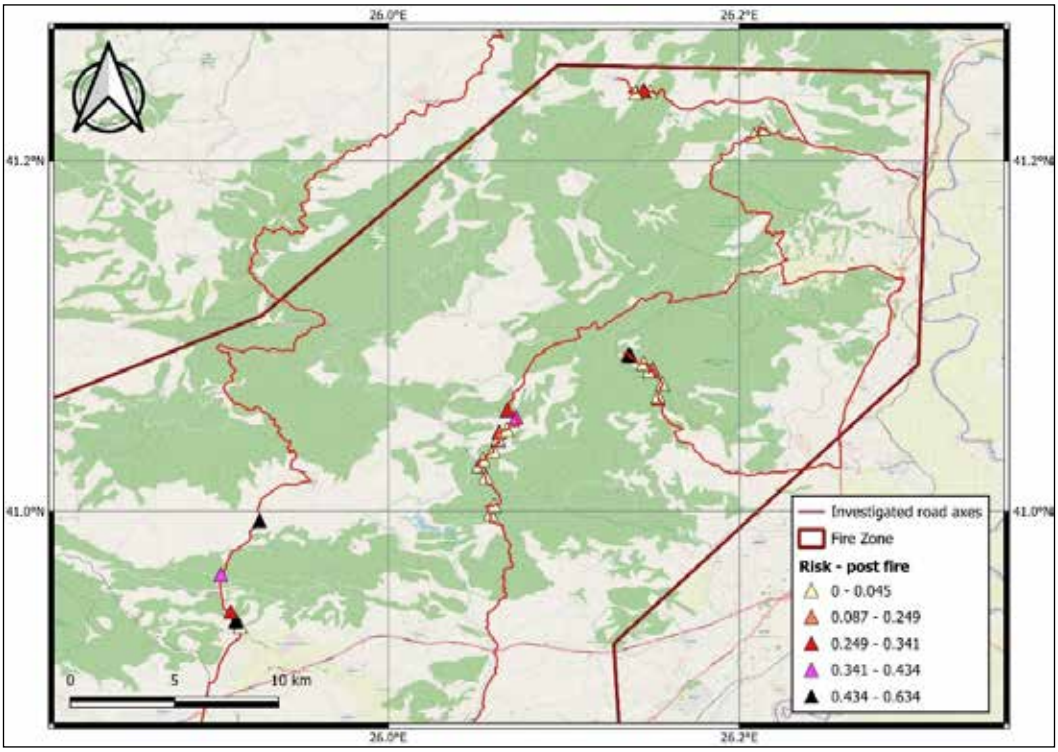

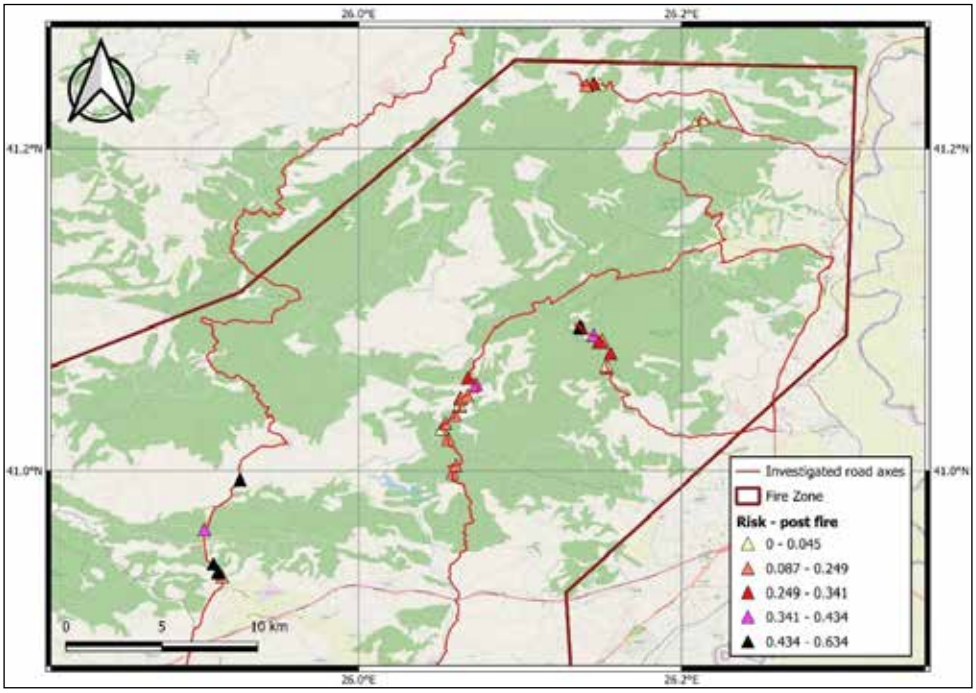

Figure 4. Normalized risk map after the wildfire of the investigated area..

Conclusions and Discussion

The FiRo-RiS (Fire Rockfall Risk System) was developed and successfully applied to the wildfire-affected region of Evros. By incorporating critical parameters from existing international methodologies and introducing modifications to account for the impacts of vegetation loss, the system provides an efficient and systematic approach for assessing rockfall hazard and risk. The system includes factors that consider susceptibility (via geological characterization of the rockmass), magnitude, intensity (through parameters such as block size and slope height), frequency of occurrence, and potential extent (through the calculation of the reach angle). The results demonstrate the system's utility in identifying high-risk sites and prioritizing them for mitigation actions, offering a practical decision-support tool for infrastructure managers and local authorities.

A key innovation of FiRo-RiS lies in its ability to quantify the impact of wildfire-induced vegetation loss on exposure and risk, a feature that addresses a growing concern in regions increasingly affected by climate change. By combining quantitative and qualitative evaluations, the system is both robust and user-friendly. Furthermore, the system can be adapted to diverse geomorphological and environmental conditions.

Despite its strengths, the proposed system has limitations, as is the case with any such system. It relies on predefined parameters that may not fully capture complex geological settings. Some criteria are based on empirical formulas derived from site-specific data. Additionally, the inclusion of subjective parameters, such as the socio-economic impact assessment, introduces variability in risk evaluations depending on the user's perspective. However, when the system is implemented by the same user, ensuring consistency and comparative evaluation of the sites, the ranking of locations remains reliable.

(3) SUPCO - sustainable urban planning consultants, Thessalonikis 121, 18346 Moschato, Attica, Greece.

Research Highlights

- DInSAR analysis of Sentinel-1 data reveals significant coseismic deformation between Santorini and Amorgos, with uplift in South Thira (+2.1 cm) and subsidence near Oia (-2.8 cm), paired with a horizontal distancing trend between Thirasia (-2.7 cm), Nea Kameni (-1.5 cm) and Oia (+4.0).
- Amorgos and Anafi show westward displacement (-4.0 cm, -2.3 cm), indicating active faulting.

Abstract

The region between Santorini and Amorgos is seismically active and recently has seen a noticeable increase in earthquake frequency, causing significant tectonic deformation linked to active faulting and, potentially, magmatic processes. This extended abstract focuses on the analysis of the coseismic displacement components of Santorini, South Ios, Anafi and Amorgos islands, using Sentinel-1 satellite data and the DInSAR (Differential Interferometric Synthetic Aperture Radar) method, which revealed noteworthy vertical (up-down) and horizontal (E-W) ground displacement. Results indicate uplift in South Thira (+2.1 cm), subsidence near Oia (-2.8 cm), and significant east-west displacement in Santorini, where Thirasia, Nea Kameni and Oia seem to move away from each other. SW and NE Amorgos show a significant westward motion (-4.0 cm in Kalofana, -3.5 cm in Aigiali), while Anafi and Ios exhibit localized subsidence and uplift. These findings seem to reference ongoing fault activity and strain accumulation, presenting the need for continued monitoring of the seismically active area.

Key words: Santorini, Amorgos, earthquake, coseismic displacement, DInSAR, Sentinel-1.

Introduction / Background

Greece and the islands of the South Aegean sea particularly are no strangers to seismic activity, due to their proximity to the Hellenic subduction zone of the African plate moving at a pace of ~ 0.9 cm/year under the Aegean plate (Reilinger et al., 2006; McClusky et al., 2000; Andinisari et al., 2021; Krassakis, 2024). For a long time, the South Aegean Islands, such as Santorini, Amorgos, Anafi, and Ios have been the focus of seismological studies, due to the complex tectonic setting and frequent seismic activity in the region between Santorini and Amorgos. More specifically, in the shear zone found NE of Santorini and NW of Amorgos, known as the Santorini-Amorgos Fault Zone (Tsampouraki-Kraounaki et al., 2021), a large number of significant earthquakes has been recorded, some reaching Mw > 5.0 (Nomikou et al., 2016; Andinisari et al., 2021). Such a seismic occurrence, arguably one of the most important events in the region were the twin earthquakes, M 7.8 and 7.2, of 1956, which caused a lethal tsunami 20 m in height (Nomikou et al., 2016; Andinisari et al., 2021).

In recent weeks, Santorini Island and the surrounding region (Figure 1) have experienced a series of earthquakes, with magnitudes reaching up to M 5.3 (10/2/2025). Most of the seismic activity is occurring approximately 25 km northeast of the Santorini complex, near Anydros, at an average depth of about 7 km beneath the seabed. Seismic activity has been gradually increasing since June 2024, with a notable surge in the first weeks of February. Initially, the earthquakes were centered around the Santorini caldera,

but their epicenters have gradually migrated northeast toward Amorgos, specifically around the small, uninhabited islet of Anydros.

The threat that earthquakes and other natural disasters pose have led to significant advancements in the field of remote sensing throughout the years, in an effort to study these events and their deformation effects more effectively. Specifically, techniques utilizing Synthetic Aperture Radar (SAR) satellite images, such as those of the Sentinel-1 mission of the European Space Agency's (ESA) Copernicus program, have been extremely reliable in the study of earthquake-induced deformation (Wright et al., 2004; Suresh & Yarrakula, 2019; Li et al., 2021). More particularly, the method of Differential SAR Interferometry (DInSAR) has been extensively utilized to estimate ground displacement due to earthquakes, using the phase difference between pre and post event images (Wright et al., 2004; Suresh & Yarrakula, 2019; Li et al., 2021).

In this research, the impact of the early 2025 earthquake swarm on the islands of Santorini, Amorgos, Anafi and South Ios was studied using Sentinel-1 SAR data and the DInSAR method. Via differential interferometry, the Line-of-Sight (LOS) displacement of the four islands was estimated and then analyzed into vertical (up-down) and horizontal (E-W) displacement components.

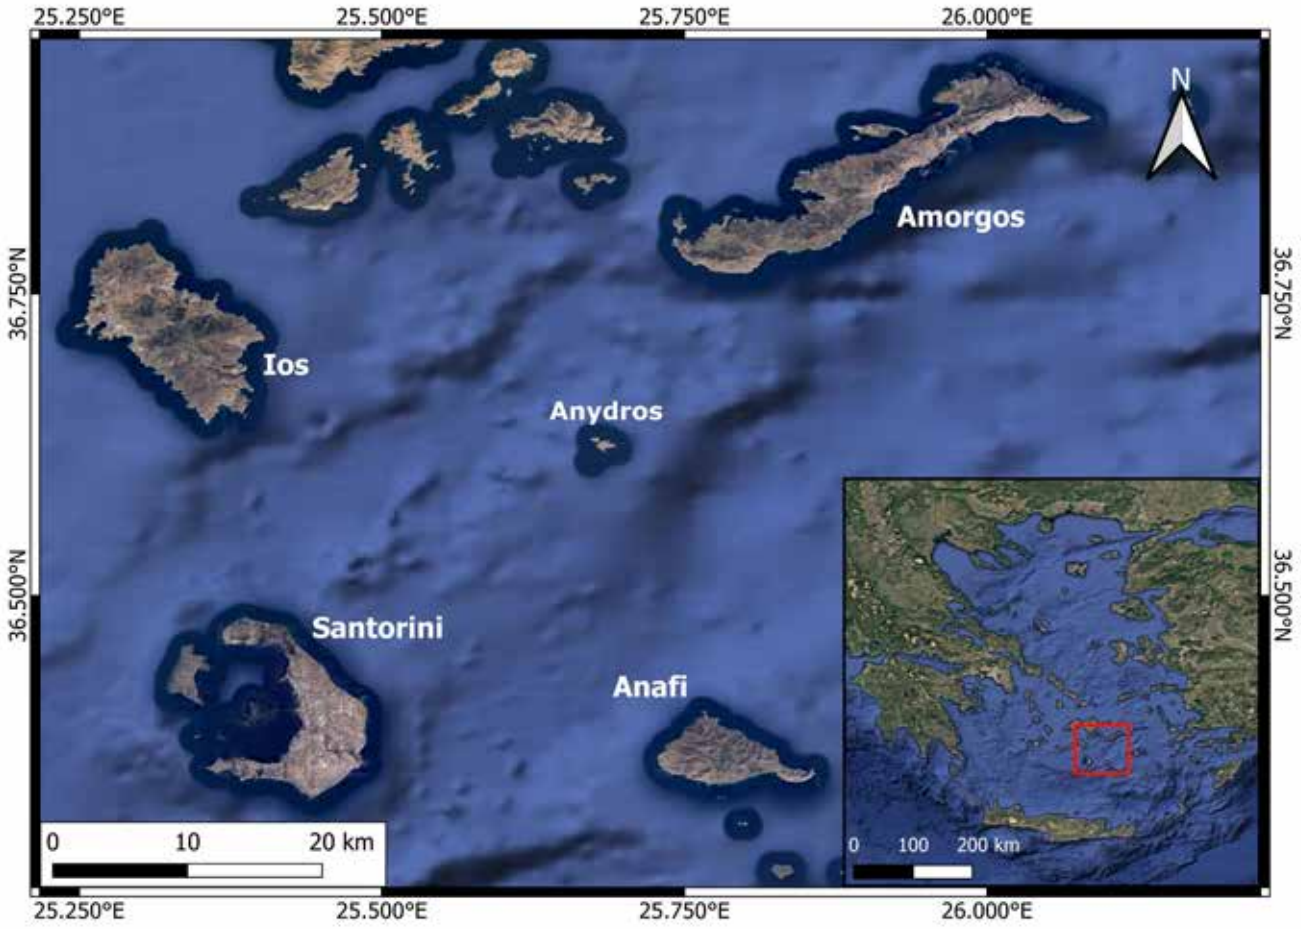

Figure 1. Study area map in QGIS v3.28.1 using the Google Satellite basemap based on Google Earth Pro. Projection: WGS84. (After Athinelis).

Data & Methodology

To study the deformation caused by the recent earthquake in the area around Anydros Island and its effects on the close islands, D-InSAR (Differential Interferometric Synthetic Aperture Radar) was utilized.

InSAR has gained widespread recognition for monitoring surface deformation, due to its many benefits (Calvet et al., 2023). SAR images were utilized for this study, obtained from the Copernicus Data Space Ecosystem browser (Copernicus Data Space Ecosystem). The time-frame studied in this research was of the seismicity during the transitional period from January 2025 to early February 2025, especially between 30/01/2025 and 05/02/2025. As such, the SAR images selected were covering this time-period while having the least time-difference possible. Specifically, a pre-event image on 30/01/2025 and a post-event image on 11/02/2025 were used for the ascending orbit pass and a pre-event image on 24/01/2025 and a post-event image on 05/02/2025 were acquired for the descending orbit pass. The Level-1 Single Look Complex (SLC) Interferometric Wide Swath (IW) data products from the Sentinel-1 are derived from the satellite's C-band SAR C-SAR instrument with a wavelength of approximately 5.5 cm (Kotzerke et al. 2022). The ESA STEP Sentinel Application Platform (SNAP v11.0) software was utilized for the process (ESA). Two pairs of Sentinel-1 IW SLC images were used in this research, for ascending and descending orbits respectively.

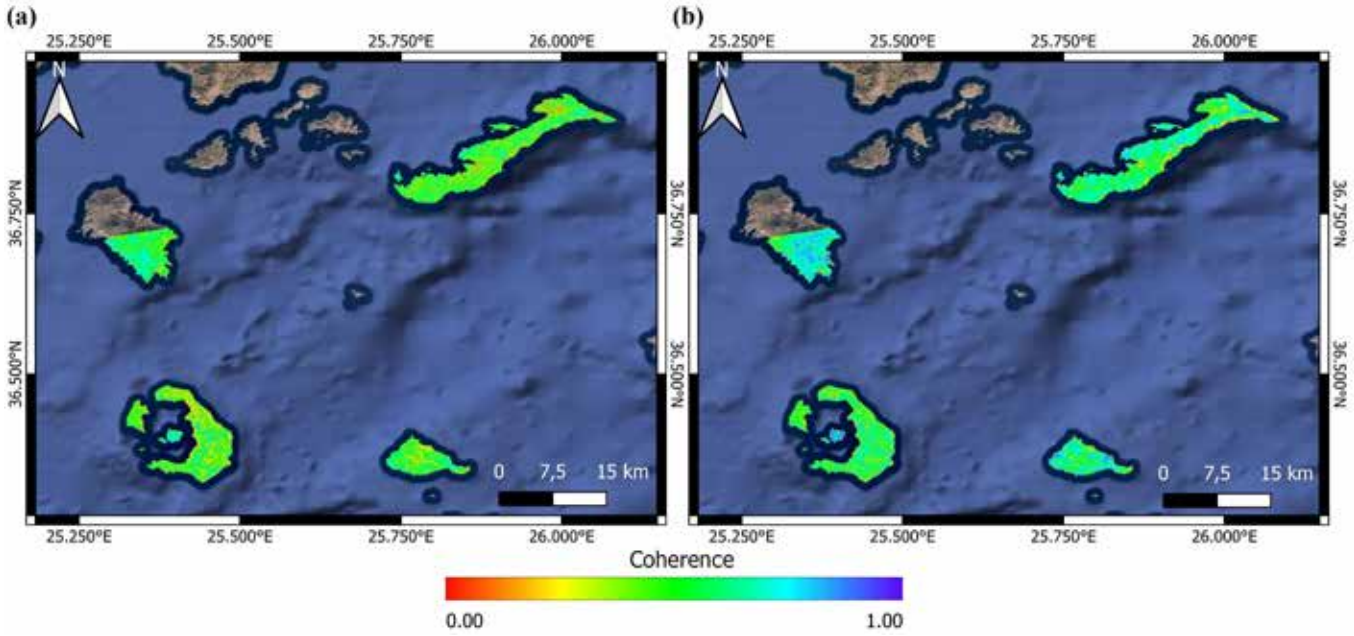

Figure 2. Coherence maps of the studied islands in ascending (a) and descending (b) pass geometry. Made in QGIS v3.28.1 using the Google Satellite basemap based on Google Earth Pro. Projection: WGS84.

The first step is to align two SAR images—a master image and a "slave" image—into a single stack, the pixels in the "slave" image are adjusted to match those in the master image. During this process, orbit correction is applied, and a DEM is utilized with back-geocoding co-registration. In this case the SRTM 1Sec HGT DEM was used, automatically downloaded by the software. The next step involves interferogram generation and coherence estimation, where the interferometric phase and coherence (Figure 2) are computed. This was accomplished through the Interferogram Formation tool, which, unlike other software, does not require the use of a specific reference point and automatically utilizes an area of multiple points for the creation of the interferograms but has been known to provide reliable results (Mavroulis et al., 2021). The interferograms were generated by pairing the aforementioned images as seen in Table 1.

Table 1. List of the interferometric image pairs used for each island.

	Interferometric image pairs		Orbit / Frame	Baseline	
Santorini	S1A	S1A		**Perpendicular**	**Temporal**
Ascending pair	30/01/2025	11/02/2025	29 / 113	49m	12d
Descending pair	24/01/2025	05/02/2025	109 / 471	39m	12d
Amorgos					
Ascending pair	30/01/2025	11/02/2025	29 / 113	49m	12d
Descending pair	24/01/2025	05/02/2025	109 / 471	39m	12d
Anafi					
Ascending pair	30/01/2025	11/02/2025	29 / 113	49m	12d
Descending pair	24/01/2025	05/02/2025	109 / 471	39m	12d
South Ios					
Ascending pair	30/01/2025	11/02/2025	29 / 113	49m	12d
Descending pair	24/01/2025	05/02/2025	109 / 471	39m	12d

Additionally, applying TOPSAR deburst eliminates the boundary areas between consecutive bursts (Marbuti et al. 2017). Before unwrapping, the SRTM 1Sec HGT was used again to remove the topographic phase and the images were multi-looked at 6 range pixels and 2 azimuth pixels. The SNAPHU software plugin (Stanford University) was utilized for the phase unwrapping. Phase unwrapping is essential for eliminating the ambiguity associated with the multiple-wavelength factor in the interferometric phase, allowing for the determination of motion (Goldstein et al. 1998). In this stage it important to specify that no tropospheric phase delay removal was applied to these results. The unwrapped phase is converted into displacement, which is geocoded, resulting in the LOS displacement (Monterroso et al. 2018). Finally, the LOS displacement (D) of the study areas is split into two components, vertical (dz) and horizontal (de), using the incidence angle (θ) of ascending (a) and descending (d) geometries, calculated in radians and the following formulas (Manzo et al., 2006; Dalla Via et al., 2012):

$$dz = \frac{Dd \cdot \sin(\theta a) + Da \cdot \sin(\theta d)}{\sin(\theta d + \theta d)} \quad (1)$$

$$de = \frac{Dd \cdot \cos(\theta a) - Da \cdot \cos(\theta d)}{\sin(\theta d + \theta d)} \quad (2)$$

The positive values of dz signify uplifting, while the negatives are attributed to subsidence. Similarly, negative de values suggest westward displacement, while positive are of an eastward displacement. The decomposition of the deformation into vertical and horizontal displacement was performed in QGIS v.3.28.1, through Raster Calculator tool, by inserting the raster layers of the incidence angles and the LOS displacement into the formulas (1) and (2) respectively (Mavroulis et al., 2021).

Results

Analyzing the resultant vertical (up-down) deformation component (Figure 3) of the four islands a few observations can be made. Santorini (fig. 3-a) shows an upward displacement trend in the southern part of Thira island, reaching up to ~ +2.1 cm (+0.021 m). Most of the rest of the island complex seems relatively stable, while the northwestern part of the island, ESE of Oia, shows an abrupt subsidence reaching up to ~ -2.8 cm (-0.028 m). This subsidence could be related to the SW - NE trending active fault found in the same region. Despite this, the uplifting in South Thira is relatively unexpected. Uplifting can be noticed in the western edge of Anafi island (fig. 3-b), as well as the southeastern coastal areas between the Katsouni

and Roukounas beaches, reaching +0.7 - +1.0 cm. The areas of Agios Nikolaos (Saint Nikolaos) northeast of Klisidi, the area southeast of Agios Nikolaos and the easternmost part of the island present subsidence, with the first two zones reaching ~ -2.2 cm, while eastern Anafi reached ~ -2.4 cm. Amorgos (fig. 3-c) shows subsidence mainly in the northeastern edge of the island reaching up to ~ -2.7 cm. While most of the island seems stable in terms of vertical up-down displacement, a zone of ~ +1.0 cm uplifting can be seen southwest of the Amorgos settlement. In the case of South Ios (fig. 3-d), northward, near the center of the island a subsidence zone of up to ~ -2.0 cm can be seen. East of that zone, a slight uplifting trend can be viewed of about ~ +1.0 cm, while uplifting of ~ +0.5 cm is presented in Petalidi. A maximum of ~ +1.7 cm is seen in the islet of Varvaronisi, southeast of the Magganari settlement off the coast.

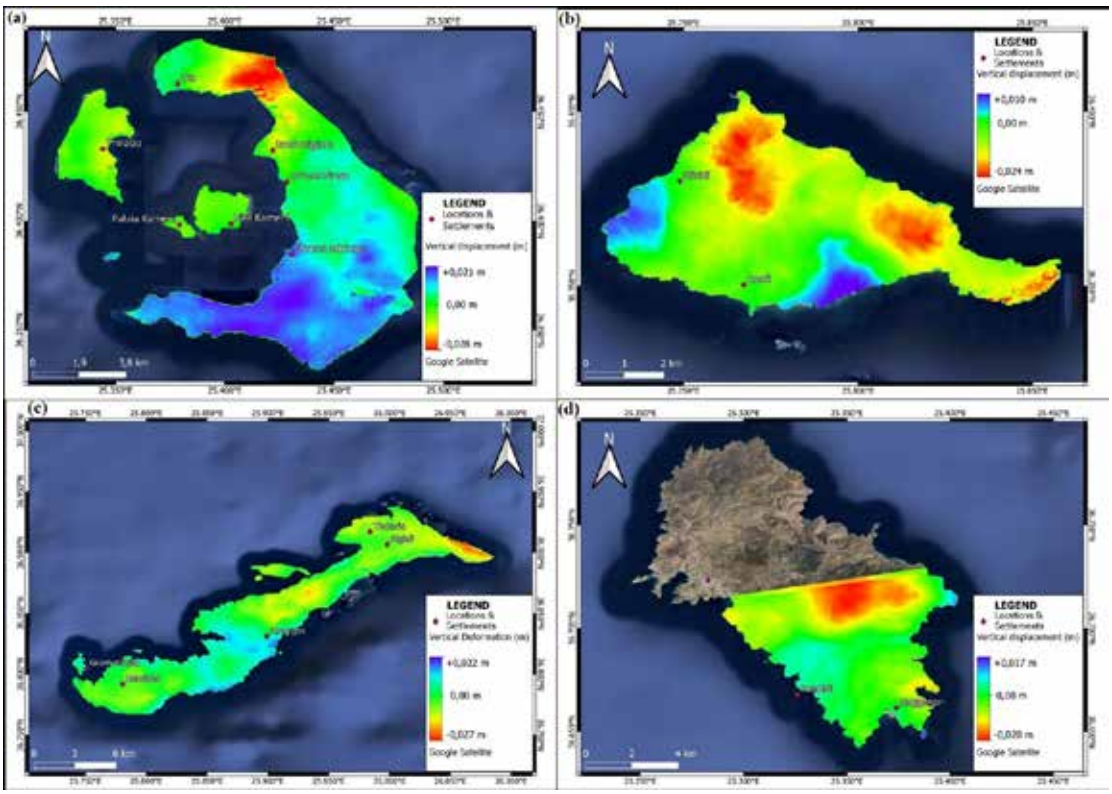

Figure 3. Interferograms showing the vertical displacement taking into account the images before and after the seismic events which happened between 24/01/2025 and 11/02/2025. The layers were overlayed on a Google Satellite basemap in QGIS v3.28.1.

The horizontal, E-W displacement of these islands (Figures 4 & 5) can also highlight some intriguing information, especially in the case of Santorini (fig 4-a). Specifically, the Thirasia island of the Santorini complex showed displacement westward at ~ -2.7 cm, while the eastern Thira island, in the Oia region, saw a significant eastward displacement of up to ~ +4.0 cm. The Nea Kameni island was displaced westward to a smaller degree of ~ -1.5 cm. In Anafi island (fig. 4-b), between the Klisidi and Anafi settlements there's a region presenting westward displacement of up to ~ -2.3 cm. The East-Southeast edge of the island presents eastward displacement of ~ +1.0 cm. Amorgos island (fig. 4-c) is particularly interesting as the entire island seems to have a mild trend westward with the SW part, in Kalofana and the NE part, east of Aigiali, presenting a more significant westward displacement of ~ -4.0 cm and ~ -3.5 cm respectively. The Gramvoussa islet shows an eastward displacement of ~ +1.3 cm. Lastly, South Ios (fig. 4-d) seems fairly stable in the E-W direction with a westward ~ -3.6 cm displacement southeast of Magganari and an eastward displacement zone of ~ +0.4 cm in the coast southeast of Ios settlement.

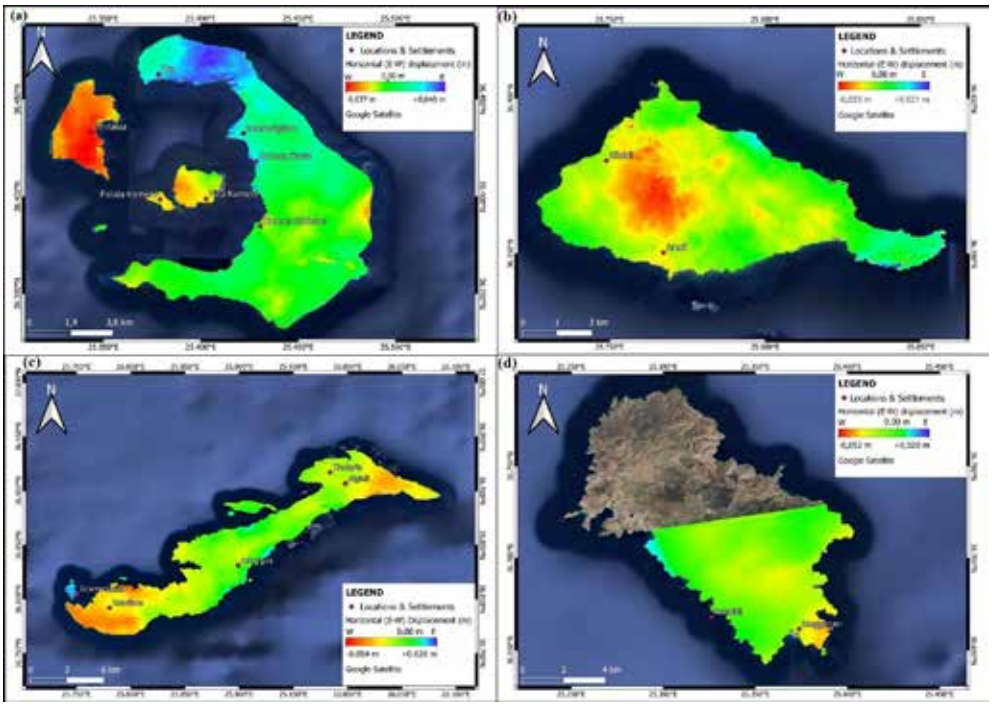

Figure 4. Interferograms showing the horizontal displacement taking into account the images before and after the seismic events which happened between 24/01/2025 and 11/02/2025. The layers were overlayed on a Google Satellite basemap in QGIS v3.28.1.

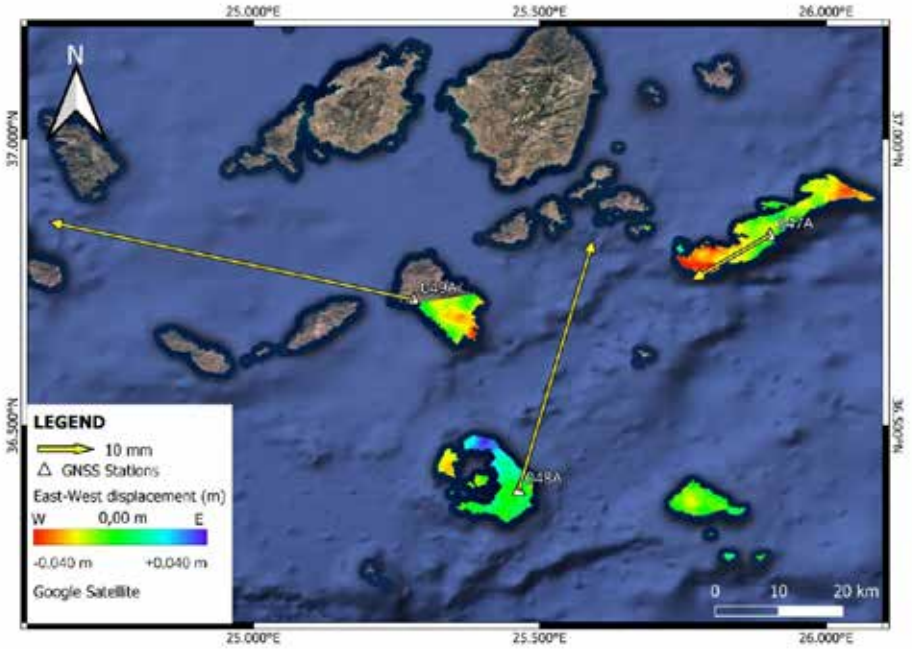

Figure 5. Horizontal shift of the South Aegean Islands shown through GNSS station data, for the period between 28/01/2025 and 20/02/2025, compared to the horizontal displacement trends of the current study. The vectors were created by the Dionysos Satellite Observatory of the National Technical University of Athens (NTUA) using data from the HEPOS GNSS station network. The layers were overlayed on a Google Satellite basemap in QGIS v3.28.1.

Conclusions

Santorini showed a spreading trend in-between the islands of Thirasia, Nea Kameni and North Thira, which were moving away from, seemingly, an underwater center. This might be caused by active tectonic and/or magmatic processes within the submerged caldera found in that region. Despite this, the uplifting trend observed in South Santorini does not seem to fit with that hypothesis and might be the result of residual atmospheric disturbances. Both Anafi and Amorgos showed significant westward displacement where, in Anafi's case, this horizontal shift seems to be due to internal stress. Moreover, uplift was noticed in western and southeastern Anafi, along with subsidence in Agios Nikolaos and the eastern island, possibly connected to similar tectonic processes. In Amorgos there was northeastern subsidence and minor uplift southwest. In the case of South Ios, the island was characterized by localized subsidence and minor uplift. The displacement in these islands does not seem to be related, necessarily, to the seismicity in Anydros, due to their geographic distribution. Overall, these trends found in the four islands studied in this research, seem to indicate ongoing fault activity and, possibly, magmatic processes, though concrete conclusions may require further research and investigation.

Acknowledgements

We would like acknowledge the contribution of Andreas Karavias (NTUA) in his support and advice during the processing phase. We also acknowledge Dionysos Satellite Observatory of NTUA for their displacement vector analysis using HEPOS GNSS data. Acknowledgements should be given to the Hellenic Cadastre, for their ownership of the HEPOS GNSS network. Moreover, we would like to thank Dr A. Ganas (National Observatory of Athens) and Prof. M. Foumelis (Aristotle University of Thessaloniki) for their help in the GNSS explanation as well as during all the crisis. Last but not least, we acknowledge ESA for openly and freely providing the Sentinel-1 satellite data of the Copernicus program through the Copernicus Data Space Ecosystem platform.

Research Highlights

- MT-InSAR processing of Sentinel-1 data unveiled significant uplifting deformation velocity in the northwestern part of the caldera, focusing in Nea Kameni, Thirasia, Imerovigli & Oia, possibly connected to swelling of the magmatic chamber due to magma accumulation.
- Increased deformation velocity was noticed past June 2024, suggesting increasing volcano-tectonic activity relating to the increased seismicity in Anydros.

Abstract

Santorini is one of the most significant islands in the South Aegean Sea and a well-known volcanic center in the South Aegean Volcanic Arc. It is known for its seismicity, caused by active volcanic and tectonic processes, such as the occurrences of 2011-2012 and 2024-2025. This study focuses on estimating the ground deformation velocity of Santorini's caldera by utilizing Multitemporal InSAR method of SBAS (Small Baseline Subset) and Sentinel-1 satellite imagery. The research found increased uplifting deformation rate in northwestern Nea Kameni and Imerovigli, up to ~ +17.6 mm/yr and ~ +17 mm/yr respectively. A lesser uplifting trend was recorded in Northwestern Thira (Oia) and Thirasia. Significant horizontal westward deformation was seen in south Thirasia and west Oia (up to -20 mm/yr) and Palaia Kameni (~ -39 mm/yr), while an eastward pattern was representing Imerovigli (up to ~ +21 mm/yr), which might signify swelling of the caldera due to magmatic and tectonic processes in the volcanic chamber. Time-series vertical and horizontal deformation diagrams attribute a more impactful effect after June of 2024.
Key words: Santorini, caldera, seismicity, ground deformation, SBAS, Sentinel-1.

Introduction / Background

Santorini (fig. 1), a prominent volcanic island complex in the Aegean Sea, is part of the South Aegean Volcanic Arc, which extends from Methana to Nisyros (Greece) (Krassakis, 2024). This arc is associated with the subduction of the African plate beneath the Eurasian plate, a process that has driven volcanic activity in the region for at least 4.7 million years (Vougioukalakis et al., 2019). The Santorini Volcanic Complex (SVC) consists of five main islands—Thira, Thirasia, Aspronisi, Palea Kameni and Nea Kameni—formed through successive eruptions, the most significant being the Minoan eruption (~1600 BCE). This event shaped the current morphology of the caldera and deposited widespread tephra layers (Vougioukalakis et al., 2019). Since then, the volcanic activity has been concentrated in the central part of the caldera, mainly at Nea Kameni, with the last eruption occurring in 1950.

The island remains an active volcanic system, experiencing recurrent unrest episodes. The most recent significant period of activity occurred between 2011 and 2012, marked by increased seismicity, ground deformation, and magmatic inflation at shallow depths (Vougioukalakis et al., 2016). During this episode, uplift reached up to 14 cm at Cape Skaros and 9 cm at Nea Kameni, as detected by geodetic techniques such as GPS and Interferometric Synthetic Aperture Radar (InSAR) (Foumelis et al., 2013). Seismicity was concentrated along the Kameni and Kolumbo fault zones, indicating a strong structural control on magma emplacement (Vougioukalakis et al., 2016). Despite these significant signals, no eruption followed, and subsequent geodetic studies from 2015 to 2021 confirmed a return to quiescence (Castro-Melgar et al., 2025).

Since June 2024, a new seismic sequence has been developing in the region, reaching its peak in a Mw 5.3 earthquake on 10 February 2025, located approximately 25 km northeast of the Santorini caldera, near the islet of Anydros, at an average depth of ~7 km. Over 7,000 earthquakes have been recorded in the broader Santorini-Amorgos area, suggesting a gradual reactivation of the regional stress field. Given the complex interplay between magmatic processes, tectonic stresses, and hydrothermal activity in Santorini, continuous geodetic monitoring is essential for understanding the current unrest. Remote sensing techniques, particularly multitemporal InSAR (MT-InSAR), offer a valuable tool for detecting and quantifying ground deformation, enabling the identification of subtle precursory signals.

Objectives

In this study, we employ Sentinel-1 imagery and the MT-InSAR method of Small BAseline Subset (SBAS) to monitor progression of the deformation rate in vertical (up-down) and horizontal (east-west) direction around the Santorini caldera from January 2023 up until February of 2025. More specifically, we aim on studying the entire development of non-linear deformation from the early 2023 rest period going into the unrest phase of late 2024 to early 2025, through the use of time-series diagrams. This approach allows for precise quantification of surface displacement patterns, offering valuable insights into the ongoing deformation dynamics of the Santorini caldera.

Methods

In recent years, MultiTemporal Interferometric Synthetic Aperture Radar (MT-InSAR) has emerged as the most effective method for detecting ground deformations and mapping potential landslides on a regional scale. This is primarily due to its cost efficiency, extensive spatial coverage, and capability to provide high-frequency and high-precision measurements of surface displacement (Zhang,2020). The interferometric processing was performed, using the GAMMA software (GAMMA Remote Sensing AG, Gümligen, Switzerland) and the SBAS technique (Berardino et al., 2002). The SBAS method is an MT-InSAR technique based on the use of multiple SAR images to estimate phase differences in time between image pairs and convert them into a pixel-based deformation time-series (Chen et al., 2024). The basis for the method is that the baseline of the interferometric pairs is smaller than the critical, thus reducing the decorrelation (Ferretti, 2014).

The study area can be characterized as peri-urban. Certain towns exhibit a high density of buildings, whereas some villages contain a comparatively lower number of structures. In the areas that the buildings

are absent, there are some objects that scatter radar signal stronger and more coherent than their surroundings. In this case, the pixel-based SBAS method was selected, which is based on DS, due to its better coverage of natural areas with less dense urban structures (Ferretti, 2014), such as the Santorini Island Complex. Moreover, this method has been found to provide more reliable results when estimated non-linear deformation (Gheorghe & Armaş, 2016; Chen et al., 2021), such as this case where both rest and unrest periods are studied in a singular dataset. The processing can be distinguished into two sub-processing stages: the pre-processing and the main processing.

The methodology for this research utilized 127 Sentinel-1 Interferometric Wide (IW) Single Look Complex (SLC) images from the Copernicus program of the European Space Agency (ESA with an orbital tube less than 100m), which were collected from the Vertex platform of the Alaska Satellite Facility Distributed Active Archive Centers (ASF DAAC).

The generation of parametric files for the 64 SLC images of ascending orbit took place during pre-processing and also the orbital refinement using precise orbits. The stack of ascending SLC images were co-registered using as reference image the scene of 12/03/2024, resulting in a stack of 186 differential interferograms. Similarly, 63 SLC descending orbit images were coregistered with the reference image of 18/03/2024 and 183 differential interferometric pairs were formed. The Shuttle Radar Topography Mission (SRTM) 1-arcsec (i.e., 30 m/pixel) Digital Elevation Model (DEM) (Farr, 2007) was used for the elimination of the topographical contribution from the interferograms. A minimum coherence threshold of 0.8 was used in this phase.

The first step in the primary SBAS processing involved the generation of a multi-reference stack, incorporating both single-look and multi-look differential interferometric phases. The differential interferograms were constructed by comparing each scene to the three consecutive scenes. The reference point was chosen near the airport area, which is regarded as the most stable on the island. After estimating height corrections and atmospheric phase delays, they were subtracted from the interferometric phase and a deformation model was produced. By repeating the final step several times, this model was improved. Ultimately, the ground deformation phases were masked based on a maximum standard deviation threshold of 1.2 for ascending and 1.3 for descending orbit and were then converted into LOS deformation time-series.

The Line-of-Sight (LOS) deformation velocity (D) of Santorini was estimated using the SBAS method. This velocity is then decomposed into vertical (dz) and horizontal (de) components by incorporating the incidence angle (θ), expressed in radians, from both ascending (a) and descending (d) acquisition geometries, following the approach of Manzo et al. (2006) and Dalla Via et al. (2012):

$$dz = \frac{Dd * sin(\theta a) + Da * sin(\theta d)}{sin(\theta d + \theta d)} \quad (1)$$

$$de = \frac{Dd * cos(\theta a) - Da * cos(\theta d)}{sin(\theta d + \theta d)} \quad (2)$$

The negative de values signify a westward displacement, while the positives are attributed to an eastward displacement. Similarly, negative dz values suggest subsidence, while positive are indicative of an uplifting trend. The corresponding results were visualized in a QGIS environment.

Results

The results of the SBAS method showed a smooth deformation pattern throughout the area, especially in the Thirasia and Oia. Particularly, the vertical (up-down) deformation component (fig. 2) suggested that Thirasia is relatively stable in this direction, with the deformation rate in the eastern part being around ~ +6 mm/yr and increasing up to ~ +9 mm/yr towards the northeastern area. Similarly, a vertical deformation rate of about +3 to +5 mm/yr was observed in the Oia region in northwestern Thira island. The most significant vertical deformation velocity was estimated in the Nea Kameni and Palaia Kameni islands, with the latter showing deformation rates in the range of ~ +6 to +8 mm/yr. Most importantly, however, Nea Kameni was represented by velocities > +10.00 mm/yr with an increasing pattern towards the northern and northwestern parts, reaching up to ~ +17.6 mm/yr. Similar deformation rates were noticed in Imerovigli with velocities exceeding +10 mm/yr up to ~ +17 mm/yr.

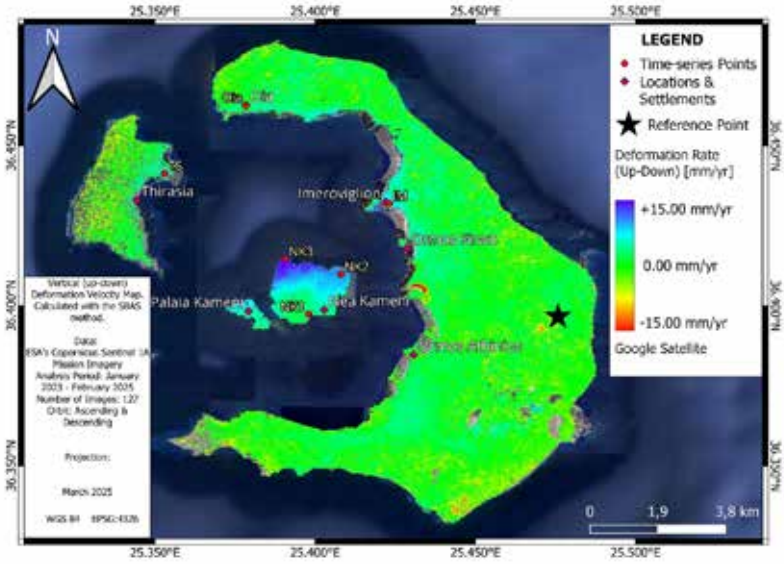

Figure 2. Vertical deformation map of Santorini using the SBAS method. Time period: January 2023 – February 2025. The layers were overlayed on a Google Satellite basemap in QGIS v3.28.1.

Analyzing the horizontal (East - West) deformation rate component (fig. 3), southern Thirasia and the northwestern edge of Thira, west of Oia, suggests a westward movement mostly between -12 to -15 mm/yr while reaching up to ~ -20 mm/yr. The remaining Thira island is dominated by a general eastward deformation, peaking in Imerovigli with velocities near ~ +7 mm/yr and even exceeding +15, up to a maximum of ~ +21 mm/yr. Palaia Kameni represents the highest horizontal deformation rate, showing significant westward displacement, mostly between -15 to -18 mm/yr, with the northern part reaching up to ~ -39. mm/yr. Juxtaposed to this, Nea Kameni seems to be rather stable in the horizontal direction with a slight westward movement of ~ -2 mm/yr.

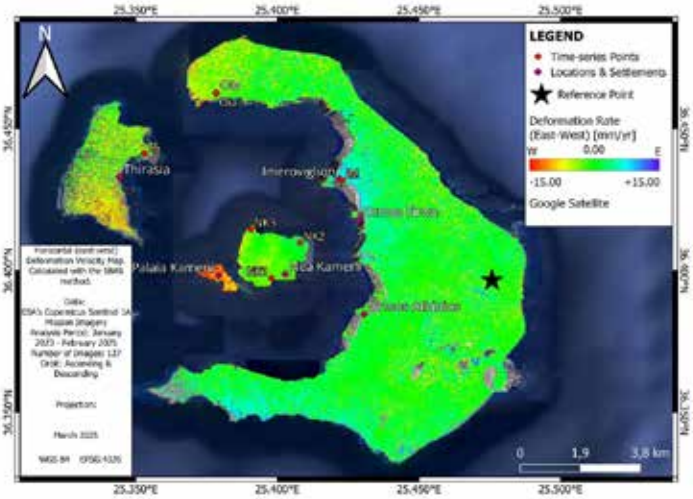

Figure 3. Vertical deformation map of Santorini using the SBAS method. Time period: January 2023 – February 2025. The layers were overlayed on a Google Satellite basemap in QGIS v3.28.1.

It is important to mention that, due to both rest and unrest phases being included in this analysis, the deformation rates calculated may be rather underestimated, as the deformation of both periods is averaged. As such, in order to better comprehend the progression of the deformation in the caldera, it is required that the deformation trend is thoroughly observed through the multitemporal time-series diagrams. The

time-series diagrams show that the multitemporal vertical deformation in Imerovigli (fig. 4-c), Nea Kameni (fig.4-a) and Thirasia (fig. 4-g) has increased significantly since June 2024,continuing climbing up until the end of the study period. More specifically, all three points in Nea Kameni (NK1, NK2 & NK3) suggest a pronounced increase in vertical deformation since June 2024, with NK3 representing a higher deformation rate in northwestern Nea Kameni compared to the eastern (NK2) and southern (NK1) parts. By the end of the study period, uplift values at NK1, NK2, and NK3 reached approximately +10mm, +25mm and 48mm, respectively, relative to the stable reference position. Thirasia presents a more anomalous increase in vertical deformation after June 2024, reaching ~ +12 mm in February 2025. Similarly, Imerovigli, located in western Thira, experienced progressive deformation beginning slightly earlier, near the end of April 2024, with a marked acceleration from June 2024 onward. This deformation reached up to ~ +16 mm by the end of the studyperiod. In contrast, the vertical deformation trend in Oia is less clear (fig. 4-e). Specifically, the time-series diagram of the vertical deformation shows an uplifting trend beginning in December of 2023, declining in June 2024 but increasing again from October 2024 onward. January 2025 presented the highest uplift in Oia at +8mm, dropping to ~ +5.5 mm by February 2025. Regarding horizontal deformation, Nea Kameni (fig. 4-b) shows a clear eastward movement beginning in June 2024 onwards in the northwestern island (NK2) up to ~ +17 mm. A similar but more significant eastward trend is observed in Imerovigli (fig. 4-d), culminating in a deformation of +40 mm east. Oia (fig. 4-f) and Thirasia (fig, 4-h) show westward deformation beginning in October 2024 which appears to reverse after January 2025, stabilizing around-6 mm in both cases.

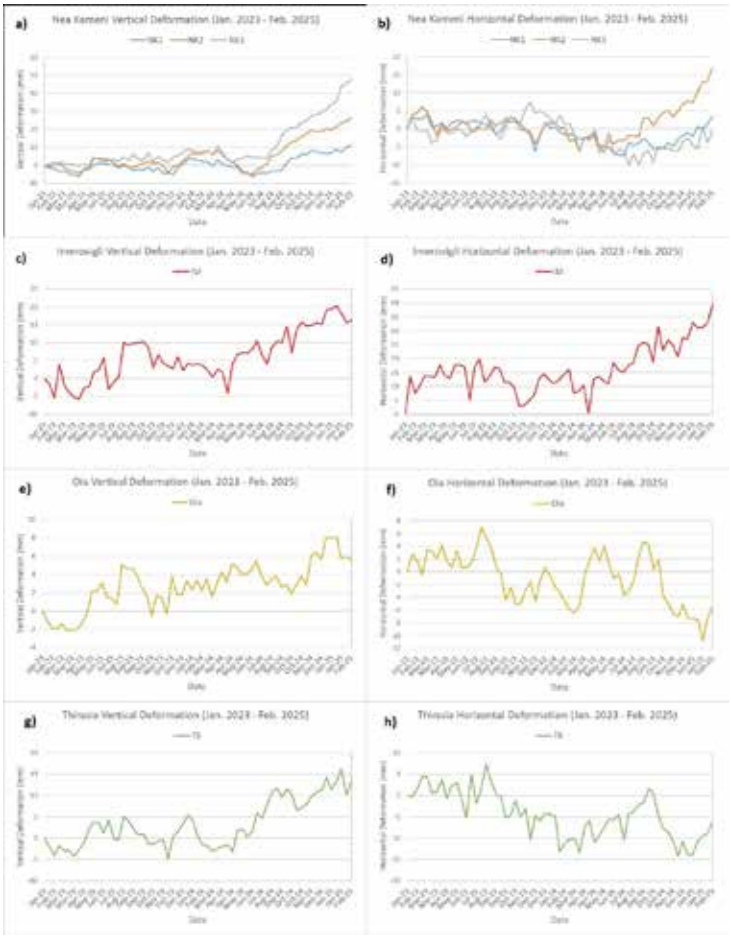

Figure 4. Time-series diagrams showing the vertical (a, c, e, g) and horizontal (b, d, f, h) deformation of Nea Kameni, Imerovigli, Oia & Thirasia respectively.

Conclusions

This research concerned the study of the deformation rate in the caldera of the Santorini volcanic island complex through the MT-InSAR technique SBAS. Using multiple satellite images throughout the studied time period (January 2023 to February 2025) several observations were made concerning the vertical and horizontal deformation velocity. Specifically, the deformation velocity was most significant in the zones closest to the interior of Santorini's Caldera, where Nea Kameni is situated. The area of mainly deformation accumulation lies northwest of Nea Kameni, directly above the submerged caldera and the magmatic reservoir beneath it. The uplifting pattern in that region could suggest swelling within the caldera due to magma accumulation in the magmatic chamber. The notable positive vertical deformation values in northwestern Thira may be the result of increased magmatic processes in the caldera due to the significant and frequent seismicity in the Anydros islet in recent months. This can also be explained by the vertical deformation time-series diagrams, showing a continuous significant increase in deformation velocity past June 2024, suggesting that the notable deformation is related to the beginning of the earthquake swarm event in Anydros. Moreover, the horizontal deformation rate component of the depicted a westward movement trend for both Thirasia, Palaia Kameni and Oia (northwestern Thira), while the remaining Thira area moves eastward, with Nea Kameni being mostly stable with a slight westward trend. These contrasting deformation vectors support the hypothesis of caldera inflation, as the islands of the volcanic complex appear to be moving away from the central caldera, suggesting radial expansion associated with magma intrusion.

Introduction

Rising sea levels, increasing frequency of extreme weather events, and transformations in marine ecosystems present significant challenges for the Eastern Mediterranean region. These changes directly affect maritime routes, port infrastructure, and the broader environment. In this context, understanding the relationship between sea surface temperature (SST) fluctuations and their effects on the environment has become a matter of increasing importance. This paper focuses on an in-depth analysis of SST trends in the Eastern Mediterranean from 1940 to 2023, examining both annual and monthly scales. By analyzing these temperature trends, the study aims to assess their potential environmental impacts, considering both operational and ecological perspectives.

In addition to SST trends, this study includes a detailed examination of extreme weather events, specifically Mediterranean cyclones, also known as Medicanes. A case study of the Mediterranean Cyclone Zorba, which significantly impacted the Eastern Mediterranean in late September and early October 2018, is included. Furthermore, the study references the average monthly SST values for September and October of 2018. Through this integrated approach, the research aims to provide valuable insights into the challenges and risks faced by the region and to offer guidance for future strategies to address these emerging environmental shifts.

Data and Methodology

This study utilized ERA5 Reanalysis data on Sea Surface Temperature (SST) to analyze the Eastern Mediterranean region, from January 1940 to December 2023. The data were examined at multiple temporal resolutions, including annual, monthly, and daily intervals, to capture both long-term trends and short-term variability in SST. The ERA5 dataset, which provides high-resolution, accurate climate data, is publicly available to the scientific community through the Copernicus Climate Change Service, in collaboration with the European Centre for Medium-Range Weather Forecasts (ECMWF). This dataset offers an invaluable resource for researchers and decision-makers involved in climate studies and environmental assessments.

To facilitate the interpretation of SST patterns over time, a series of thematic maps were generated, illustrating spatial and temporal variations of SST across different periods. These maps highlight significant trends, anomalies, and fluctuations in SST within the study area. The maps were created using Python programming, employing data visualization libraries such as Matplotlib and Plotly, in combination with ArcGIS software for spatial analysis and cartographic rendering. This methodological approach allowed for a detailed and comprehensive representation of the SST data, offering insights into both regional and temporal dynamics.

The integration of Python code and ArcGIS software enabled the efficient processing, analysis, and visualization of large datasets, ensuring that the results are both scientifically rigorous and easily interpretable. These visualizations not only serve to illustrate the trends in SST over the decades but also provide a tool for identifying areas of concern, such as regions experiencing rapid warming or significant deviations from historical patterns. The availability of this data to the broader scientific community, alongside the advanced mapping techniques employed in this work, provides a valuable contribution to the ongoing research on climate change and its effects on the Mediterranean region.

Results

The analysis of Sea Surface Temperature (SST) trends in the Eastern Mediterranean region from 1940 to 2023 reveals significant spatiotemporal variations, which are essential for understanding regional climate dynamics and their potential impacts on marine ecosystems and maritime activities.

The average annual SST for the Eastern Mediterranean during the study period is presented in Figure 1, with the red

trend line indicating a clear upward trend from 1940 to 2023. Over this period, SST has increased by approximately 1.5°C, despite notable interannual variability—particularly between 1940 and 2000. Relatively low temperatures are evident between 1975 and 1992, while higher values observed from 2005 to 2023. Post-2000, SSTs rise more consistently and sharply. It is important to note that the rate of increase in sea surface temperature (SST) is directly correlated with the rate of increase in air temperature. However, due to the distinct heat capacity of the ocean as a fluid, compared to atmospheric air, these rates are not equal. Additionally, the acceleration of the warming trend in recent decades is noteworthy, with SST consistently exceeding 20°C from 2010 onwards.

Although fluctuations with unusually cold or warm years are expected, the overall pattern reveals a steady long-term increase.

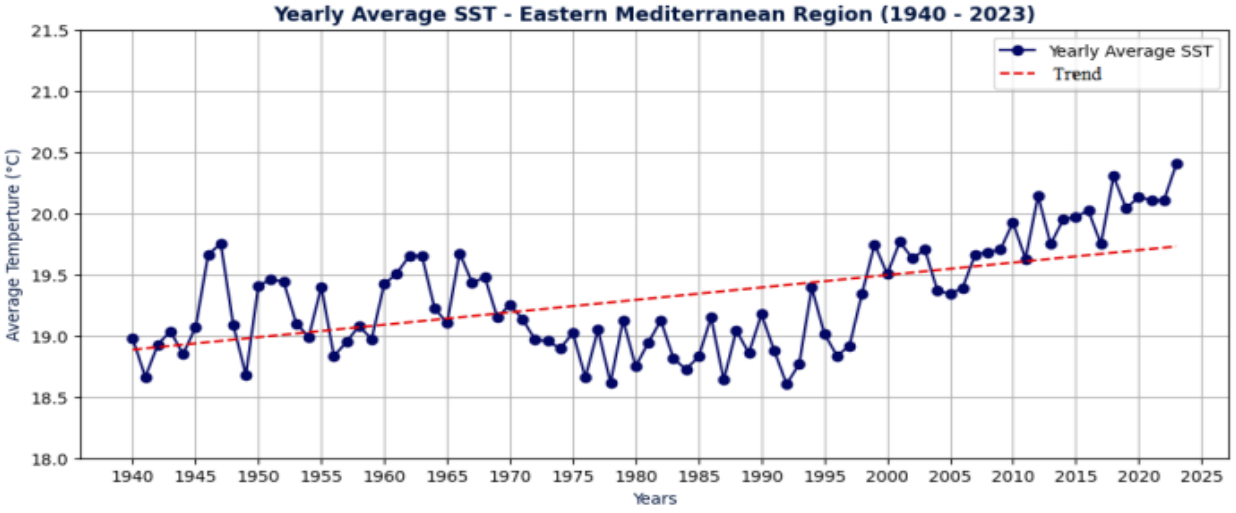

Figure 1. Annual Average Sea Surface Temperature from 1940 to 2023 for the Eastern Mediterranean region, with trend line

The spatial distribution of the average annual SST across the Eastern Mediterranean basin for the period 1940 to 2023 is shown in Figure 2. The spatial analysis of SST reveals several key areas of variability. The warmest waters are in the Gulf of Sirte, south of Crete, around Cyprus, and along the northern coasts of Africa, particularly in the southern and southeastern parts of the basin. In these areas, the average annual SST consistently exceeds 21°C. Previous studies (e.g., Ozer et al., 2022) suggest that the Eastern Mediterranean, due to its relatively small size and limited connection to the Atlantic Ocean, reflects and intensifies global warming trends. Notably, the southeastern part of the basin, bordering Israel, shows the highest temperatures, as water from the Atlantic Ocean has ample time to warm as it moves toward the region.

In contrast, the central and southern Aegean Sea, the Ionian Sea, and the southwestern parts of the Eastern Mediterranean exhibit average annual SSTs ranging from 19°C to 20°C. These regions show a more gradual but consistent warming trend compared to the period prior to 1940 (Bruno, M., 2019 & Lough, J. M., & Coughlan, L. M., 2015).

The coldest SSTs in the Eastern Mediterranean are found in the Adriatic Sea, with average temperatures ranging from 16°C to 18°C, particularly in the northern sections. This area experiences a significant influx of cold, fresh water from rivers in the Italian Alps. Similarly, the northern Aegean Sea is affected by the inflow of water masses from the Black Sea through the Bosporus Strait and the Dardanelles. This water, known as the Black Sea Water (BSW) current, has a lower temperature and salinity, further reducing the average SST in this region (Poulos et al., 1997; Zodiatis, 1996). Moreover, the northern Aegean Sea also receives freshwater contributions from the Evros, Strymon, and Nesto's rivers, as well as from rivers in the Turkish mainland, which further influence the temperature and salinity of the surface waters (Therianos, 1974).

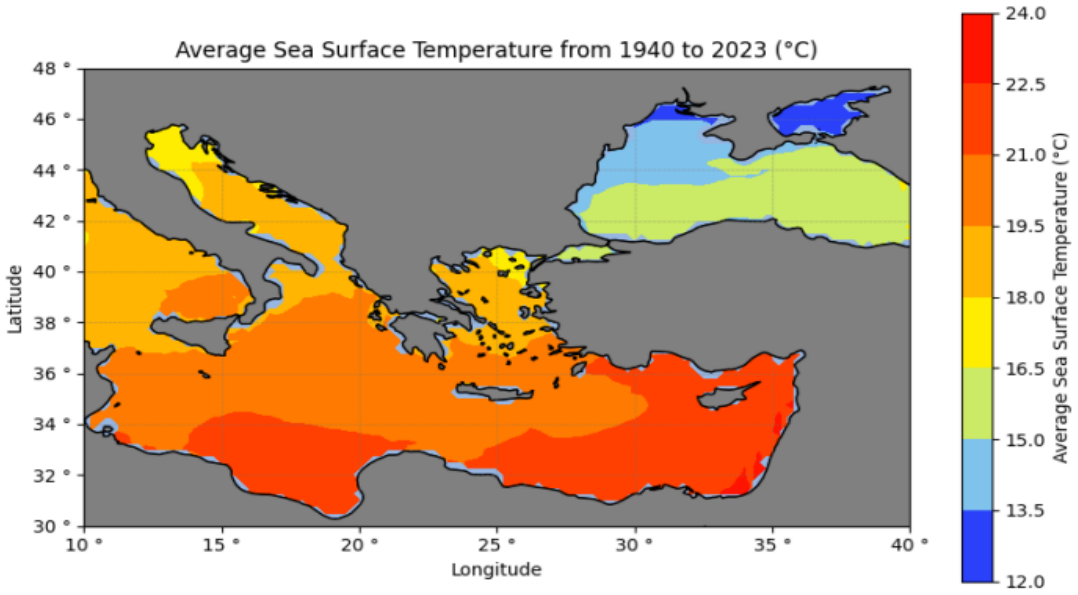

Figure 2. Spatial distribution of the annual average SST in the Eastern Mediterranean from 1940 to 2023

Figure 3 illustrates the average sea surface temperature (SST) in the Eastern Mediterranean for September during the period from 2000 to 2023. The SST range for this period varies from 19°C to 23°C, with the coldest waters located in the Adriatic Sea and the northern Aegean, while the warmest waters are found along the northern African coasts and around Cyprus. This represents a warm period compared to other times, as previously mentioned, with the average SST exceeding 20°C in many locations. The climatic average SST in the Eastern Mediterranean depends on the season, geographical location, and local climatic conditions.

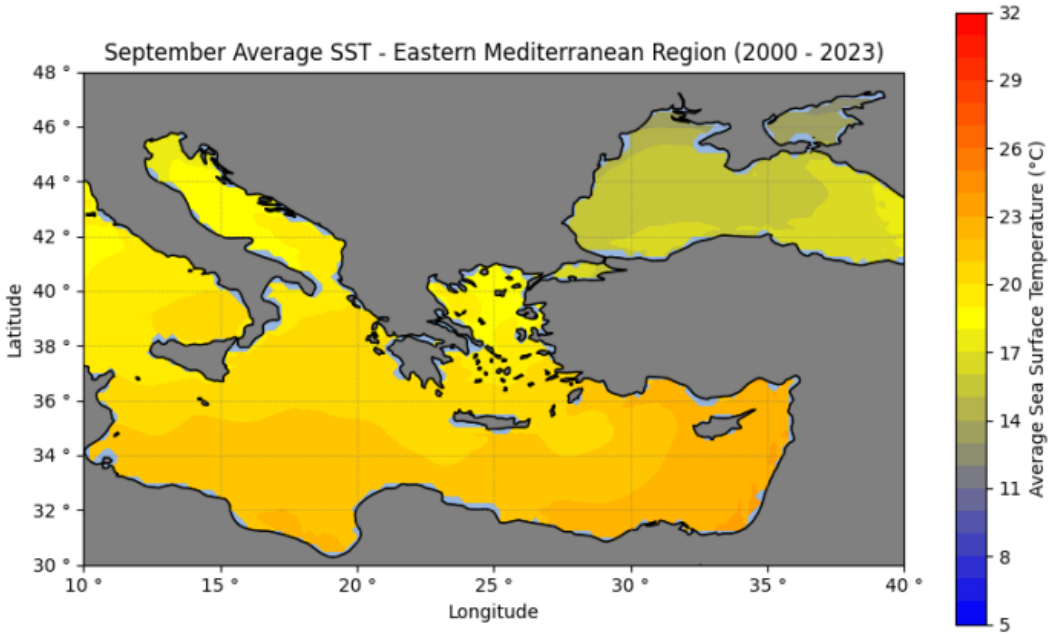

Figure 3. Average SST for September – Period 2000–2023, Eastern Mediterranean

The Mediterranean Cyclone “Zorbas,” which occurred in September 2018, is a significant event that serves as an illustrative case study of the relationship between sea surface temperature (SST) and cyclone formation in the Eastern Mediterranean.

September 2018 was characterized by notably high temperatures, both in terms of air temperature and SST. As depicted in Figure 4, the average SST for several locations across the Eastern Mediterranean basin exceeded 25°C, with temperatures reaching up to 29°C near the Gulf of Sirte and to the east of Cyprus. These elevated sea surface temperatures provided a conducive environment for the development and intensification of a Mediterranean cyclone.

The warm SSTs in the Gulf of Sirte played a crucial role in the cyclogenesis that occurred south of Italy. The energy from the warm waters contributed to the further strengthening of a low-pressure system, transforming it into a Mediterranean Cyclone with tropical characteristics (Tsikoudi, I., et al. 2019). The dynamics of this cyclone underscore the significant influence of SST on the formation and development of such systems in the Mediterranean region.

As the cyclone moved northward toward the Aegean Sea, and with October already underway, the system began to weaken. The decreasing SSTs in the northern regions of the basin no longer provided sufficient energy to sustain the cyclone. Consequently, the system lost strength, and its intensity diminished (Ziv, B., et al., 2018 & Papageorgiou, A., et al., 2020). To illustrate this, Figure 5 presents the average SST for October 2018, highlighting the contrast in sea surface temperatures compared to those in September 2018, as depicted in the preceding figure.

This case study reinforces the critical role that SST plays in the development, intensification, and eventual weakening of Mediterranean cyclones. The warm waters in the southern parts of the Eastern Mediterranean can significantly enhance cyclonic activity, while lower SSTs in the northern regions lead to the dissipation of these systems. Understanding these SST dynamics is essential for improving forecasting and risk assessment of Mediterranean cyclones, which have considerable implications for coastal areas and maritime operations in the region.

The Mediterranean Cyclone Zorbas (Medicane Zorbas) also struck Greece. Specifically, on September 29, 2018, it reached the Peloponnese with maximum winds of 120 km/h and a central pressure of 987 hPa, classifying it as a Category 1 Cyclone. It then moved through the Aegean Sea before weakening in Turkey on October 2. In its path, it caused extensive damage, particularly in the Peloponnese and central Greece. Heavy rainfall, flooding, and strong winds (up to 10-12 Beaufort) affected areas such as Argos, Corinth, and Attica. Rivers overflowed, roads were blocked, and many homes were flooded. In several areas, such as the Municipality of Argos - Mycenae, a state of emergency was declared due to the widespread damage. Zorbas highlighted the increasing risks from such extreme weather events in the Mediterranean, confirming concerns about the impacts of climate change in the region.

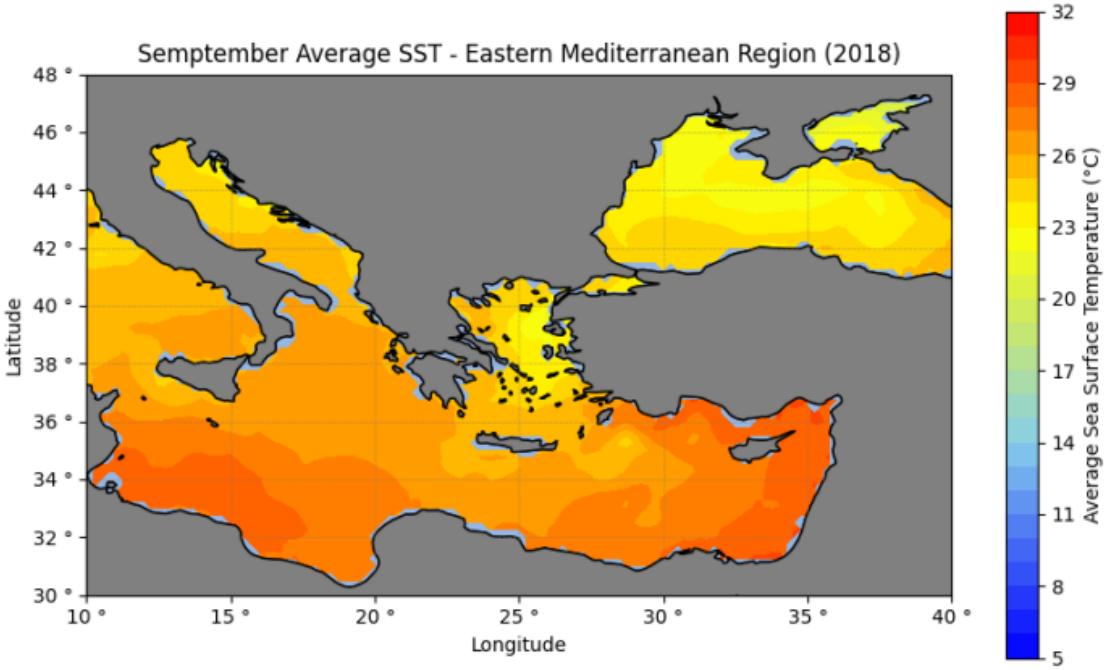

Figure 4. Average SST for September 2018, Eastern Mediterranean

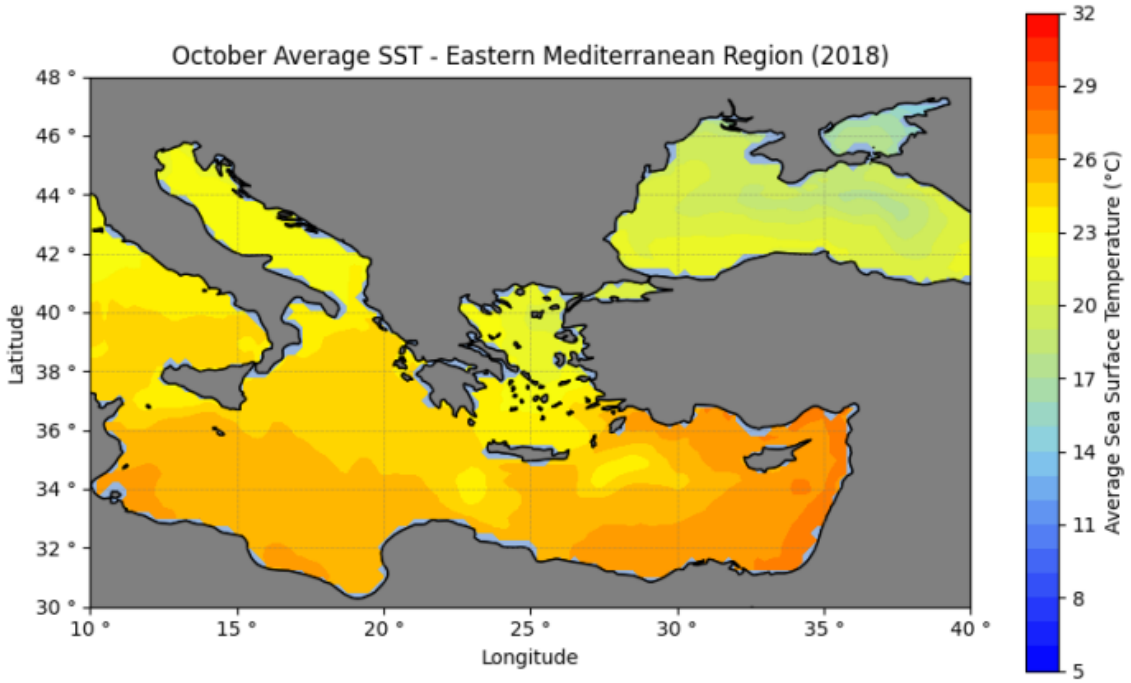

Figure 5. Average SST for October 2018, Eastern Mediterranean

Discussion and Conclusion

The results of this analysis demonstrate a clear warming trend in the Eastern Mediterranean, particularly over the past few decades, with significant regional variability. The southern and southeastern parts of the basin are experiencing the highest SSTs, while the northern Aegean and Adriatic Sea remain cooler due to the influence of freshwater inflows and the BSW current. These findings underscore the importance of continued monitoring of SST in the region.

This study has examined the rising Sea Surface Temperature (SST) in the Eastern Mediterranean from 1940 to 2023, highlighting the significant trends, contributing factors, and implications for the region's environment and maritime industry. The Eastern Mediterranean was selected for this research due to its unique characteristics, such as its semi-closed nature, which results in an accelerated increase in sea temperatures compared to other global seas, as well as its crucial role in linking three continents directly influenced by the weather phenomena that originate here.

Over the past eighty-three years, the SST in the Eastern Mediterranean has consistently risen, with a noticeable acceleration of this warming since the 2010s. The region has experienced an increase of approximately +0.4°C to +0.6°C per decade since the 1980s. During the summer months, SSTs often exceed 26°C, with September being the warmest month. This warming trend, driven by factors such as rising greenhouse gas emissions, alterations in atmospheric circulation, and the reduction of polar ice, has led to a marked increase in the frequency and severity of Mediterranean cyclones (Giorgi, F., et al., 2019 & Gaertner, M. A., et al., 2017). These cyclones, which combine characteristics of both tropical and extratropical systems, have become more prevalent, with notable events including Cyclones "Zorbas" (2018).

The increased SST and the intensification of extreme weather events, such as Medicanes, have profound implications for maritime operations. The impact of Cyclone "Zorbas" on the ports of Peloponnese serves as a clear example of how such events can severely affect the maritime sector.

Considering these findings, it is evident that the rising SST and the increasing frequency of extreme weather events pose substantial challenges to the coastal communities in the Eastern Mediterranean. Therefore, it is crucial to implement strategies to adapt to these changing conditions. Advanced weather forecasting

systems should be developed to improve preparedness, while the resilience of port infrastructure must be strengthened to withstand the impact of these extreme events. Additionally, international cooperation is essential to address the underlying drivers of climate change, such as CO_2 emissions, and to mitigate further environmental impacts.

This research underscores the urgent need for further studies to monitor the ongoing changes in SST and to better understand their long-term effects on marine ecosystems, biodiversity, and global trade routes. Ultimately, proactive measures and informed decision-making will be critical to managing the evolving challenges posed by climate change in the Eastern Mediterranean and beyond.

Acknowledgements

We would like to express our sincere gratitude to the European Centre for Medium-Range Weather Forecasts (ECMWF) and the Copernicus program for providing the essential data used in this study. Their invaluable resources and support have significantly contributed to the success of our research. Without the access to ECMWF's advanced weather and climate data and the Copernicus Earth Observation program's rich datasets, this work would not have been possible. We also appreciate the efforts of all teams involved in data collection, maintenance, and dissemination.

Research Highlights: **water stratification and anoxic condition as important environmental parameters for the dam's life cycle**

Introduction

Reservoirs are artificial lakes that play a critical role in water resource management worldwide, providing essential services such as water supply for drinking and irrigation, flood control, and hydroelectric power generation (Directive EU 2020/2184). However, reservoirs, like natural lakes, are susceptible to environmental and anthropogenic influences that can alter their ecological balance. The stratification of water bodies is a key physical process that affects the distribution of temperature, dissolved oxygen, and other physicochemical properties, which in turn impacts water quality and aquatic life. Thermal stratification, particularly in monomictic and dimictic lakes, causes the development of distinct layers in the water column that can become isolated from atmospheric oxygen, leading to hypoxic or anoxic conditions in the deeper layers. These conditions, often exacerbated by nutrient inputs and organic matter decomposition, can significantly affect water chemistry, particularly the solubilization and mobility of heavy metals from sediments. This creates potential environmental hazards, particularly in drinking water reservoirs where water quality is a priority.

The study area is Pinios Dam which is located at northwest Peloponnese which has already recorded as reservoir with high concentrations of Mn and Fe (Michalopoulou et al, 2024). For this study, a detailed bathymetric survey was conducted, four monitoring stations were installed, and seasonal water column profiles were recorded. Additionally, physicochemical parameters, including pH, temperature, conductivity, redox potential, and heavy metal concentrations of Mn and Fe, were measured and analyzed".

Methods

Water samples were collected from the artificial reservoir of the Pinios Dam at four pre-determined stations (SPA1–SPA4), strategically selected to provide comprehensive coverage of the study area. These stations were located along the reservoir's main axis, with depths ranging from 9 m to 35 m. Sampling occurred seasonally, between February 2023 and October 2023, and utilized a multi-depth water sampler equipped with valves suitable for depths up to 100 m. Samples were collected at 4 m intervals from the surface to the bottom, yielding a total of 74 samples.

Physical and chemical parameters, including pH, temperature, dissolved oxygen, and conductivity, were measured using a portable multi-parameter probe (IN-SITU AQUA TROLL 6000). Measurements were taken along the vertical profile of the water column at 10 cm intervals.

Collected samples were analyzed for various chemical parameters, such as chloride (Cl^-), nitrate (NO_3^-), nitrite (NO_2^-), ammonium (NH_4^+), phosphate (PO_4^{3-}), sulfate (SO_4^{2-}), total organic carbon (TOC), total nitrogen (TN), manganese (Mn), and iron (Fe). Analyses were conducted using an ion chromatograph (Dionex ICS-1100) and a spectrophotometer (HACH-LANGE), with quality assurance adhering to ISO 17025 standards.

Results

Seasonal Variations

The study identified notable seasonal variations in the reservoir's physical and chemical parameters.

Temperature stratification was evident during the summer, with surface temperatures peaking at 25°C and bottom temperatures remaining around 15°C. Dissolved oxygen levels decreased with depth, particularly during summer and autumn, indicating thermal stratification and oxygen depletion at deeper layers.

Chemical Composition

Chloride concentrations ranged between 10.12 mg/L and 20.96 mg/L, showing minimal seasonal fluctuation. Nutrient concentrations, particularly nitrates (0.11–1.43 mg/L) and ammonium (0.02–0.36 mg/L), varied with depth and season, reflecting biological activity and nutrient cycling within the reservoir. Phosphate levels were generally below detection limits, except for occasional peaks (up to 0.06 mg/L).

Heavy Metals

Manganese and iron concentrations exhibited significant depth-dependent trends. Mn concentrations ranged from 0.01 mg/L to 0.198 mg/L, while Fe varied from 0.01 mg/L to 0.204 mg/L. Both metals showed elevated concentrations in bottom layers during late summer and autumn, coinciding with reduced oxygen levels.

Conclusions

Thermal stratification played a significant role in shaping the reservoir's chemical profile. The development of distinct temperature layers during summer inhibited vertical mixing, leading to oxygen depletion in deeper layers. This, in turn, facilitated the release of Mn and Fe from sediments into the water column, as indicated by their elevated concentrations at depth.

The distribution of nitrates and ammonium highlighted the complex interplay between biological uptake, decomposition, and nutrient cycling. Elevated nitrate levels near the surface during spring suggest enhanced productivity, while higher ammonium concentrations at depth during late summer point to decomposition processes under low-oxygen conditions.

The observed seasonal and depth-dependent variations in key parameters underline the reservoir's susceptibility to eutrophication and metal mobilization, particularly during stratified periods. These findings are critical for designing management strategies to mitigate potential water quality issues.

Research Highlights

A new locality with amphibians, reptiles, fishes, gastropods, and ostracods is described from the Early Pleistocene of Koukos region in Kos Island. These findings are valuable for palaeoecosystem reconstruction and biogeographical interpretations and represent a rare assemblage of that age in Greece.

Introduction

The island of Kos in the southeastern Aegean Sea was part of the Anatolian peninsula during the Pleistocene and maintained a connection to the mainland till the Last Glacial Maximum (Rohling *et al.* 2014). During the Early Pleistocene, several extinct mammals inhabited the area such as *Anancus* sp., *Homotherium* sp., *Leptobos* sp. (Desio, 1928). During the Late Pleistocene, fossils show a shift towards shallow marine environments (Drinia *et al.* 2010). The area of Koukos has been studied by Charrier and Giglio (1969) who refer to the locality as 'Iliopeia' where some large mammal fossils have been found. The presence of microvertebrates had never been reported before the discovery of the site of Koukos, in Kardamena village of the island. The newly discovered site contains a rich assemblage of amphibians, reptiles and fishes, also described as ectothermic fauna. The co-occurrence of fossil gastropods and ostracods is valuable for palaeoecological interpretations. Further analysis on the biogeographical affinities of these findings will be valuable for deciphering the origins of modern-day distributions of several extant taxa. Finally, this locality is the only site in Greece from the Early Pleistocene which bears both ichthyological and herpetofaunal remains (Argyriou 2022, Delfino & Georgalis 2022, Vlachos, 2022).

Geological Setting

The site is located in the Koukos area of Kardamena village of Kos Island, in Southeastern Mediterranean (fig.1). According to Willmann (1983), the site belongs to the lowermost Tafi formation, which is dated as Lower Pleistocene. Additionally, Magrograssi (1928) has described a gastropod species *Melanopsis pseudopigmea* from the same outcrop.

The section of Koukos consists of claystones, siltstones and sandstones, with the latter dominating. The first layer (fig.2) consists of fossil-free grey claystone, the second layer (fig. 2) is a 25cm green claystone layer with amphibians, reptiles, fishes, ostracods, and gastropods (Table 1). The third layer is yellowish siltstone. The last (fourth) layer, consisting mostly of fossil free sandstones and conglomerates, overlies the previous beds with an erosive base suggesting high energy river deposition (fig. 2).

Materials and methods

Test samples of 2 kg have been obtained from each layer, which have been treated with a solution with 0.1% perhydrol. They have been washed using a series of four sieves of 1 cm, 500 μm, 250 μm and 125 μm mesh sizes. After the discovery of the fossiliferous layer of green clay, another sample of 20 kg was washed.

For the taxonomy of the gastropods, we used Neumayr (1880), Magrograssi (1928), Willmann (1981), Bouchet *et al.* (2005), as well as numerous other studies focusing on the classification of lacustrine

gastropods from the Pleistocene. The ecoregions concept Barbieri et al. (2015) has been applied for the interpretation of fish forms.

Results

The fauna consists of 22 taxa. The vertebrate taxa are 14, of which 6 belong to ray-finned fish, 4 to amphibians, 3 to reptilians and 1 to mammals. The invertebrates are represented by 5 gastropod species and 3 ostracod species.

Class	Family	**Taxon**
Actinopterygii	Cyprinidae	? *Barbus* sp.
		Leuciscus sp.
		Luciobarbus sp.
		Chondrostoma sp.
	Cobitidae	Cobitidae indet.
	Gobiidae	Gobiidae indet.
Amphibia	Salamandridae	Salamandridae indet. (small-sized)
	Ranidae	*Pelophylax* sp.
	Hylidae	*Hyla* sp.
		Bufonidae / Pelobatidae indet.
Reptilia	Geoemydidae	*Mauremys* sp.
	Colubridae	Colubridae indet.
		Colubrinae indet.
Mammalia	Cricetidae	Cricetidae indet.
Gastropoda	Melanopsidae	*Melanopsis pseudopigmea* Magrograssi, 1928
	Valvatidae	*Valvata hellenica* Tournouer, 1877
	Melanopsidae	*Melanopsis gorceixi polyptycha* Tournouer, 1875
	Neritidae	*Theodoxus doricus doricus* (Neumayr, 1880)
	Hydrobiidae	*Iraklimelania coa* Willmann, 1981
Ostracoda	Candonidae	*Fabaeformiscandona* cf. *brevicornis* (Klie, 1925)
		Candona sp.
	Cyprididae	*Ilyocypris gibba* (Ramdohr, 1808)

Table 1. Fauna of Koukos locality

Discussion-Conclusions

The ectothermic vertebrate fauna suggests the presence of running freshwater water body (rivers) with very (*Leuciscus* sp., *Luciobarbus* sp., *Chondrostoma* sp., Cobitidae indet.) slowly flowing or stagnant parts (Gobiidae indet., *Pelophylax* sp., *Mauremys* sp.). The water body was surrounded by hedgerows and meadows with higher vegetation (Salamandridae indet. (small-sized), *Hyla* sp.).

The herpetofauna of the Koukos site contains forms which are broadly present also in present-day Kos and other nearby islands (Valakos et al., 2008). From the perspective of the fossil fauna, Koukos contributes so far to the scarcely studied record of ectothermic vertebrates. *Mauremys rivulata* found previously in Kos but the exact location was missing (Vlachos, 2022) and another freshwater turtle that was discovered in the broader area belonged to the family Trionychidae (Avrithis and Georgalis, 2024). For the amphibians, only 4 sites of that age are found in Greece mainland (Delfino & Georgalis, 2022).

The mollusk fossil assemblage from the Koukos region indicates deposition in a low-energy aquatic system, such as a shallow lacustrine or slow-flowing riverine environment. The investigation of the gastropod species that were found suggest warm, temperate climatic conditions and abundant vegetation with large aquatic plants. Forms like *Melanopsis pseudopigmea*, *Valvata hellenica*, *Iraklimelania coa*, and *Theodoxus doricus doricus* appear to have been adapted to these freshwater habitats. The presence of

Iraklimelania coa in fine-grained lacustrine and riverine deposits suggests the species inhabited low-energy environments, where fine sediments like muds and silts accumulated in areas of reduced flow. These depositional environments are characteristic of slow-moving waters with high sedimentation rates.

Ostracod findings of *Ilyocypris gibba* and *Candona* species are indicative of freshwater bodies like lakes or ponds. Those two genera of freshwater ostracods are often found together in sedimentary deposits. *Ilyocypris gibba* may suggest more stable and warmer freshwater habitats while *Candona* species are adapted to a wider range of temperatures, salinities and dissolved oxygen. Thus, the co-occurrence of these two ostracods may indicate fluctuations between warmer and cooler phases.

The fish fauna contains a remarkable complex, suggesting a link between the Koukos fauna with Asia Minor. This fits with a further fact that the recent freshwater fish fauna of the Island of Kos, being in the ecoregion 7 (the Eastern Aegean), according to Barbieri et al. (2015), which have Asia Minor affinities.

EXTENDED ABSTRACT 023

Impact of Emission Regulations on the Temporal Trends of Toxicity of Fine Particulate Matter in Los Angeles

Authors: Mohammad Mahdi Badami[1], Yashar Aghaei[1], and Constantinos Sioutas[1]
Affiliation: (1) University of Southern California, Department of Civil and Environmental Engineering, Los Angeles, California, USA

Research Highlights

- Initial reductions in $PM_{2.5}$ mass due to emission controls were followed by increased toxicity from non-tailpipe sources.
- The oxidative potential of $PM_{2.5}$ has risen since 2012, indicating a shift towards more harmful aerosol constituents.

Background

Ambient particulate matter (PM) is a major environmental health challenge worldwide, associated with a variety of serious health issues, including respiratory and cardiovascular diseases, lung cancer, and increased mortality rates. PM is classified based on its size into coarse particles, fine particles ($PM_{2.5}$), and ultrafine particles (UFPs). Among these, $PM_{2.5}$ is particularly hazardous because its small size allows it to penetrate deep into the lungs and enter the bloodstream, leading to systemic inflammation and affecting multiple organs. In densely populated urban areas like Los Angeles, vehicular emissions are the primary source of $PM_{2.5}$, resulting in higher incidences of asthma, heart disease, and other health problems compared to less polluted regions. The frequent air quality alerts in the early 2000s raised significant public health concerns, especially for vulnerable groups such as children and the elderly, prompting urgent regulatory actions aimed at reducing PM emissions from both vehicles and industrial sources.

Over the past few decades, extensive regulatory measures at both federal and state levels have substantially improved air quality in Los Angeles and throughout California. Programs initiated by the U.S. Environmental Protection Agency and the California Air Resources Board have successfully lowered the mass concentrations of primary combustion-related pollutants like organic carbon and elemental carbon. These efforts have led to significant reductions in $PM_{2.5}$ levels and associated health risks. However, despite these successes, the number of ultrafine particles has not decreased proportionally and has even plateaued in recent years. This indicates that current regulations may not fully address all sources of PM, particularly non-tailpipe emissions such as brake and tire wear, as well as the formation of secondary aerosols from volatile organic compounds. Additionally, the chemical composition of $PM_{2.5}$ has become more complex, incorporating a diverse range of toxic substances, including metals and organic compounds, which contribute to its overall oxidative potential and health impacts. These developments highlight the need for regulatory frameworks to evolve, incorporating strategies targeting particulate matter's most harmful components to further enhance air quality and protect public health.

Objectives

The primary aim of this study is to analyze the temporal trends in both the chemical composition and oxidative potential of $PM_{2.5}$ in Los Angeles over the past two decades. Specifically, the research seeks to determine the effectiveness of emission regulations in reducing $PM_{2.5}$ toxicity and to identify emerging sources contributing to any observed changes in oxidative potential. By understanding these dynamics, the study aims to provide insights that can inform more comprehensive and effective air quality management strategies.

Methods

Data on $PM_{2.5}$ oxidative potential were compiled through an extensive review of studies conducted over the past two decades (Badami et al. 2023; Cho et al. 2005; Farahani et al. 2022; Hu et al. 2008; Li et al. 2003; Ntziachristos et al. 2007; Saffari et al. 2014; 2016; Shirmohammadi et al. 2016; 2017; Verma et al. 2009; 2011). The dithiothreitol (DTT) assay data were originally reported in various units (activity per mass or per volume) and were standardized using corresponding PM mass and sampling duration measurements to ensure comparability. Detailed information

on measurement methods, equipment calibration, instrument specifications, and uncertainties can be found in the original publications (Badami et al. 2023; Cho et al. 2005; Farahani et al. 2022; Hu et al. 2008; Li et al. 2003; 2009; Ntziachristos et al. 2007; Saffari et al. 2014; 2016; Shirmohammadi et al. 2016; 2017; Verma et al. 2009; 2011; Zhang et al. 2016). The majority of DTT data were obtained from the Particle Instrumentation Unit (PIU) at the University of Southern California (USC), located in an urban area near downtown Los Angeles, 150 meters from a major freeway (I-110) that is generally situated in the downwind direction of this freeway. Additionally, trends of various chemical species such as metals (e.g., Barium [Ba], Copper [Cu], Manganese [Mn], Zinc [Zn], Chromium [Cr], Nickel [Ni], Cadmium [Cd], Iron [Fe]) and inorganic ions (sulfate [SO_4^{2-}] and nitrate [NO_3^-]) were sourced from the North Main Street monitoring station, operated by the U.S. Environmental Protection Agency (EPA) as part of the Air Quality System (AQS) and Chemical Speciation Network (CSN). These trends correspond to the sampling periods of the reviewed DTT studies, noting that data were only available from 2005 to 2024 due to the absence of CSN data prior to 2005 and the lack of metals data in 2005.

Additional sampling was conducted in January and February 2024 at the PIU of USC to assess contemporary conditions under the latest regulatory environment. $PM_{2.5}$ was collected using pre-baked quartz filters in Sioutas Personal Cascade Impactor Samplers (PCISs, SKC Inc., Eighty-Four, PA, USA) with a flow rate of 9 liters per minute to ensure accurate mass measurements. The oxidative potential of collected $PM_{2.5}$ samples was assessed using the DTT assay, adhering to established protocols.

Results

The long-term analysis of $PM_{2.5}$ oxidative potential in Los Angeles from 2001 to 2024 identified two distinct phases corresponding to different regulatory periods. Between 2001 and 2008, there was a significant decline in DTT activity per volume, decreasing from approximately 0.84 to 0.37 nmol/min/m³. This reduction coincided with stringent tailpipe emission regulations that effectively lowered primary combustion-related pollutants such as organic carbon (OC) and elemental carbon (EC). However, starting in 2012, despite a continued slight decrease in overall $PM_{2.5}$ mass, the oxidative potential began to rise, reaching around 0.97 nmol/min/m³ by 2024. This increase is primarily driven by the stabilization and slight rise in concentrations of metals like Fe and Zn, which are associated with non-tailpipe emissions such as brake and tire wear, as well as the formation of secondary organic aerosols. These changes indicate a shift in the toxicological profile of $PM_{2.5}$, where non-tailpipe sources are increasingly contributing to its oxidative potential consistent with the increase in the vehicle miles traveled (VMT) in this period (Badami, Tohidi, and Sioutas 2024).

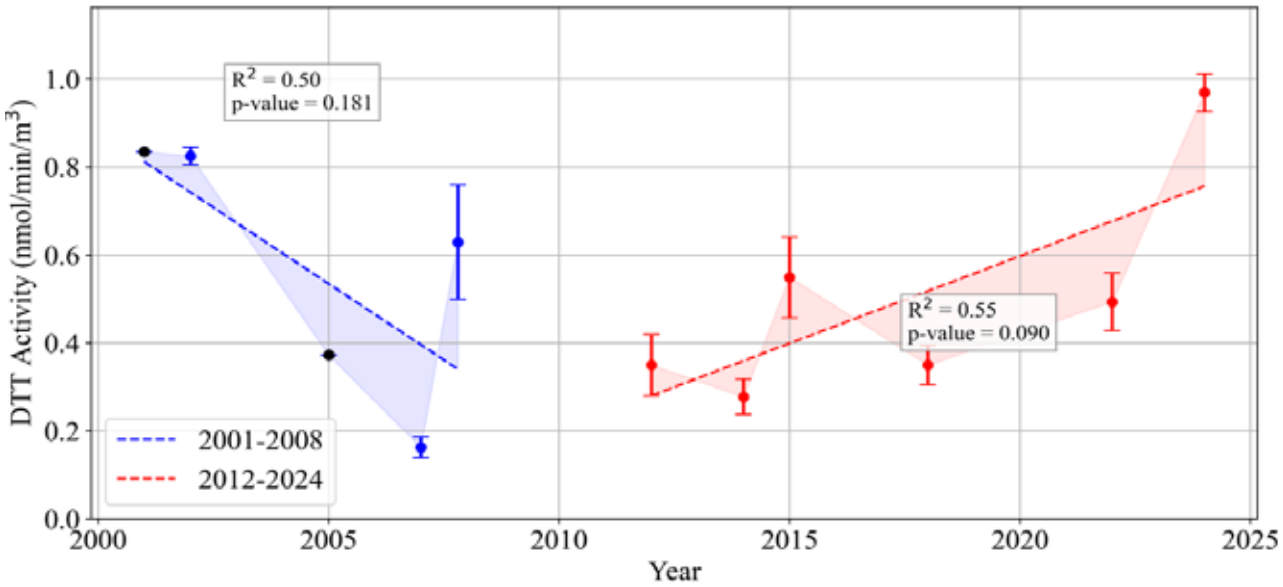

Figure1. $PM_{2.5}$ DTT activity Long-term trends (2001–2024).

Additionally, the correlations between DTT activity and specific $PM_{2.5}$ components have evolved over the study period. Metals including Fe, Zn, Cu, Mn, and Pb demonstrated strengthening correlations with DTT activity, highlighting their growing role in driving the oxidative potential of fine particulate matter. In contrast, the correlation between OC and DTT activity showed a slight decreasing trend, suggesting a reduced influence of tailpipe emissions on oxidative potential over time. EC exhibited a modest increase in its correlation with DTT activity, potentially reflecting its association with non-tailpipe sources rather than its inherent toxicity. These findings underscore the importance of addressing non-tailpipe and secondary emission sources in regulatory frameworks to effectively mitigate the oxidative toxicity of $PM_{2.5}$ and improve public health outcomes.

Conclusions

This study investigated the long-term trends in both the chemical composition and oxidative potential of $PM_{2.5}$ in Los Angeles over the past two decades, utilizing the DTT assay as a measure of particle-induced oxidative stress. The findings reveal that while regulatory measures effectively reduced mass concentrations of primary combustion markers such as OC and EC, notably before 2016, a significant shift has occurred in the composition of $PM_{2.5}$ towards non-tailpipe emission tracers. These unregulated species, including stable or proportionally increasing metals Fe, Cu, and Zn, have contributed to a partial resurgence and stabilization of DTT activity per mass from 2012 to 2024. Additionally, the oxidative potential per volume of fine $PM_{2.5}$ has continued to rise, underscoring the growing impact of non-tailpipe sources and secondary aerosol formation on $PM_{2.5}$ toxicity.

Extended Abstract

School environment poses a challenge for the protection against the increasing occurrences of natural disasters (Lekkas & Andreadakis, 2015), and the education of teachers and students alike should be a first-order priority. This pilot study is a first step to reveal teachers' attitudes and skills after the Daniel storm 2023 (Thessaly, Greece) in order to record awareness level in terms of flood risk reduction toward the development of an educated resilient and adaptable school community to decrease flood vulnerability and susceptibility.

Within the scope of this quasi-experimental research, semi-structured interviews were conducted in October and November 2023, focusing on teachers at local primary schools that suffered from the Daniel flood. Questions of the research tool were cross-checked by two educators and responses were qualitatively elaborated by two geoscientists to keep internal validity.

After the qualitative elaboration of interview responses and in terms of teachers' attitude about Daniel flood and their flood background knowledge, it comes out in general that a) there is a diversity in the pre-existing knowledge of teachers regarding floods usually exhibiting low scores of awareness, which is in line with other research (Bakopoulou et al, 2022), and b) the real-life experience of Daniel events has significantly contributed to the raising of awareness within the local school community. The majority of teachers: (i) point out the importance of targeted educational initiatives; (ii) recognize the increased risk in the local flood-affected areas; (iii) highlight the severe interrelation between personal and professional challenges during natural disasters, emphasizing the need for broad and systemic support; (iv) assure that the flood impact on the school environment extends beyond the immediate effects on the classroom, affecting infrastructure and the overall functionality of the school; and (v) acknowledge the importance of preparedness and resilience and the need for further training.

Regarding the emergency management cycle, all teachers are partially aware of it, which means that they either are not aware of the different cycle phases, or are unable to accurately discriminate among each management phase. At the same time, all teachers point out that it was not possible to implement emergency management measures immediately, due to the timing of the storm occurrence. Therefore, they recognize the importance of student and teacher education and skill development on prevention and protection measures, even in cases that students have not been directly affected. Some teachers emphasized the critical role of collaboration and mutual support among school authorities, colleagues, parents and the wider community, while the involvement of school counsellors, psychologists, and social workers is recognized as essential for providing emotional support to students and addressing the psychological impacts of the flood beyond the school environment. External support from other schools and volunteerism are also identified as valuable resources. Donations are claimed to have fostered a positive and inclusive atmosphere within the school community. The use of various communication channels, including social media platforms, has been emphasized as a necessary contribution and seminars and guidelines from educational authorities after the storm provided teachers with valuable insights for addressing the consequences of the floods, highlighting the importance of professional development and guidance.

As far as the flood consequences on school community and school environment are concerned, the storm had a significant impact on students and teachers demolishing their living and learning environment (Lekkas et al 2024). Additionally, the disruption of students' routine, the potential relocation of home or school, and exposure to abundant challenges disturbed their emotional balance and required careful

management and support. Students experienced increased anxiety and fear, with some facing stress and depression. Relocation and adjustment to new environments are recorded as the main factors that contributed to increased emotional stress; while students exhibited violent behaviour after the disaster emphasizing that they should be treated with more compassion, care, patience and tenacity in the post-flood schooling. Additionally, failures in living and learning environment caused concentration disorders to students, which in turn led to low learning abilities in the post-flood period. Besides, teachers expressed emotions of depression, stress and mental and bodily exhaustion; and suffered from severe stress of how to achieve the annual learning goals within such adverse circumstances after the disaster. Despite curriculum rigidity, teachers transformed their teaching goals to emotional ones, addressing the emotional impact and adopting measures, such as engaging in therapeutic activities in classrooms with collaboration with counsellors, psychologists, and parents, where students shared their stories focused on emotional expression and resilience. This goal transition created extra stress on teachers as they had doubts about whether they would succeed in their new goals or not, while the demand to keep in line with educational curriculum goals increased teachers' stress. Another stress factor is the fact that despite their using their own means and resources voluntarily to help especially poor students to overcome difficulties, they often felt inadequate to contribute. Finally, the need for emotional support, relocation and the adaptation of teaching methods emerges as recurring patterns that all teachers faced after the occurrence of the event.

In terms of skill development school programmes, ensuring the safety of students and teachers is an utmost priority, as reflected in the multifaceted approaches adopted by schools; therefore, all teachers claimed that the whole local school community should be trained and educated on flood risk reduction, according to the age of each target-team. Teachers should be trained to effectively support the mitigation of symptoms of post-traumatic stress among student population individually. Berger, Abu-Raiya & Benatov (2016) emphasize the long-term strong benefits and effectiveness in minimizing the symptoms of post-traumatic stress of individual education by trained teachers. However, no teacher had participated in a flood risk reduction programme in the past, even though it is a flood-prone area. Nonetheless, all teachers claimed that skill development school programmes should be engaged and enriched with flood risk reduction, protection and management activities. In addition, teachers insisted that training school community towards making quick, immediate and appropriate decisions in emotionally stressed and adverse during the flood and post-flood periods is of major importance. This could be achieved through skill development school workshops. In this sense, teachers proposed that these skill programmes or workshops should definitely include: (a) concrete simulations, (b) drills organized by local authorities, (c) digital simulations and (d) expert lectures.

Concluding, the implications of the aforementioned data are manifold: the importance of education, training and skill development on flood risk reduction and emergency management before the occurrence of severe weather events and floods constitutes a necessity, while continuous education, adapted to local needs and based on local experiences and local flooded-area history, is crucial for building resilience and preparedness for local schools and local community. Skill development school programmes or workshops can serve as a means to address flood risk reduction and protection education. Addressing these challenges can forward the development of effective support systems, ensuring the mental well-being of school community and fostering an environment that promotes effective post-disaster education. Authorities should consider the aforementioned data so that they establish educational policies aimed at enhancing the preparedness and resilience of school community in the face of flood vulnerability and risk reduction, flood mitigation, resilience and adaptability.

Introduction

In this study, quartz crystals from Greece and Brazil are studied and characterized regarding their macroscopic and microscopic characteristics, emphasizing on their inclusions. Generally, quartz crystals present a tremendous variety of crystal and fluid inclusions (liquid and gas). So many mineral varieties have been identified in quartz that it would be impossible to mention them all. Specifically, this study focuses on samples originating from Internal Hellenides, namely Serbo-Macedonian and Rhodope Massifs (Greece), and Espinhaço Range (Brazil). Solid and liquid inclusions can provide information about the formation processes, the specific environment and the age that quartz crystals were formed, while they also characterize the quality of these as gemstones (Brace-Thompson, 2023; Deer, Howie, & Zussman, 1992; Roedder, 1984). The results presented in this publication are preliminary as our study is in progress. Different techniques are used in order to investigate the mineral inclusions of the studied samples such as X-ray diffraction (XRD), Scanning Electron Microscope (SEM), Raman spectroscopy (Raman) and the results of their full characterization will be presented in the future.

Geological setting-Geologic Background

Based on recent publications quartz found in Greece is distinguished in two main groups in respect to its formation environment (Maneta & Voudouris, 2010; Voudouris et al., 2004, 2019). The first group involves quartz that is formed in alpine fissures hosted in lithologies such as ortho- and paragneisses (in the Rhodope Massif: Drama, Thassos Island and the Attico-Cycladic Massif: Penteli Mt, Evia, Ios Islands), as well as in amphibolites (Evros, Thassos, Evia and Andros Islands), phyllites (Lesvos Island) and meta-quartzites (Crete Island). The second group, providing gem quality quartz, is related to Tertiary and Mesozoic magmatic-hydrothermal environments and associated rocks (e.g. granitoids, pegmatites, skarns, non-skarn carbonate-replacement deposits, hydrothermal-altered volcanic rocks) found across Greece (Voudouris *et al.*, 2019).

Quartz in Brazil is also found in two main geological settings (Favacho-Silva, 2000). The first includes the hydrothermal vein system of the Serra do Espinhaço, where quartz is of hydrothermal origin and is embedded in rocks of the super-group Espinhaço. Rocks observed are mainly quartzites, followed by phyllites and to a lesser extent meta-conglomerates and carbonate rocks. The second geological setting is the pegmatitic province of Eastern Brazil, where quartz is part of the core of pegmatite veins, associated with granites that have penetrated the synorogenetic turbidities of Salinas formation or its basement (Macauba Group) (Favacho-Silva, 2000).

Materials and Methods

Quartz from Greece was collected from multiple places in the Serbo-Macedonian and Rhodope Massifs, northern Greece. In detail, Greek samples were derived from outcrops found near Lefkopetra in Xanthi, Koinira in Thassos Island, Dassoto, Kato Vrontou, Panorama in Drama and Madem Lakkos in Chalkidiki. The samples from Brazil comprised of colorless and light brown quartz and there is no precise evidence of origin beyond the state where they were sourced from.

Quartz samples from both Greece (19) and Brazil (19) were polished and observed under a Proapex gemological microscope with x10 and x30 magnification. Their selection was based on whether the samples were free of inclusions or presented inclusions for further investigation. This was the reason why seventeen (17) and two (2) samples were

selected from group one and two respectively of the Brazilian quartzes. Most of the samples of the second group were inclusion free. All the studied quartz samples had their refractive indexes and specific gravity calculated. Following, based on previous observations, fifteen samples were chosen and thin sections of these samples were produced. Thin sections were examined under a Leitz Ortholux polarizing petrographic microscope and photographed using a Jenoptik ProgRes C3 digital camera.

Results and discussion

The quartz samples from Greece consist of multiple varieties and derived from the geological environments that are mentioned above. According to their macroscopic characteristics they are classified in four (4) different groups of varieties and they have further been characterized. Representative results of studied samples derived from Greece are presented below.

Amethyst

Five (5) amethyst samples (DAS01A, DAS01B, DAS01C, DAS01E, DAS01F) from the area of Dassoto, Drama were macroscopically and gemologically analyzed and their refractive indices values are 1.543 ± 0.003 and 1.552 ± 0.003 and the specific gravity showed values of 2.62 ± 0.01. These specimens are scepter-shaped and have a light purple color on the crown. In the three crystals where the body of the scepter is preserved, light to dark smoky quartz is observed (Figure 1a).

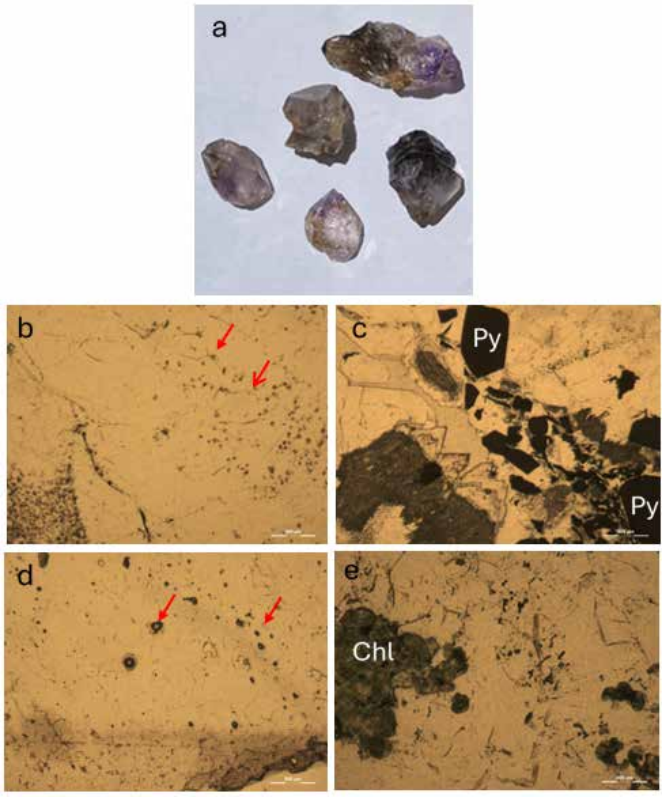

Figure 1. (a) Photo of scepter-shaped amethyst samples from the area of Dassoto, Drama. (b) Photomicrograph of zebra-like inclusions in DAS01B taken in parallel Nicols in transmitted light with magnification x25.(c) Photomicrograph of pyrite included in quartz in MAN01D taken in parallel Nicols in transmitted light with magnification x25. (d)Photomicrograph of two-phase fluid inclusions in KOI01 taken in parallel Nicols in transmitted light with magnification x25. (e) Photomicrograph of chlorite in LEY01A taken in parallel Nicols in transmitted light with magnification x4.

Regarding their microscopic observation, DAS01B sample was selected. Zebra-like inclusions, alternating dark and light parallel color bands related to twinning in the crystal (Gem-A, 2022), iron oxides, negative crystals and feldspars were observed in the DAS01B sample (Figure 1b). In this context, “negative crystals” will refer to hollow, crystal-shaped cavities, particularly exhibiting trigon-like geometry.

Rock crystal

This group includes six (6) samples (DAS01D, PAN01, MAN01A, MAN01B, MAN01C, MAN01D) from the areas of Dassoto, Panorama in Drama and Madem Lakkos in Chalkidiki. Along with amethyst samples from the Dassoto area of Drama, a prismatic crystal of colorless quartz with a few chlorite inclusions was collected and analyzed. This crystal gave values of 1.544 and 1.533 for refractive indices and for specific gravity 2.62. The crystal from Panorama has several inclusions of chlorite, rutile and possibly actinolite. The values of the refractive indices are 1.548 and 1.557 and the specific gravity 2.60. Three of the four samples from the Madem Lakkos deposit in Chalkidiki had their refractive indices measured, while the fourth sample (MAN01D) was excluded due to measurement constraints. Therefore, the refractive index values for Madem Lakkos are1.547±0.002 and 1.556±0.002 and the specific gravity was determined to be 2.65±0.02.

DAS01C and MAN01D samples were analyzed using microscope. Iron oxides in cracks, negative crystals, feldspar, muscovite and chlorite were identified in the DAS01C sample. In the sample MAN01D, pyrite, chlorite, iron oxides in cracks, negative crystals, feldspars and fluid inclusions were identified (Figure 1c).

Table 1. Summary of the refractive indexes of Greece’s quartz.

Samples	**Refractive Indexes**	
Amethyst		
DAS01A	1.540	1549
DAS01B	1.543	1.552
DAS01C	1.545	1.554
DAS01E	1.544	1.553
DAS01F	1.546	1.555
Rock crystal		
DAS01D	1.544	1.553
PAN01	1.548	1.557
MAN01A	1.549	1.558
MAN01B	1.548	1.557
MAN01C	1.545	1.554
MAN01D		
Smoky quartz		
KOI01	1.540	1.549
DAS02A	1.530	1.539
DAS02B	1.548	1.557
DAS03A	1.542	1.551
DAS03B	1.550	1.559
Milky quartz		
LEY01A	1.544	1.553
LEY01B	1.548	1.557
KAT01	1.540	1.549

Smoky quartz

Refractive index measurements were taken from five (5) samples (KOI01, DAS02A, DAS02B, DAS03A, DAS03B), with colors ranging from light to dark, from the areas Koinira in Thassos and Dassoto in Drama. For Koinira, measured values were 1.544 and 1.553. However, they varied significantly between light quartz samples or between light and dark. Specifically, the refractive indices were 1.539 ± 0.009 and 1.548 ± 0.009 for light smoky quartz and 1.546 ± 0.004and 1.555 ± 0.004 for dark smoky quartz from Dassoto. The specific gravity measured for all samples gave values limited to 2.66 ± 0.03.

Samples KOI01, DAS02B, and DAS03C (equivalent to DAS03A and DAS03B) were selected for microscopic observation. Iron oxides in cracks, negative crystals, muscovite and fluid inclusions (one and two-phase) were identified in the KOI01 sample (Figure 1d). In DAS02B iron oxides, fluid inclusions (both one- and two-phase), negative crystals, muscovite and possibly metallic minerals were recognized, while in DAS03C iron oxides in cracks, muscovite and liquid inclusions (both one- and two-phase) occur.

Milky quartz

Three (3) samples were analyzed (LEY01A, LEY01B, KAT01) from Lefkopetra in Xanthi and from Kato Vrontou in Drama. The refractive indices are 1.546 ± 0.002 and 1.535 ± 0.002 for Lefkopetra of Xanthi and for Kato Vrontou 1.540 and 1.459. The specific gravity for all samples is 2.62 ± 0.01.

Samples LEY01A and KAT01 were examined under the microscope. Chlorite and muscovite were the main mineral inclusions found in sample LEY01A (Figure 1f). Iron oxides were detected in cracks, while fluid inclusions and negative crystals are common. In sample KAT01, feldspar, muscovite, clinopyroxene, iron oxides in cracks, fluid inclusions (both one- and two-phase) and chlorite (near the margin) were observed.

Most of the samples from Brazil are consisted of colorless quartz, with two exceptions. They are likely of hydrothermal origin, as the majority predominantly contain two-phase fluid inclusions. The studied samples of Brazil are divided in two varieties and representative results of their characterization presented as follows:

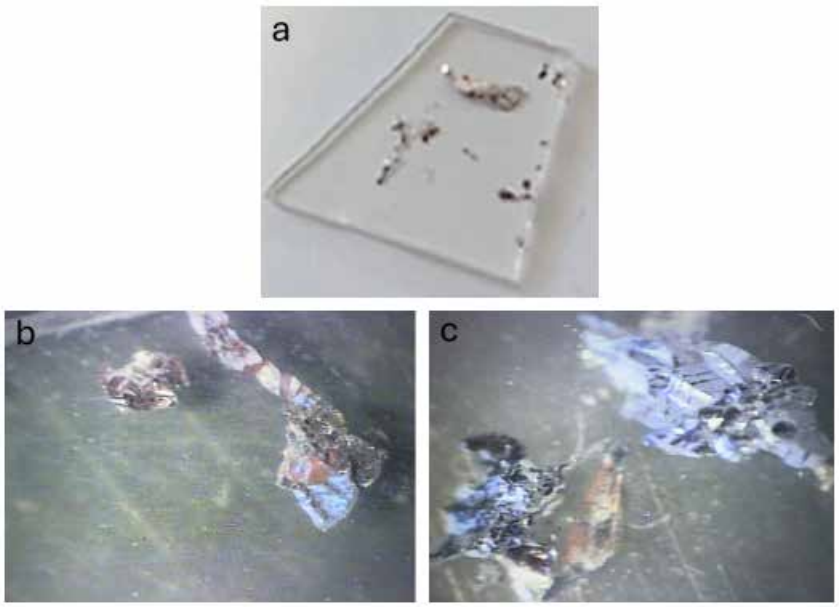

Figure 2. (a) Photo of red and black inclusions showing dendritic form in sample MIN04 from Minas Gerais, Brazil. (b, c) Photomicrographs of red and black inclusions in sample MIN04 as shown in a gemological microscope with magnification x 30.

Rock crystal

In total, seventeen (17) samples were analyzed. Based on macroscopic observation, eleven (MIN03,

MIN05, MIN06, MIN09, MIN10, MIN11, MIN13, MIN14, MIN15, MIN16, MIN17) appear clear and vitreous, containing little to no inclusions. Their refractive indices range from 1.543 to 1.550 and from 1.552 to 1.599with specific gravity of 2.60 ± 0.05. Samples MIN01 and MIN19 exhibit high concentration of liquid inclusions, with measured values1.549+ 0.001 and1.558 + 0.001for refractive indices and 2.63 + 0.01 for specific gravity. In MIN04 and MIN08, red and black inclusions that in localized spots are showing dendritic form were macroscopically visible (Figure 2a), while MIN12 contained orange-colored iron oxides. The refractive indices are limited to 1.543+ 0.007 and 1.552 + 0.007and the specific gravity is 2.59 + 0.05. Finally, although MIN07 appeared mostly transparent, chlorite was observed macroscopically. Its refractive index values are 1.539 and 1.548 and its specific gravity is 2.64.

For their microscopic observation, samples MIN01, MIN03, MIN07, MIN08, MIN12 and MIN15 were selected. Plagioclase, muscovite and fluid inclusions (both one- and two-phase) were observed in MIN01 sample. In MIN03 and MIN07 samples, iron oxides in cracks, fluid inclusions (both one- and two-phase), muscovite, negative crystals and chlorite were distinguished, while in MIN15 negative crystals, iron oxides, muscovite and chlorite were distinguished (Figure 2b). Also, iron oxides, negative crystals, muscovite and hematite were identified in MIN08.

Table 2. Summary of the refractive indexes of Brazil's quartz.

Samples	**Refractive Indexes**	
Rock crystal		
MIN01	1.550	1.559
MIN03	1.550	1.559
MIN04	1.543	1.552
MIN05	1.543	1.552
MIN06	1.550	1.559
MIN07	1.539	1.548
MIN08	1.550	1.559
MIN09	1.549	1.558
MIN10	1.548	1.557
MIN11	1.544	1.553
MIN12	1.550	1.559
MIN13	1.550	1.543
MIN14	1.543	1.552
MIN15	1.543	1.552
MIN16	1.550	1.559
MIN17	1.550	1.559
MIN19	1.549	1.558
Smoky quartz		
MIN02	1.543	1.552
MIN18	1.550	1.559

Smoky quartz

The color of MIN02 and MIN18 samples is presented as light brown color. The refractive indices obtained from the measurement of the two (2) samples are 1.543 + 0.007 and 1.552 + 0.007 and the specific gravity showed values 2.62 + 0.03.

Sample MIN02 was chosen for microscopic observation. Iron oxides in cracks, negative crystals and fluid inclusions (both one- and two-phase) were identified in the sampleMIN02.

Conclusions

Samples from Greece include mineral varieties such as: amethyst, rock crystal, smoky quartz and milky

quartz, while those derived from Brazil mainly include smoky quartz. So far, the following conclusions can be drawn:

- The difference between refractive indices of the same variety or the same country or the two countries is random and no correlation can be concluded.
- As for the specific gravity (SG) in Greek samples, is observed that amethysts, rock crystal from Drama and milky quartz have SG < 2.65 but rock crystal from Chalkidiki and smoky quartz have SG > 2.65. On the other hand, in Brazilian samples, all except two have SG < 2.65. However, they are exceptions in their variety because one is a rock crystal and the other is smoky quartz.
- Even though Brazilian amethyst was not included in this study, it was observed that amethyst from Greece contains zebra-like inclusions. Zebra-like" inclusions are typical of amethyst, but there are not always present in a sample. The observation of this type of inclusion in a Greek sample is worth mentioning.
- Inclusions that were present in every sample were iron oxides in cracks, negative crystals and fluid inclusions. Both muscovite and chlorite were frequently found in both Greek and Brazilian samples.

As this study is still evolving, the evaluation of XRD data of some samples is not completed while their characterization via other analytic techniques (e.g. SEM, FTIR and Raman) is in progress. The results of a fully characterization in macro-micro-nano scale of quartz gem crystals with combined methods will be presented in the future in order to be used as a new data base of gems from Greece and/ or other areas. It is considered that it will be enriched by new research in the future, providing significant geological, gemological information in a more systematic mode.

Acknowledgements

Thanks to the postgraduates student Pahaki M. and graduate student Skontovolou L. for their help, the cutting workshop Michael Hatzimihail that polished the samples and the EAGME laboratories for preparing the thin sections of samples.

Introduction

UNESCO Global Geoparks are geographically defined areas that combine monuments of significant geological value with elements of ecological, cultural, and aesthetic importance. They are managed with a holistic approach to protection, education, and sustainable development. They are ideal destinations that support local communities and serve the 17 goals of the United Nations' Green Agenda in various ways.

Education in the frame of a UNESCO Global Geopark

One of the main axes of action for geoparks is Education. UNESCO Global Geoparks implement educational programs based on the geodiversity and biodiversity they host. Through collaborative partnerships, they educate and prepare societies for new, modern challenges. Geosites function as experiential laboratories, welcoming students, educators, and visitors to offer them unique experiences.

A good practice of such actions, aimed at preparing societies to tackle the climate crisis and adapt to new conditions, are the workshops for educators organized by the Lavreotiki UGGp in collaboration with the Lavrion Environmental Center (KEPEA) and/or other educational institutions active in the area. These workshops are often organized in the frame of the celebration of an established World Day.

Figure 1. Workshops for teachers and educators within the Lavreotiki UGGp.

The geosites of the Lavreotiki Geopark play a leading role during the workshops, offering stimuli and many opportunities for exploration and interaction with the environment, engaging and inspiring teachers and educators. In the field, the participant does not remain a mere spectator but experiences a rich learning experience. The Lavreotiki Geopark boasts numerous geosites that demonstrate the different environments (terrestrial, lacustrine, marine) that have developed in the territory and record climate changes over geological time, along with the impact on the palaeoenvironment, the societies and the living organisms. Among the notable geosites, are the lacustrine deposits of the "Alogari" hill, the submerged paleo-coasts along the geopark's coastline (such as the submerged port of Thorikos) and the karstic geomorphs of Kaki Thalassa.

Figure 2. Lavreotiki UGGp's geosites: Left: the lacustrine deposits of Alogari hill. Middle: karstic geomorphs of Kaki Thalassa. Right: submerged port of Thorikos.

However, the monuments that make Lavreotiki UNESCO Global Geopark unique in the world, except for its geological heritage and geodiversity, are the sites of mining heritage. The installations of the ancient Greeks for mining and metallurgy represent a perfectly designed infrastructure, harmonized with the climatic conditions of the time.

In antiquity, similar to the present time, Lavreotiki was an arid area with limited water resources but significant water needs. In ancient societies, water covered the biological needs of people, the needs for cultivating the land and raising animals, while large quantities were needed in mining and metallurgy. Given the large industrial zones that had developed in Lavreotiki (for the collection and processing of the ore deposits), the presence of water was of crucial importance. The ancient Greeks had addressed the high demand with innovative methods of water recycling and reuse for the time.

A characteristic example of such a mining heritage monument is the geosite named *"Souriza valley,"* located in the National Park of Sounion. It is the most representative site of ancient mining and metallurgical activity in the geopark, which gave birth to an unparalleled civilization. The entire area (now a declared archaeological site) hosts numerous mining galleries and metallurgical workshops, as well as other facilities for housing miners. Mining and metallurgical work followed a specific practical process, related to the type of extracted product, the depth of the deposits, and the necessary processing and subsequent smelting for the extraction of argentiferous lead. With the development of technology, mining and metallurgical practices improved relatively, and more productive technological installations were invented (Morin, D. *et al*., 2021). As a result, the entire ore-bearing land of Souriza became a vast working area. Today, many of the ore enrichment workshops are very well preserved. The working areas included ore crushing and grinding areas, a washing plant, storage areas for processed ore and concentrate, and one or more water tanks for the operation of the washing plants (Konofagos *et al*., 1970; Papadimitriou, 2017).

Figure 3. Aerial photo of the "Souriza valley" – mining and metallurgy center.

Water management was very well studied. The washing plant installations were developed within the valleys to utilize rainwater runoff from the slopes. Given the lack of atmospheric precipitation, the main concern of the ancient metallurgists was to prevent water loss, which was essential for the operation of the washing plants. For this reason, the internal surfaces of the rainwater tanks, as well as the washing plants and pipelines, were lined with a special hydraulic mortar (Meimaroglou *et al*., 2023).

Case study: World Water Day - sustainable water use

In the context of celebrating World Water Day (on 22nd March each year), the Lavrion Environmental Center, with the participation of the Lavreotiki Geopark, organizes a workshop for all educators, including a 3hours visit to the "Souriza valley" geosite. The main thematic units of the workshop are:

- The importance and use of water in modern societies.
- The importance and use of water in antiquity.
- The journey of water through geological time in the Lavreotiki UNESCO Global Geopark.
- Sustainable management of water, the example of water recycling – the ancient mining center of "Souriza valley".
- Modern challenges in the era of the climate crisis.

The role of the Lavreotiki UGGp

The Lavreotiki geopark hosts geosites that narrate impressive changes related to the distribution of water on the Earth's surface over geological time. From sea-level changes during the Quaternary period to the ancient lakes that existed during the Miocene era and the changes in the hydrological basins of its streams (Pavlopoulos, 1992 & Vasileiou, 2010), the participants of the workshop can understand how significant changes occur on the land we inhabit, cultivate, and exploit. A characteristic example is the ancient Greeks and their efficient water management, as evidenced by the archaeological/mining findings in the Souriza Valley. During the seminar, the aforementioned data are presented, emphasizing the importance of adapting to climate changes and the sustainable management of Earth's resources.

Results

The participation of educators is always high, and they fulfil the program with great interest. Upon completion of the workshop, an evaluation process follows. The table below presents the statistical results of the last workshop (year 2024).

Table 1. Indicative statistical results of the workshop's evaluation form.

No of applications	Hosting capability (No of participants)	No of participants	gender		Evaluation of the workshop		Comments for improvement
			male	female	Satisfied	Not satisfied	
95	20-60	62	19	43	62	-	Longer duration / recurrence

Workshops, such as the latter study case, that offer educators modern scientific knowledge, new perspectives in fundamental issues, such as the sustainable use of water and present free educational tools, enhance school communities and the next generations. Meaningful partnerships, such as the example between the Lavrion Environmental Center and the Lavreotiki UGGp, represent good practices for the adaptation and sustainability of local communities in the era of the climate crisis. They cultivate interdisciplinarity and communicate science and universal values, such as cooperation, respect, inclusion, and quality education, to the general public. These values are included and promoted by the United Nations Sustainable Development Goals (such as SDG 4, SDG 11, SDG 12, SDG 13, and SDG 17).

Figure 1. The SDG's promoted through this educational action of the Lavreotiki UGGp and the Lavrion Environmental Center.

EXTENDED ABSTRACT 027

The world class geodiversity of the Lavreotiki UNESCO Global Geopark's minerals, Lavreotiki Municipality, Greece

Barsaki V.[1], Voudouris P.[2] & Moraiti E.[1]

(1) Lavreotiki UNESCO Geopark, 1 Koundouriotou str., 19500 Lavrion, Attica, Greece. e-mail: vasilikibarsaki@gmail.com

(2) Faculty of Geology and Geoenvironment NKUA, University Campus, Zografou, 15784 Attica, Greece.

Lavreotiki UGGp mineralization

The Lavreotiki Geopark occupies the area where both hypogene and supergene processes created an amazing underground world, decorated with an exquisite variety of minerals of international recognition and value. Its mineralization is unique and of high geodiversity, as the territory contains 748 naturally occurring mineral species, the most of any other district in the world (Rieck, 2024; https://www.mindat.org/loc-1942.html). From about 10 to 7 million years ago, massive tectonic movements along the so-called "Western Cycladic Detachment System", accommodated magma emplacement, and facilitated hydrothermal fluid circulation and ore deposition within permeable lithologies. These processes in combination with subsequent supergene oxidation of the ores, gave birth to one of the most important, historically and economically, polymetallic deposits in the world exploited by the Ancient Greeks and during the modern times (Voudouris *et al.*, 2008; Boshall *et al.*, 2011; Ross *et al.*, 2021).

The mining and metallurgical industry, developed in antiquity -which triggered the cultural and economic development of the city-state of Athens, as well as its hegemonic role in classical times- has gained worldwide scientific interest. Essential questions concerning the mining of ores and their processing remain unresolved (Conophagos, 1980).

Geodiversity

- 5 different types of mineralization are present in the geopark's ore deposits.
- The Lavreotiki UGGp hosts some of the best mineral specimens in the world.
- It hosts the biggest collection of the most impressive pseudomorphs.
- 60 chemical elements of the periodic table are presented in the geopark's ore deposits.
- The extended and ongoing oxidation of the primary ore resulted in the formation of one of the best developed oxidation zones on Earth (up to 270 m thick).
- 25 Type Locality (TL) minerals.
- Slag minerals (150 valid mineral species and 7 Type Locality Minerals).
- The Lavreotiki UGGp is included in the top ten areas, worldwide, with the highest variety in minerals.

Figure 1. Left: Hilarionite FOV: 3mm, right: Agardite-[Nd] FOV: 3mm, (copyright Toth Lazlo).

The TL mineral list of the Lavreotiki UGGp

The geopark hosts ten geosites (ancient and modern mining galleries), where 25 minerals have been identified for the first time worldwide and are included in the International Mineralogical Association's list of Type-locality minerals (IMA list) (Pekov *et al*., 2011; Voudouris *et al.*, 2021; Rieck, 2024). The localities belong to the most impressive and probably the most unique labyrinth mining centers in the world.

Table 1. List of the Type – locality minerals from the Lavreotiki UGGp.

Mineral	Formula	Mining gallery
Agardite – (Nd)	$NdCu(AsO_4)_3(OH)_6 \cdot 3H_2O$	Hilarion 50
Attikaite	$Ca_3Cu_2Al_2(AsO_4)_4(OH)_4 \cdot 2H_2O$	Christiana 132
Drobecite	$CdSO_4 \cdot 4H_2O$	Esperanza
Fabrizite	$Zn_9(SO_4)(OH)_{12}Cl_2 \cdot 6H_2O$	Hilarion
Glaucocerinite	$(Zn_{1-x}Al_x)(OH)_2(SO_4)_{x/2} \cdot nH_2O$	Serpieri
Hilarionite	$Fe^{3+}_2(SO_4)AsO_4)(OH) \cdot 6H_2O$	Hilarion 50
Kamarizaite	$Fe^{3+}_3(AsO_4)_2(OH)_3 \cdot 3H_2O$	Kamariza
Kapellasite	$Cu_3Zn(OH)_6Cl_2$	Sounion 19
Katerinopoulosite	$(NH_4)Zn(SO_4)_2 \cdot 6H_2O$	Esperanza
Katsarosite	$Zn(C_2O_4) \cdot 2H_2O$	Esperanza
Ktenasite	$ZnCu_4(SO_4)_2(OH)_6 \cdot 6H_2O$	Jean Baptiste
Laurionite	$PbCl(OH)$	Kamariza
Lazaridisite	$Cd_3(SO_4)_3 \cdot 8H_2O$	Esperanza
Mereiterite	$K_2Fe(SO_4)_2 \cdot 4H_2O$	Hilarion 50
Natroglaucocerinite	$[Zn_5Al_3(OH)_{16}][(SO_4)_{1.5}Na_{1.5}(SO_4)_{0.75}(H_2O)_9]$	Hilarion
Nickeltsumcorite	$Pb(Ni,Fe^{3+})_2(AsO_4)_2(H_2O,OH)_2$	"km3"
Niedermayrite	$CdCu(SO_4)_2(OH)_6 \cdot 4H_2O$	Esperanza
Pracharite	$CaSb^{5+}_2(As^{3+}_2O_5)_2O_2 \cdot 10H_2O$	Plaka 80
Serpierite	$Ca(Cu,Zn)_4(SO_4)_2(OH)_6 \cdot 3H_2O$	Serpieri
Stergiouite	$CaZn_2(AsO_4)_2 \cdot 4H_2O$	Plaka 80
Voudourisite	$Cd(SO_4) \cdot H_2O$	Esperanza
Tzeferisite	$CaZn_8(SO_4)_2(OH)_{12}Cl_2(H_2O)_9$	Damianos
Zincaluminite	$Zn_6Al_6(SO_4)_2(OH)_{16} \cdot 5H_2O$	Hilarion
Zincolivenite	$CuZn(AsO_4)(OH)$	Kamariza
Zincowoodwardite	$[Zn_{1-x}Al_x(OH_2][(SO_4)_{x/2} \cdot n(H_2O)]$	Christiana

Lavreotiki Geopark's geological heritage contains geosites of international value, most of them representing its amazing underground world. In particular, the geopark hosts ten ancient and modern mining galleries, all branches of the following three mining centers, Plaka, Agios Konstantinos (Kamariza) and Sounion center. The geopark maintains a geodatabase concerning its minerals of international value and the labyrinth mining centers, constantly enriched with the latest scientific discoveries and the corresponding localities.

EXTENDED ABSTRACT 028

Highlighting the Geological Heritage of the Island of Kythira, Greece

Barsaki V.[1], PhD. Zananiri I.[1]& Moraiti E.[1]
(1) Hellenic Survey of Geology and Mineral Exploration (HSGME), Acharnes, Greece, email: vmparsaki@eagme.gr, vasilikibarsaki@gmail.com

Introduction

The geological heritage of a country consists of sites that reflect its geological history. Geosites are locations where the historical record of the Earth is preserved and testify to its long-term evolution, as well as areas where contemporary planetary processes are recorded. Geological heritage combined with biodiversity constitutes the natural heritage of a territory, describes its unique identity and should be protected for the benefit of present and future generations.

To achieve these goals, in the frame of the "GEOINFRA" project ("Geological Mapping of Greece for the support of innovation and entrepreneurship"), Work package 5 "Documentation of Geosites and Geotrails, Geopark studies" (NSRF 2014-2020/2023), the Hellenic Survey of Geology and Mineral Exploration selected Kythira Island for recording and promoting its geological heritage. Due to its geographical and geotectonic setting, lying in the convergence of two tectonic plates in the southwestern part of the South Aegean Hellenic Arc and between the Ionian and the Aegean Sea, Kythira boasts significant geological, geomorphological and paleontological wealth. Tectonic structures, fossils, gorges, caves, coastal geoforms and rocks await visitors to narrate their own stories and myths.

Geography – geomorphology

Kythira island, located between Peloponnese and Crete along the Hellenic island arc, spans over an area of 280 km^2. The climate is characterized as "Mediterranean", with high relative humidity and strong winds mainly in winter. The dominant relief is semi-mountainous with deep valleys and a maximum altitude of 507 meters (Mermigaris Mount). A smooth plateau exists along the central part of the territory with a few arable zones. The coastline has a length of approximately 52 km and forms many pocket beaches, while the rugged coastal terrain is the combined result of tectonics and lithology along with the significant wave energy, shaping its shores into steep rocky cliffs with deep bays (Gaki *et al*., 2011).

Geology

The geological structure of the island of Kythira constitutes post-Alpine formations, the Pindos Unit overlying the Tripolis Unit and a metamorphic crystalline basement. The latter is highly folded and occupies the northern part of the island. Tripolis Unit and its carbonate rocks form the elongated mountain masses in the eastern and western part of the island; especially in the west limestones reach sea level, creating abrupt cliffs due to offshore faults. Pindos Unit domains are mainly located in the central and southern part of the island. The Neogene sediments extend mainly in the south and are primarily marine with intercalations of fluvial and lacustrine deposits. The latter are composed of sandstones, marls, marly limestones and conglomerates of transgressive (at the top) and regressive (at the bottom) origin. Concerning the tectonics of Kythira, an older pre-Alpine phase of ENE-WSW direction can be distinguished, which folded the metamorphic crystalline basement, followed by an Alpine phase responsible for the folding and faulting of the Tripolis and Pindos Units. Post-Alpine tectonism with NNW-SSE trending faults formed the modern terrain of grabens and horsts. Today, extensional tectonism has resulted in the ongoing uplift of the island and the recording of many catastrophic earthquakes (Lyberis *et al*., 1982).

The geological heritage of Kythira Island

The island of Kythira hosts a geological heritage of national significance. Lying in the convergence of two tectonic plates, next to the orogenic arc of East Mediterranean Sea, the island has been uplifted for millions of years. Kythira rise from the sea and the elements of this movement are reflected in its rocks, relief, and coastlines; ancient Greeks associated these movements with the birth of goddess Aphrodite and her emergence from the sea foam. During the Alpine Orogeny the rocks comprising Kythira's surface, were deformed, folded, and displaced due to the presence of

large-scale fault surfaces (Danamos, 1992 & Marsellos, 2008). Complex processes, accompanied by intense seismic activity, caused significant changes in the paleoenvironment, forming lakes or shallow seas, which are evidenced by the palaeontological findings across the island, e.g. the Mitata settlement (Bartsokas, 1998). The contemporary processes of the Earth sculpt the surface of Kythira and create landscapes of natural beauty and rarity that enrich the nine (9) thematic geotrails designated in the framework of the GEOINFRA project. More than one hundred geosites were recorded and classified in 14 different main categories (fig.1), according to their predominant geological features (Drandaki, 2009 & Moraiti, 2016).

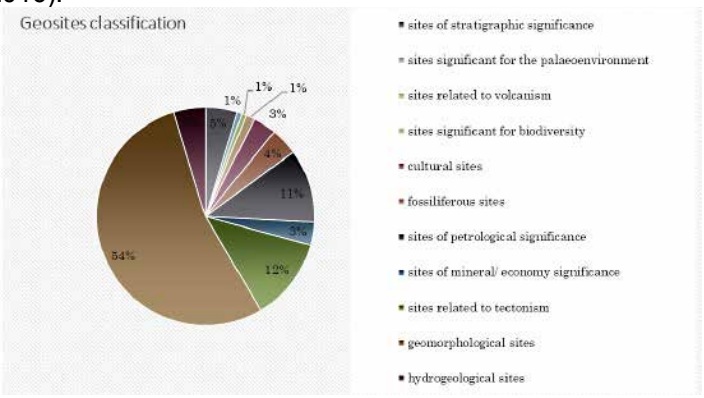

Figure 1. Classification diagram of the geosites recorded at Kythira Island, in the framework of GEOINFRA project.

The marine terraces of Platia Ammos, the oldest rocks of Kythira forming the pre-alpine basement (fig.2), the gorge of Kakia Lagada, Lykodimos beach, the cave of Agia Sophia in Mylopotamos hosting fossils of rudists and fault mirrors forming an impressive steep cliffed coast (fig.3), Kaladi beach, the marine cave on Chytra islet and the thanatocoenosis of lamellibranchia at Mitata (fig.4) are some examples of the most representative sites defining the core of Kythira's geodiversity.

Figure 2. Left: marine terraces at Platia Ammos beach, middle: regressive conglomerates at Platia Ammos beach and right: the oldest rocks of Kythira Island (pre-alpine basement).

Figure 3. Left: Kaki Lagada gorge, middle: Lykodimos beach, a cliffy coast of high aesthetic value depicting, in the left photo, the earth's modern processes and a record of tens of millions of years, while hosting the most impressive isoclinal folded limestones on Kythira Island as shown in the next photoand right: rudist limestones at Agia Sophia cave of Mylopotamos settlement.

Figure 4. Left: Kaladi beach hosting a tombolo/ coastal geoform, middle: marine cave of Chytra islet and right: thanatocoenosis of lamellibranchia at the Mitata suburbs.

Geotourism of Kythira

Geotourism is a mild form of tourism that has been rising during the last decades, especially in Europe (Ólafsdóttir, 2019). In the scope of promoting the geoheritage of Kythira, nine (9) geotrails were designated, connecting attractions of geological, archaeological, historical, cultural, environmental, and religious significance, as well as sites important for biodiversity, aiming to narrate the story of a destination in a holistic way. They were designed either to follow geographical boundaries or to support specific themes and have varying levels of difficulty, while one is a marine route visited solely by boat. During the designation of the trails specific safety specifications for travellers were followed, based on international and national standards

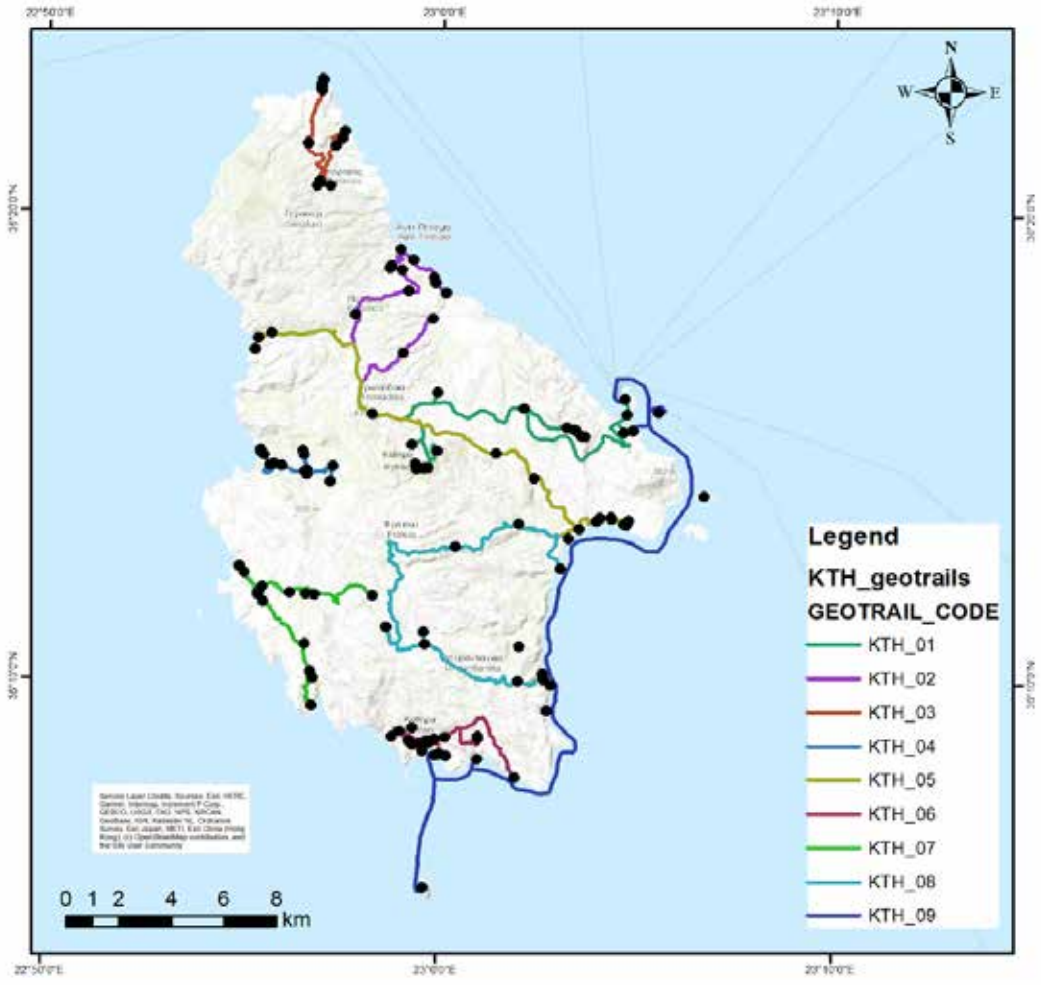

Figure 5. Mapped geotrails of Kythira Island.

Table 1. Presentation of the designed geotrails of Kythira Island.

Code	Name	Descriptive name	Short description	Nr of sites
KTH_01	Diakofti - Mitata	Discovering Kythira	This pleasant and scenic trail starts from the port of Kythira in Diakofti, where visitors first arrive, and ends inland, in the settlement of Mitata. From the first stops, the unique character of Kythira and the main geological features that have contributed to the creation of the island's identity are revealed. At the same time, one observes the dynamic relationship between humans and their natural environment over time and meets the living world of both the modern era and the geological past.	20
KTH_02	Palaiochora - Kaki Lagada	The gorge of the pirates	Linked to the raid of the pirate Barbarossa and the destruction of the Palaiochora Castle, this trail travels us through landscapes of exceptional natural beauty and picturesque settlements of another era, highlighting both modern processes of nature, as well as processes of millions of years that are still active and shape the unique biodiversity and geodiversity of Kythira.	14
KTH_03	Moudari - Karavas - Platia Ammos	Kythira from a different viewpoint	The geotrail starts from Cape Spathi, the northernmost point of Kythira, with its imposing monuments, the geological formations and landforms that compose a familiar landscape for the visitor. Soon the scenery changes and the trail lead us through rocks that do not resemble any other rock of the territory, narrating their own story. These are the most ancient rocks on the island, which today, 350 million years later, lie on the surface.	16
KTH_04	Arei - Mylopotamos - St. Sofia Cave	Unique landscapes	This geotrail of unique natural beauty starts from the traditional settlements of Arei and Mylopotamos, with its picturesque alleys and churches and elaborate bell towers. The valley of the watermills is an important attraction of the island, where nature and man mix in a unique way. The geotrail leads to the castle of Kato Chora and its amazing panoramic view and ends at the cave of Agia Sophia Mylopotamos. The cave hosts impressive speleothems and ecclesiastical elements of high value, while outdoors the scenery is comprised of fossilized limestones, hosting numerous marine organisms, such as rudists (~65 million years old).	16
KTH_05	Avlemonas - Paleopoli - Fratsia - Aroniadika - Lykodimos beach	Contrasts	Starting from the eastern shore of the island and its diverse beaches, the geotrail crosses the Paleopolis basin with its significant archaeological and palaeontological findings and through small, traditional settlements, ends up at the western coastline of the island. Lykodimos beach combines a landscape of wild and rare beauty, hosting steep cliffs, the most impressive isoclinal folds and unique coastal geoforms, remnants of the timeless struggle between the exogenous and endogenous forces of nature.	19
KTH_06	Agia Elessa - Chora (Kythira) - Kalamos - Chalkos beach	Geology and culture	This geotrail highlights the geological and cultural attractions of the capital city of Kythira. Over the centuries, the island has been a crossroad of cultures, mainly due to its geographical location and the many conquerors who controlled the territory during different eras. Visits to the museums of Chora provide reach information on the long history and the identity of the island. Along the geotrail the geology intertwining with man offers beautiful geosites, revealing interesting stories.	16

KTH_07	Keramoti - Kalokerines - Limnaria - Melidoni	Wild nature	This geotrail crosses the western part of Kythira, offering visitors the possibility to wander around rocky landscapes, next to the highest mountain peaks of the territory. The mountainous mass of Agia Elessa, with the homonymous monastery, at an altitude of 476m, owes its formation to a large tectonic structure, perhaps the largest mapped on the island, extending for several kilometres. Heading to Limnaria beach, the type locality of the wildflower *Limonium aphrodita sp.*, the trail crosses "Tyros layers", a geological formation only seen here. The tour ends at Melidoni beach, with an amazing view of the Chytra islet.	15
KTH_08	Kaladi - Agios Ilias - Livadi - Fyri Ammos	Landscapes and colours	The geotrail connects two enchanting destinations on the eastern coasts of the island, Kaladi beach and Fyri Ammos Livadi beach. These are the two most famous beaches of Kythira, where visitors can enjoy the sun and sea in a riot of colours. The geological formations create unique landscapes, with impressive coastal geoforms, alternating with white, red, and yellow rocks, giving the waters turquoise and deep blue hues. Modern earth processes sculpt the relief, and landslide phenomena dominate. Almost the entire trail passes through rocks that formed millions of years ago in a deep ocean, and many Byzantine chapels. Fields with shrub vegetation, and olive groves dominate.	17
KTH_09	Kapsali - Diakofti	...from the sea	This marine geotrail starts from the port of Kapsali. After visiting the islet of Chytra, with the impressive sea cave and its unique biodiversity, hosting the *Sempreviva sp.*, the flower of Paris and beautiful Helen, traverses the coastline of Kythira back to the port. It offers alternative, memorable experiences, allowing visitors either to reach some inaccessible beaches or admire the island's most famous ones by sea. The last attraction is the "Nordland" shipwreck at Diakofti beach, an ideal destination for divers.	20

Geotouristic products designed for Kythira Island in the frame of GEOINFRA project

A total of 150 sites of geological interest were recorded, processed and evaluated, while data concerning the island's biodiversity, cultural heritage and history were collected and enriched the HSGME's geodatabase. The project's outcomes concerning Kythira included:

- 9 mapped geotrails
- 18 interpretation panels for 9 different areas of geological interest, in Greek and English
- 1 mobile application
- 1 geotouristic guide entitled "Kythira"
- 1 ESRI story map entitled "Geotourism in Kythira Island".

Figure 6. Examples of the interpretation panels designed by the HSGME for the promotion of geotourism in Kythira Island.

Introduction and objectives

The area offshore the central Ionian Islands (Cephalonia, Lefkada, Zakynthos, and Ithaca), western Greece, is considered as one with the highest seismic activity and tsunamigenic potential among the seismogenic Mediterranean regions. A series of destructive earthquakes, such as the 1953 events (Mw > 6.6; Stiros et al. 1994) that destroyed the island of Cephalonia and Zakynthos, or more recent events such as the 28 October 2018 Mw 6.8 Zakynthos (Ganas et al., 2020) affect the area and most of these have the epicentre located in the offshore. The earthquakes are due to plate convergence across the Ionian Sea, as Africa (Nubia) subducts beneath Peloponnese while a major right-lateral fault (the Cephalonia Transform Fault) transfers horizontal motion towards North where Adria (Apulia) subducts beneath Northwest Greece (Epirus) and Albania (Fig.1). However, a complete mapping and understanding of the all-geological risk elements affecting the offshore of the islands has not yet been produced to date. During recent surveys, carried out in June 2023 on board of the R/V Laura Bassi - the POSEIDON project supported by the Eurofleet+ program and in May 2022 on board of the R/V G. Dallaporta supported by the Italian CNR - IONIANS cruise carried out, a multiscale geophysical dataset has been collected together with sediment samples. The collection of such data was fundamental for our seabed interpretation and for the production of an accurate map of submarine geohazards in this area.

Method

The morphological interpretation is based on TOPAS seismic profiles, EMODNET bathymetry and higher resolution bathymetric data collected in the frame of the POSEIDON 2023 project.

First, we geolocated and uploaded all seismic data on Kingdom software, which we used to view georeferenced seismic profiles and annotate visible morphologies of interest, such as faults, landslide bodies, gas and fluids trapped within sediments (Fig.2).

We then proceeded with the bathymetric interpretation of the seabed in Global Mapper software, which provides tools such as 3D models and 2D bathymetric profiles, through which we were able to locate and recognize several elements of interest (canyons, canyon heads, landslide scars, tectonic deformations etc.).

Finally, merging the seismic interpretation with the bathymetric one, we produced a map of all the morphologies that represent geohazards in the Ionian Island area (Fig. 3). The map was graphically refined using Adobe Illustrator.

The map of geohazards, produced using geophysical data, will be in a second step integrated with geological data obtained by sediments sampled with a gravity corer in a very deep basin (4220 m below sea level) offshore Zakynthos.

Results

The analysis of all available data, following the method above shortly described, allow us to map a series of morphological scarps bounding the western slope of Cephalonia and Lefkada. These scarps correspond with the shallow expression of the Cephalonia Transform Fault, which to the south is organized into a system of horseshoe-shaped faults that to the north merge into a single fault boarding the area off northern Cephalonia and the coast of Lefkada. The entire fault system results more than 120 km-long and, in the southern part, more than 20 km-wide (Fig. 3). We were also able to identify and map in high detail the seafloor displacement and the fault plane north of Lefkada by using Topas data.

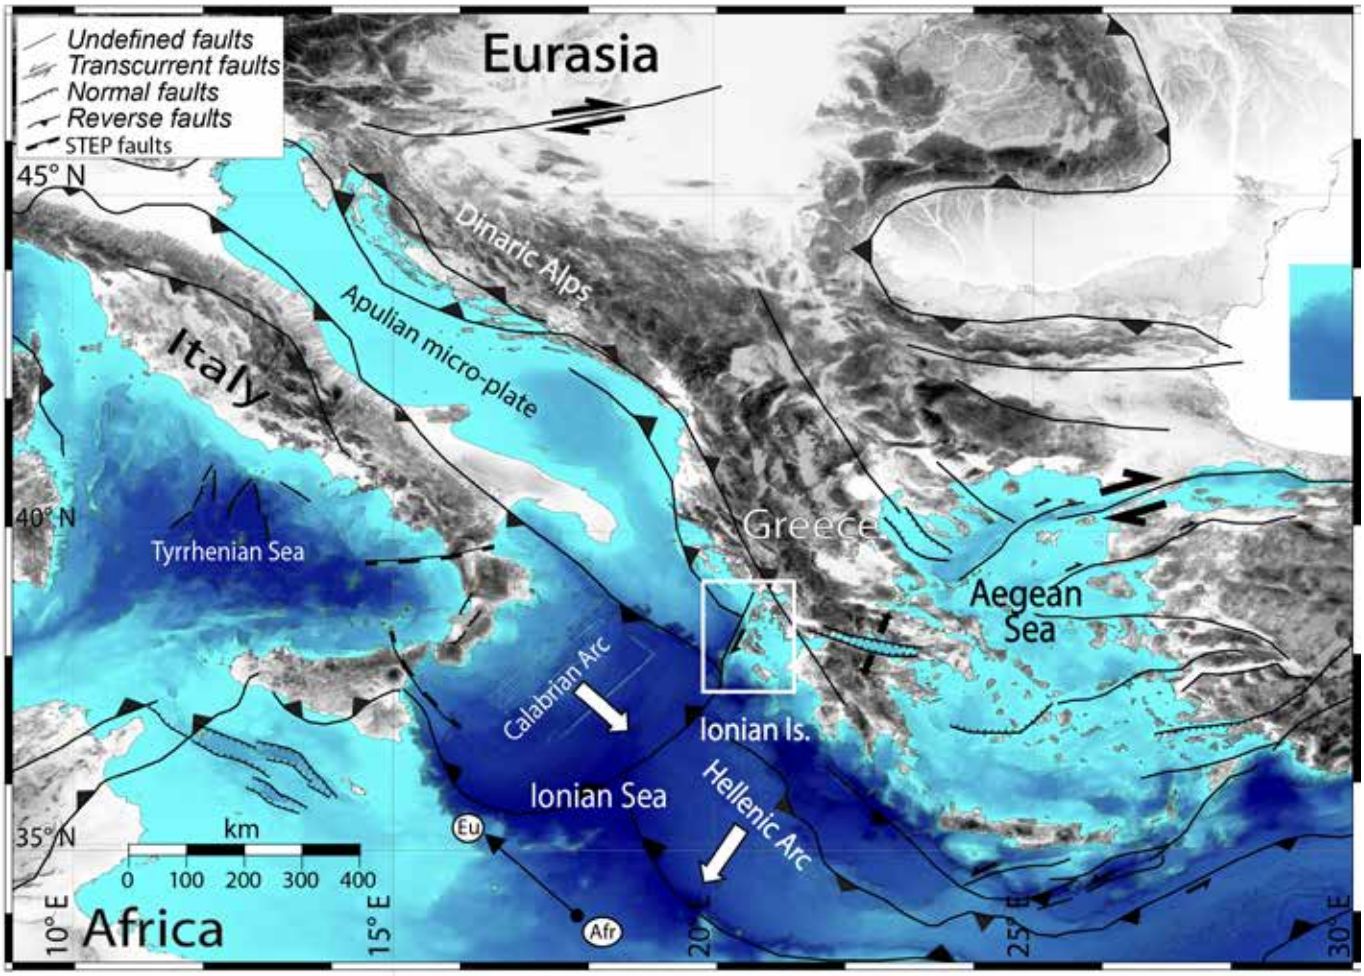

Figure 1. Tectonic map of the central Mediterranean with location of the study area (white box). Bathymetry data download from EMODnet portal https://emodnet.ec.europa.eu/en/bathymetry#bathymetryapproach) and gridded using GMT software (Wessel et al., 2019). Mediterranean structural sketch modified after an online Tectonic Map (Woudloper - Own work, CC BY-SA 1.0) and by Loreto et al., 2020. The Thick white arrows mark the migration of the active accretionary prisms; Black thick arrows mark the main cinematic of faults. Thin black arrow marks the convergence of Africa toward Eurasia. The map is represented in geographic coordinates on Mercator Projection.

A series of submarine channels and canyons have been mapped, most of them located off Lefkada and others along the slope of the elongated N-S ridge south of Cephalonia. Some of these channels

are interrupted or dislocated by the morphological scarp associated with the Cephalonia Fault System. Other canyons, but in smaller quantities, are found along the slope south of Zakynthos and west of the Peloponnese. Here, the numerous landslide scars that have been mapped show a regressive/erosive character. While south of Zakynthos there is a giant landslide with a scar more than 10 km-wide responsible for the intense erosion affecting the slope, which is further shaped by the presence of NE-SW oriented morphological scarps.

The internal basin, bounded by the Ionian Islands and Western Greece (Fig. 3), shows a few small randomly distributed ridges sometimes associated with evaporite upwelling other times associated with tectonic activity. However, the most interesting finding in this basin are the several huge landslides or body collapses buried under recent, Holocene, sediments. These landslide bodies are characterized by great internal chaos and intense gas/fluid release capable of deforming the overlying well-stratified sediments. Several gas/fluid upwellings have also been recorded in the sea strip between Cephalonia and Ithaca (Fig. 2), where they remain trapped under a well-identifiable layer, probably characterized by a lithology with low permeability.

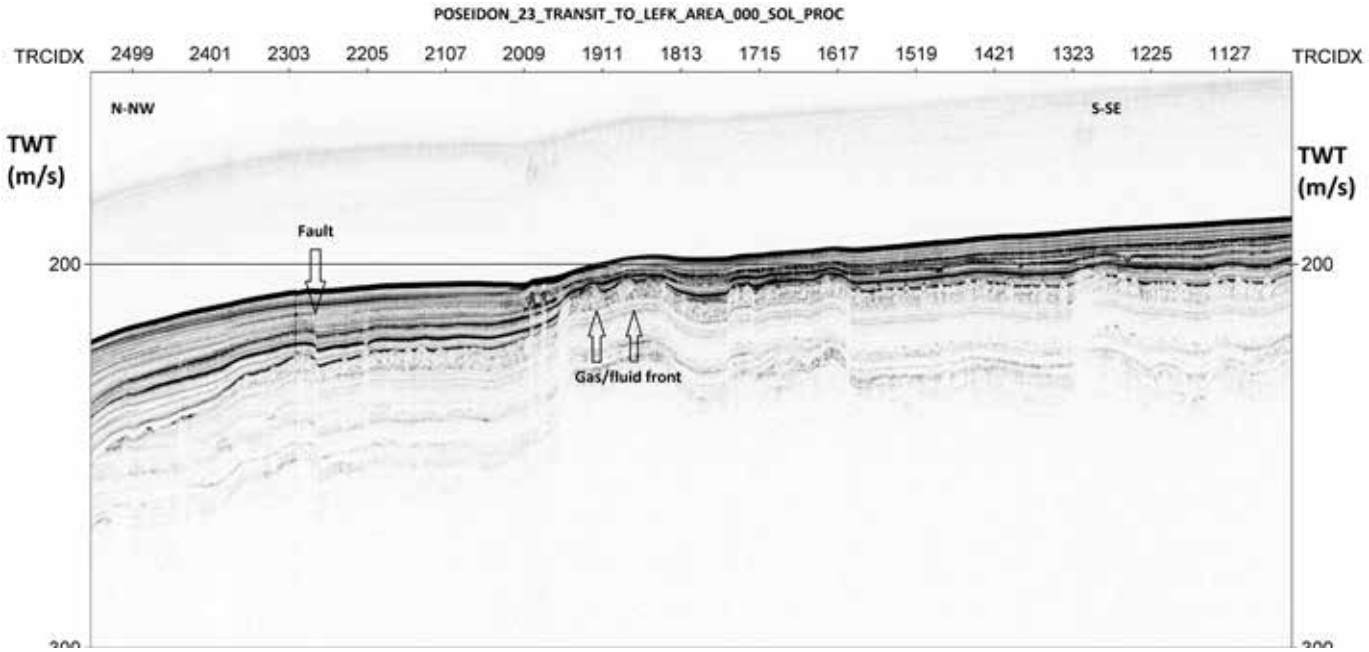

Figure 2. Section of a Chirp profile from data collected during POSEIDON 2023 oceanographic cruise. The fault highlighted on the left is recognizable because of the horizons' offset, while the gas/fluid bubbles can be identified because of whitening effect and of deformation they cause on the host layer.

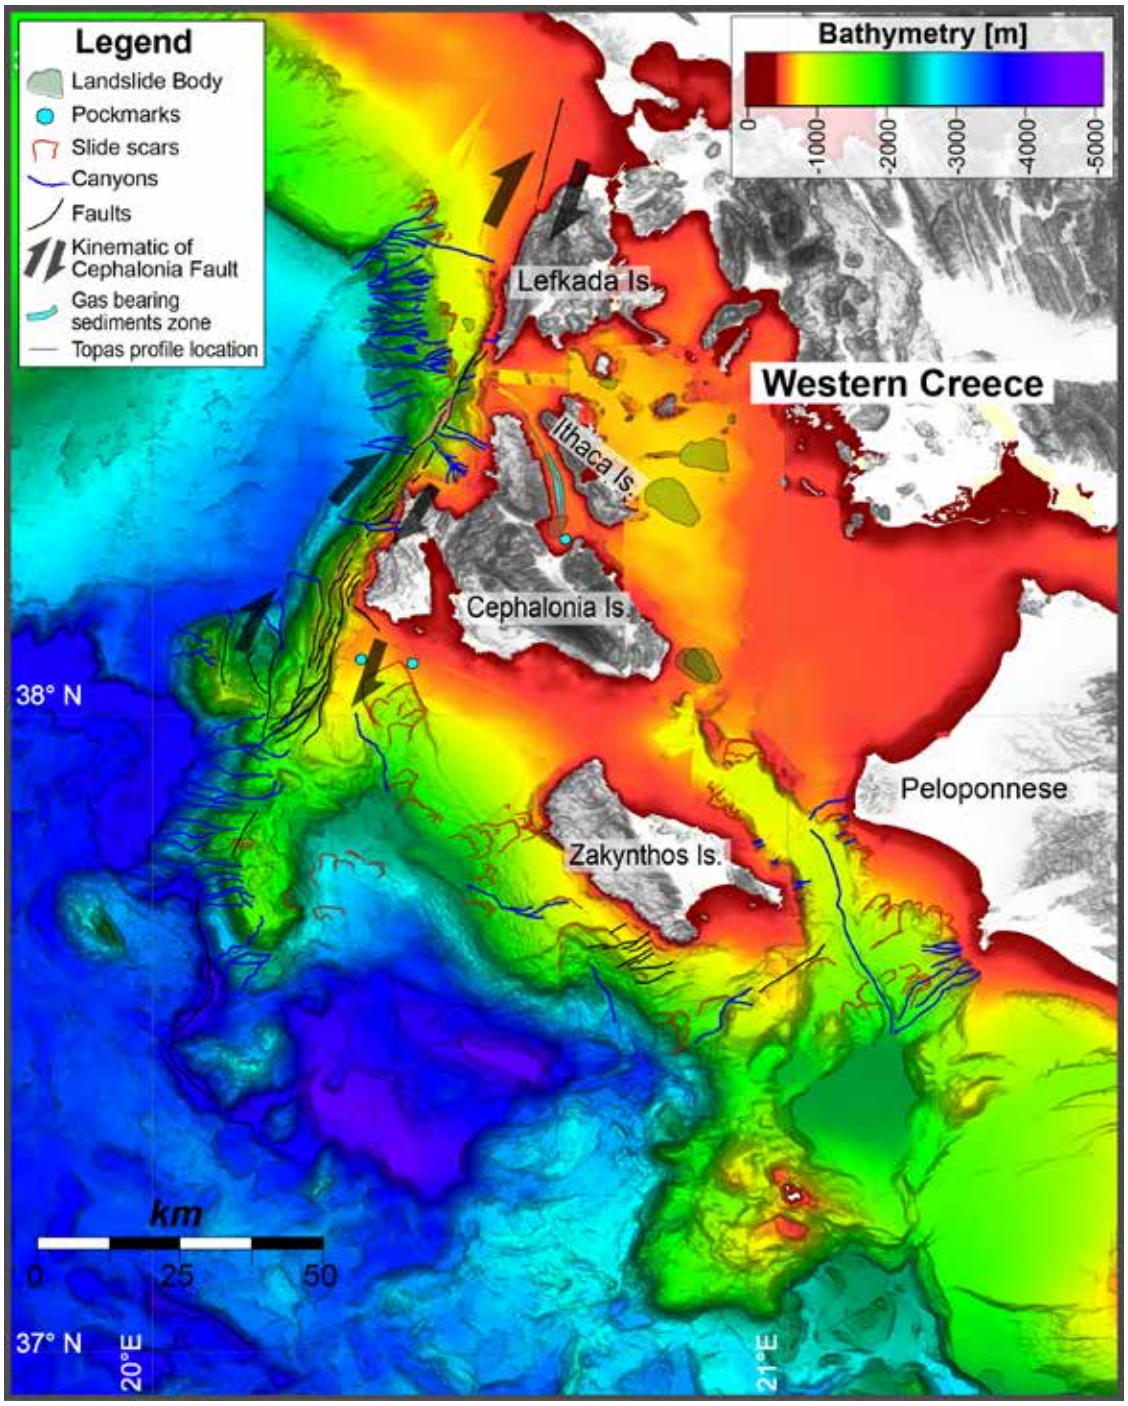

Figure 3. Morpho-bathymetric map of the Ionian Islands (Western Greece) showing the mapped morphological elements that can be associated with the geological hazard of the area. The most relevant hazard elements are represented by the Cephalonia Fault System, which delimits the western side of the islands of Cephalonia and Lefkada, and by the numerous locally large landslides that erode mainly the southern margin of Zakynthos and the Peloponnese. Furthermore, some canyon heads erode sediments very close the coastal line. Some pockmarks have also been mapped, witnessing the abundant gas that fills the shallow sediments. The bathymetry is a combination between EMODnet data (https://emodnet.ec.europa.eu /en/ bathymetry#bathymetry-approach) and the newly collected data during the Poseidon cruise.

Discussion

Based on the method described above, a map of the morphological features associated with geohazards in the offshore area of the Ionian Islands has been produced (Fig. 3). Based on this map, the area can be divided into two main zones: 1) the Kefalonia Transform Fault (CTF) zone and 2) the zone surrounding the island of Zakynthos.

The CTF zone is characterized by a steep slope (with maximum inclination of ca. 44° or 97%) shaped by a series of incisions that delimit small sigmoidal ridges, area south of Cephalonia (Fig. 3). The sigmoidal morphology has been associated with a series of positive flower-like structures bounded by strike-slip faults with a reverse component (Loreto et al., under review). The Cephalonia system becomes very broad to the south and deforms both sediments and rocks (Pre-Apulian unit), resulting in a 25 km-wide deformed area. West of Lefkada, the fault system changes its behavior becoming a single incision associated with a very well-defined morphological scarp (Fig. 3). Furthermore, this area is strongly incised by numerous channels and canyons, some of which are interrupted against the CTF system, others less evident are displaced by the CTF and where it has been possible to do the measurements the dislocation is approximately 500 m. The group of channels and canyons that are located to the north are set along a slope that delimits an anomalously deep plateau. This anomalous tendency of the plateau could be due to the tectonic activity of the Cephalonia fault. At the present stage the analyses carried out are not sufficient to provide the complete correlation between morphologies and tectonics, a step that will be developed in the future.

The surroundings of Zakynthos (zone 2; Fig. 3) are mainly affected by landslides with variable sizes ranging from hundreds of metres to tens of kilometres in scar width. The largest landslide, a giant landslide, located south of Zakynthos (Fig. 3) is in close correlation with the NE-SW oriented morphological steps mapped next to one its flank. These morphological steps have been associated with normal faults displacing sediments towards the southeast. The gravitational control on tectonics has been best explored in Loreto et al. (under review). Since this area is dominated by compressional tectonics, the gravitational instability here must be of enormous magnitude since it has also been recorded on land with earthquakes with normal kinematics (Kassars et al., 2016). Most of the faults inferred from morphological features on the seabed are active. The assessment of the seismogenic potential of these faults will be investigated at a later stage; here we want to drive the attention on the offshore morphological elements that have been mapped in this area for the first time.

Finally, the presence of gas-bearing sediments (Fig. 2) represents a significant risk for the surrounding areas. It has been observed along several margins that when gas accumulates in the sediments the shear strength is greatly reduced predisposing the slope to gravitational instability (Sultan et al., 2004). When the gas accumulated in the sediments is released into the water column it results in the formation of pockmarks (Hovland, 1989) which are frequently related to submarine landslides that can be triggered even in conditions of slope inclination lower than 1° (Kvalstad et al., 2005). Consequently, all the infrastructures installed offshore are exposed to high risk from landslides, sediment subsidence and gas explosion on the seabed (Hovland et al., 2002).

Summary

By combining bathymetric data from Emodnet with the new high-resolution swath bathymetry and comparing this map with the Topas profiles and high-resolution seismic profiles, we have mapped all geohazard elements affecting the area. From the northern part of Lefkada up to the southern part of Cephalonia, the 120 km-long Cephalonia transform fault has been completely mapped. A series of channels, channel heads, landslide scars and multiple slide deposits have been mapped all around the islands, at the continental slope and in the narrow inner basin between the island of Ithaca and the Peloponnese. This new dataset has revealed a seabed extremely shaped by faults, gravitational instabilities, channels and often tectonically-controlled channels, and adds a further step forward in the geological risk assessment of Western Greece.

Acknowledgements

Interpretation of all seismic data combined with morpho-bathymetry has been done using the Kingdom Suite software (S&P Global), freely available under the S&P Global University Grant Program. Geophysical data were collected during the IONIANS cruise supported by internal CNR funding (https://www.ismar.cnr.it/web-content/rapporto-tecnico-n-11/) and aboard of the R/V L. Bassi – INOGS during the POSEIDON cruise supported by the Eurofleet program (http://eurofleet.maris2.nl/cds-report/25). A thanks the the ISMAR-CNR institute of Bologna for hosting my internship.

EXTENDED ABSTRACT 030

Assessing earthquake-triggered tsunami hazard in Santorini-Amorgos Tectonic Zone: A deterministic simulation-based approach

Batzakis D.-V.[1], Karymbalis E.[1], Tsanakas K.[1]
(1) Department of Geography, Harokopio University, Athens, Greece, mpatzakis@hua.gr

Introduction

The Aegean region is shaped by the dynamic interactions caused by tectonic plate kinematics. To the north, the Aegean is bounded by the North Anatolian Fault (NAF), the major strike-slip fault that accommodates the westward motion of the Anatolian microplate at a rate of about 2.4 cm/year (Taymaz *et al.*, 2007). The Hellenic subduction zone defines the southern boundary, where the African plate subducts beneath the Aegean microplate at a rate of 0.9 cm/year (Andinisari *et al.*, 2021, and references therein). This process, combined with the westward extrusion of Anatolian microplate, drives the southward retreat of the Aegean microplate at an estimated rate of around 3.5 cm/year (Andinisari *et al.*, 2021, and references therein), resulting in extensive crustal deformation, the development of diverse tectonic and volcanic structures, and various faulting mechanisms in the broader region (Papazachos & Kiratzi, 1996). The south Aegean is characterized by an extensional deformation environment driven by the rollback of the subducting slab (Sachpazi *et al.*, 2016), where crustal stretching leads to the formation of numerous normal faults (Papazachos *et al.*, 1999). This ongoing extensional regime is associated with the presence of active tectonic zones with high seismicity accompanied by the evolution of volcanic centers (Hooft *et al.*, 2017). One of the most distinctive zones is the Santorini-Amorgos Tectonic Zone (SATZ), a geodynamically complex area influenced by subduction processes and extensional tectonics. It is characterized by active faulting, significant seismic activity, and the presence of volcanic centers (Nomikou *et al.*, 2018).

In the early months of 2025, a notable seismic activity was recorded in the area between the islands of Santorini and Amorgos. From January 25 to March 6, more than 4,000 earthquakes were documented, with the largest event reaching a magnitude of 5.3 (IG-NOA, 2025). The high frequency and the magnitude of these earthquakes raised concerns regarding the potential for a stronger earthquake, particularly given the region's complex tectonic setting and its history of significant seismic events. Furthermore, the possibility of a tsunami generated by a major earthquake heightened these concerns, considering the region's experience with such events. This study aims to assess the tsunami hazard in the SATZ by simulating earthquake-triggered tsunami waves. A deterministic approach is adopted, developing worst-case earthquake scenarios based on the dimensions and characteristics of the major active faults within the tectonic zone. Using simulation techniques, the propagation and inundation extent of earthquake-triggered tsunamis are calculated, providing insights into the potential impact of the waves on specific coastal areas of the surrounding islands.

Study Area

The SATZ is located in the South Aegean Sea, bordered by the islands of Santorini, Ios, Amorgos, Astypalaea, and Anafi. It is a seismically active structure that marks the transition from the relatively quiescent western part of South Aegean to the highly active eastern part (Bohnhoff *et al.*, 2006). Recent seismic reflection and bathymetric data revealed that the SATZ is a structural feature composed of tectonic grabens and horsts, formed by the presence of several major and minor faults oriented in a NE-SW direction (Nomikou *et al.*, 2018; Tsampouraki-Kraounaki *et al.*, 2021). Crustal deformation in the zone is mainly dominated by several major faults which control the development of graben-horst structures (Nomikou *et al.*, 2018). These faults exhibit varying dip angles and are characterized by significant fault throws, indicating normal faulting (Nomikou *et al.*, 2016; Nomikou *et al.*, 2018; Preine *et al.*, 2020). However, a right-lateral strike-slip component has been observed, suggesting a trans-tensional stress in the area (Heath *et al.*, 2019; Tsampouraki-Kraounaki *et al.*, 2021, and references therein).

In recent times, the SATZ experienced significant seismic activity, including the M_w ~6 events in 1911 and 1919 (Andinisari *et al.*, 2021). The most prominent event was the 1956 M_w 7.8 earthquake along the Amorgos Fault (AmF), which triggered a tsunami that caused significant run-up along the coasts of the surrounding islands, although the exact source mechanism remains debated (Okal *et al.*, 2009). The major faults within the SATZ include the Ios Fault

Zone (IF) and Amorgos Fault (AmF), which extend across the northern part; the Santorini-Anafi Fault (SAF) and Anydros Fault (AF) located in the central part; and the Anafi-Astypalaea Fault Zone (AnF-AsF), across the southern margin of the SATZ (Figure 1). AmF and SAF exhibit southeastward dipping, IF exhibits southwestward dipping, while AF and AnF-AsF show opposite polarity with northwestward dipping motion (Tsampouraki-Kraounaki *et al.*, 2021). Apart from the AF, these faults are sufficiently long to generate earthquakes of $M_w \geq 7$ (Leclerc *et al.*, 2024).

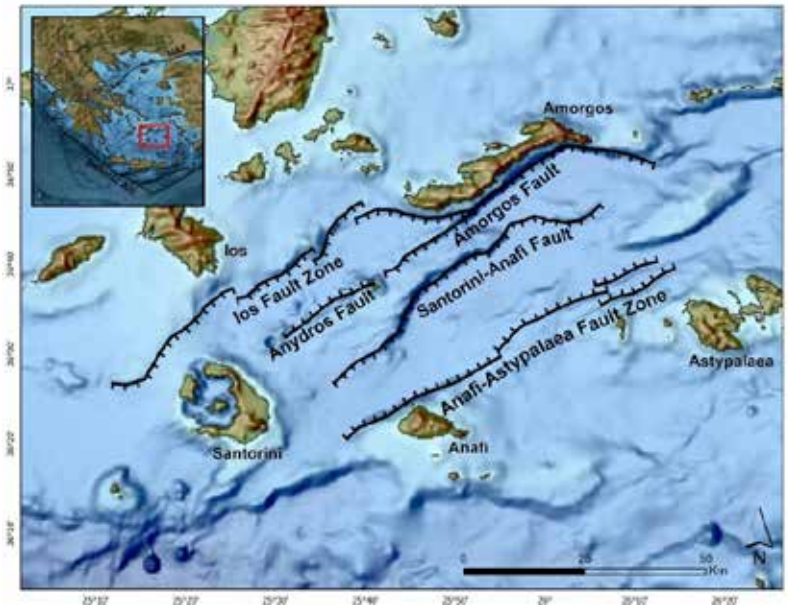

Figure 1. Map of the major active faults in the Santorini-Amorgos Tectonic Zone (modified after Leclerc *et al.*, 2024; Nomikou *et al.*, 2018; Tsampouraki-Kraounaki *et al.*, 2021).

Methodology

Seismic events along the major faults were considered, to analyze the propagation patterns and the potential impact of earthquake-triggered tsunamis within the SATZ. Moreover, five coastal areas hosting settlements—Kamari and Perissa in Santorini, Katapola in Amorgos, Gialos in Ios, and Chora in Astypalaea—were selected for hazard assessment due to their touristic development, extensive human activities, and the presence of critical infrastructure, that make them particularly exposed to tsunami.

The MOST (Method of Splitting Tsunami) numerical model, implemented through ComMIT (Community Model Interface for Tsunamis) modelling framework developed by NOAA, is employed to simulate tsunami generation, propagation, and onshore inundation (Titov *et al.*, 2011). ComMIT utilizes three nested computational topo-bathymetric grids for tsunami simulation. Two coarser grids, which cover broader areas, are used to calculate the initial conditions and the wave propagation in the open sea. A third finer grid, which covers the coastal area, is used to perform the inland penetration calculations. For the coarser grids, topo-bathymetric data from the General Bathymetric Chart of the Oceans (GEBCO-2024), with a resolution of approximately 375 m, were utilized. For the finer grid, a detailed elevation dataset with a resolution of 5 m was used. This dataset was created by combining the 5 m resolution topographic data provided by the Hellenic Cadastre with the bathymetric data from Navionics nautical charts, which have a resolution ranging from 10 m in the nearshore zone to 50 m in deeper offshore areas. The data processing was conducted using GIS software to generate a seamless elevation model for the coastal areas of interest. Adjustments to the coarser grids were performed based on the finer grid to improve their accuracy in the coastal areas under study, where the tsunami impact will be assessed, utilizing the Map Algebra tools in GIS software.

The seismic source mechanism parameters required for the initial phase of tsunami generation were obtained from studies conducted in the SATZ, where bathymetric and seismic data have been presented and analyzed (Nomikou *et al.*, 2016; Nomikou *et al.*, 2018; Tsampouraki-Kraounaki *et al.*, 2021). The fault length and strike used in the simulation were derived from the fault trace as mapped in the study area. The fault width (W) was calculated as W

= H / sinδ, where H is the thickness of the seismogenic layer, assigned a value of 12.5 km according to Andinisari *et al*. (2021), and δ is the average fault dip angle, estimated from the values provided in the aforementioned studies. The magnitude of the potential earthquake was estimated using the regression equation correlating the M_w with the rupture area (S) of the fault, while the mean displacement (u) was calculated using the regression equation that correlates M_w with u, as proposed for dip-slip continental faults by Papazachos *et al.* (2004). Furthermore, it was assumed that the faults would rupture along their entire length, with IF and AnF-AsF considered as a single fault. These estimations were obtained by applying Equations (1) and (2), respectively.

Log(S)=0.78Mw-2.56 (1)

Log(u)=0.72Mw-2.28 (2)

A depth of 10 km was assigned to the potential earthquake for all the faults, based on observations of recent seismicity in the SATZ (IG-NOA, 2025). The epicenter of the earthquake was defined as the midpoint of the fault length, and the distance (d) from the fault trace was calculated as d = D / tanδ, where D is the earthquake depth. A rake value of -135° was used, consistent with the NOA fault catalog for the AmF (Ganas *et al.*, 2013), adopting a normal right-lateral oblique slip for the faults. All the parameters used in the simulations are listed in Table 1 and the fault planes are represented in Figure 2. The results were overlaid on a satellite imagery basemap using GIS to visualize the extent of inundation and calculate the run-up.

Table 1. Seismic source parameters used for tsunami simulation calculations.

Seismic source	Earthquake epicenter (°)		Length (km)	Width (km)	Rupture area (km²)	M_w	Depth (km)	Mean displacement (m)	Strike (°)	Dip (°)	Rake (°)
	Latitude	Longitude									
Ios Fault Zone	36.54925	25.50823	55	17.7	973	7.11	10	2.00	48	45	-135
Amorgos Fault	36.77155	25.93779	40	16.3	652	6.89	10	1.38	48	50	-135
Anydros Fault	36.64383	25.51760	20	17.7	354	6.55	10	0.79	235	45	-135
Santorini-Anafi Fault	36.64002	25.90768	60	15.2	912	7.08	10	1.89	45	55	-135
Anafi-Astypalaea Fault Zone	36.57636	25.90581	65	15.2	988	7.12	10	2.03	237	55	-135

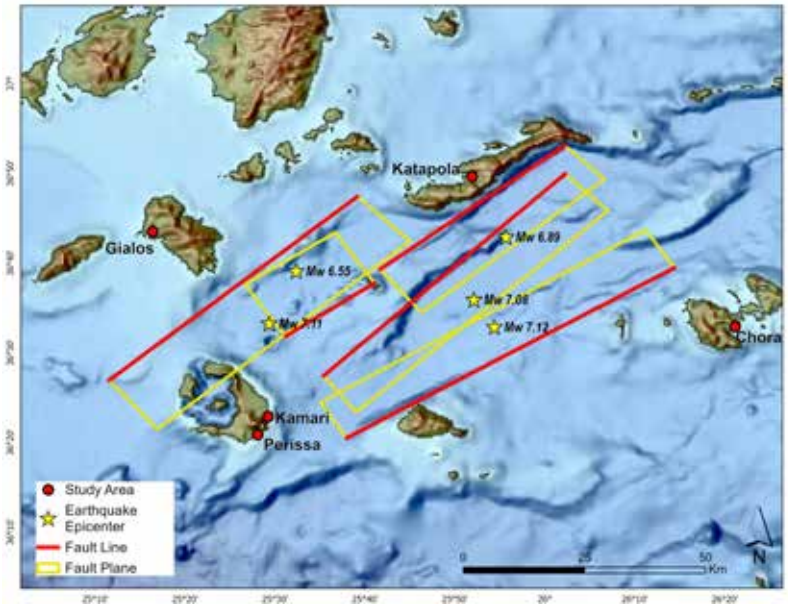

Figure 2. Map of the selected tsunamigenic earthquake sources and study areas. The rectangles represent the surface projection of the fault planes used in this study for tsunami simulations.

Results

The numerical simulations illustrated the generation and propagation of tsunami waves triggered by the five selected earthquake scenarios (Figure 3). The computed initial wave amplitude fields revealed the sea surface displacement, which corresponds to the uplift and subsidence associated with each seismic event. The main wave direction and the maximum observed amplitudes were aligned with the fault strike, primarily propagating toward the northwest and southeast. The wavefront time frames also captured the interactions with underwater features which create bathymetric variations, influencing tsunami propagation. Notably, the Anydros horst, which hosts Anydros Islet in the central-western part of the SATZ, plays a significant role in wave diffraction. These bathymetric variations, along with coastal morphology, impact the wave refraction and amplification, especially in the nearshore zone. The highest wave heights, reaching up to 2.5–3 m, were observed near the southern coasts of Ios and the western coasts of Astypalaea, generated by the largest earthquake scenarios of IF, SAF and AnF-AsF.

Table 2 summarizes the estimated tsunami arrival times at the study areas for each tsunamigenic source, measured in minutes after the earthquake. The arrival times range from several minutes to tens of minutes, with variations due to the proximity of each study area to the respective fault. Among the study areas, Perissa and Chora experienced the fastest tsunami arrival following an earthquake along the AnF-AsF, and Kamari after an earthquake along the AF, with waves reaching the coast in just 10 minutes. In contrast, the longest arrival time of 40 minutes was observed in Chora following an earthquake along the IF.

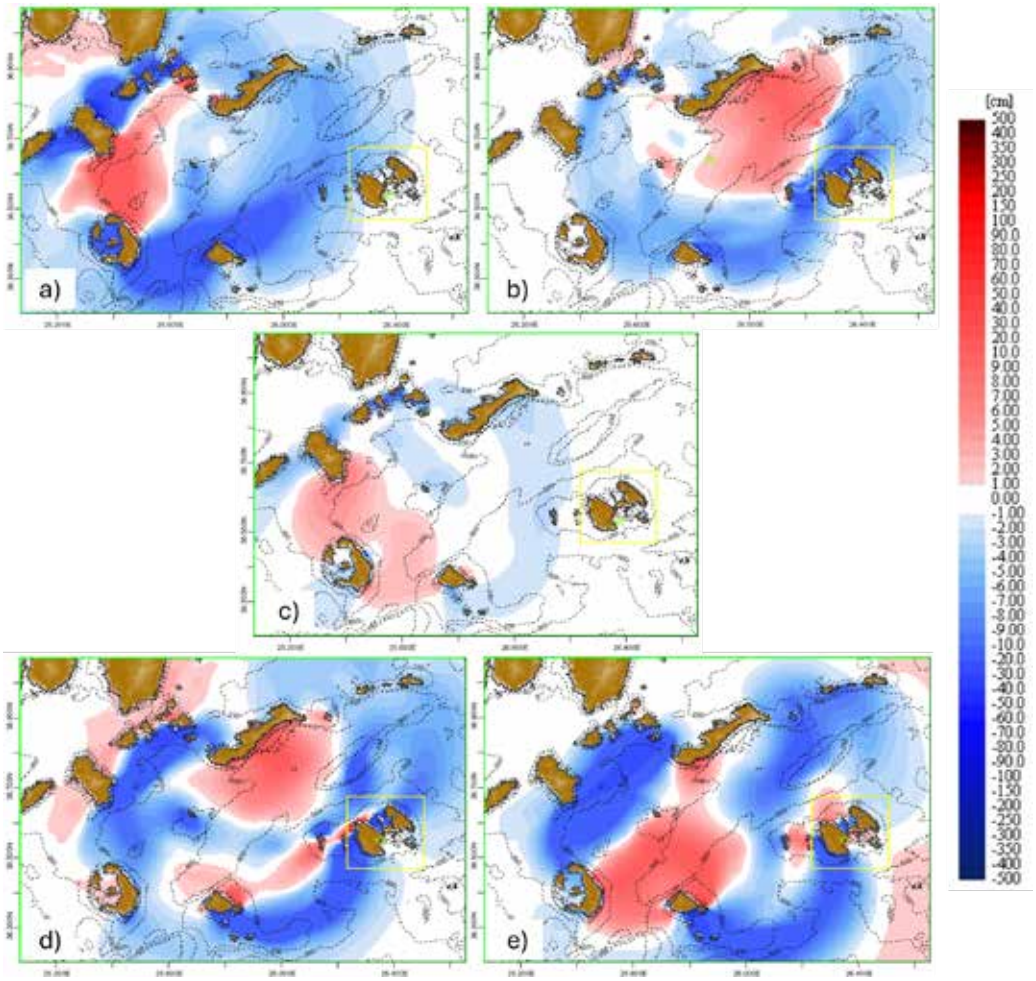

Figure 3. Wave propagation and amplitude distribution for the seismic sources along: a) IF, b) AmF, c) AF, d) SAF, and e) AnF-AsF, shown as snapshots approximately 10 minutes after the seismic events.

Table 2. Tsunami arrival times for each seismic source at the study areas, measured in minutes following the seismic events.

Seismic source	Calculated arrival times (in minutes after the seismic event)				
	Gialos	Katapola	Kamari	Perissa	Chora
Ios Fault Zone	15	25	20	25	40
Amorgos Fault	30	15	20	25	30
Anydros Fault	25	25	10	15	35
Santorini-Anafi Fault	30	35	20	25	30
Anafi-Astypalaea Fault Zone	30	35	15	10	10

The tsunami simulations also provided insights into the extent of coastal inundation and the run-up in the studied coastal areas. The run-up values varied across the five coastal areas, reflecting both the magnitude of the seismic events and the coastal morphology (Table 3). The IF, SAF and AnF-AsF scenarios consistently produced higher run-up values in most study areas. Specifically, IF resulted in the highest run-up value in Gialos, while AnF-AsF produced the highest run-up in Ghora, with both areas experiencing a maximum run-up of 2.8 m. The SAF and AnF-AsF also exhibited high run-up values along the eastern coast of Santorini, with maximum run-ups of 2.4 m observed in Kamari and 2.2 m in Perissa. High run-up values of 2.3 m were observed in Gialos, resulting from the AnF-AsF scenario, and 2.1 m in Gialos and Chora from the SAF. The highest run-up from the AmF was recorded in Perissa, with a value of 1.8 m, followed by 1.5 m in Gialos. The AF appeared to generate the smallest run-up, with values of 0.4–0.6 m observed in Kamari, Perissa, and Gialos. This suggests that the fault may not produce large tsunamis due to its smaller size. Figure 4 illustrates the maximum inundation extent and corresponding flow depth values in the study areas for the various seismic scenarios.

Overall, the observed tsunami inundation extent and run-up values in the selected study areas are not substantial enough to cause a major disaster. However, in Gialos (Ios), Katapola (Amorgos), and Chora (Astypalaea), the inundation flows extend into the coastal zone, affecting the residential zone. Notably, these coastal settlements also host the main ports of the islands, meaning that a potential tsunami could exacerbate a seismic crisis by disrupting critical infrastructure used for emergency response efforts. In Kamari and Perissa, Santorini, the inundation does not appear to extend beyond the coastal front, possibly resulting in large waves along the shoreline without extensive inland penetration.

Table 3. Observed run-up values (in meters) in the study areas for the various seismic sources. N/A indicates no observed run-up.

Seismic source	Observed run-up values (in meters)				
	Gialos	Katapola	Kamari	Perissa	Chora
Ios Fault Zone	2.8	2.3	1.6	1.4	0.8
Amorgos Fault	1.5	1.3	1.4	1.8	0.6
Anydros Fault	0.4	N/A	0.6	0.5	N/A

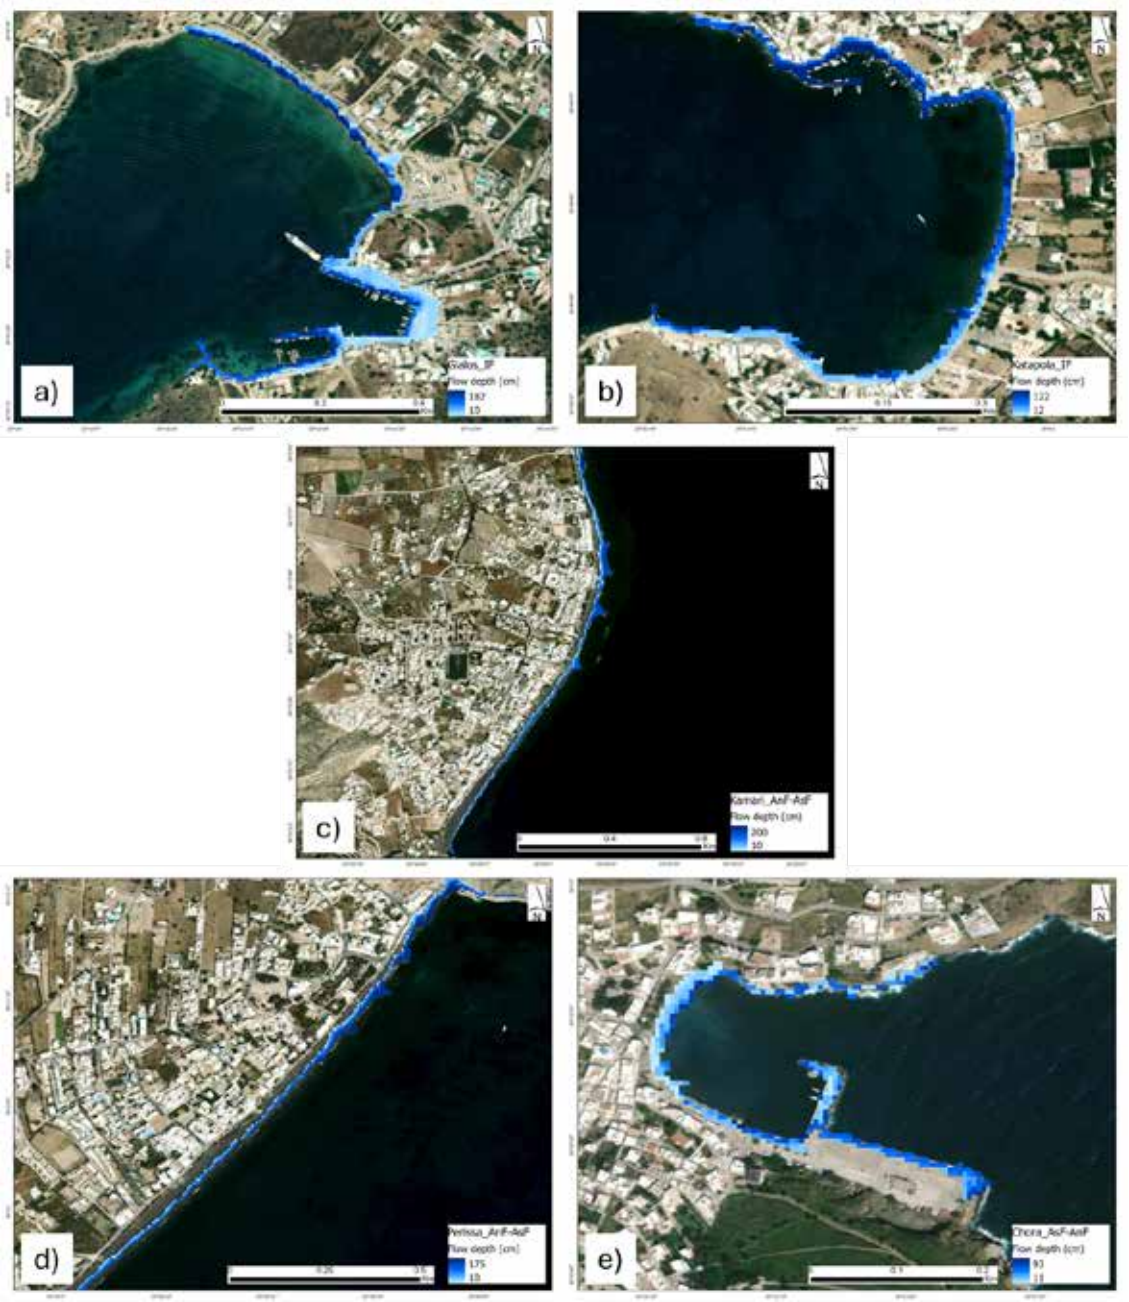

Figure 4. Maximum observed inundation extent in the study areas for the various seismic sources considered in the simulation scenarios: a) Gialos, Ios b) Katapola, Amorgos c) Kamari and d) Perissa, Santorini and e) Chora, Astypalaea. The associated fault is indicated in the map legends.

Concluding Remarks

The study assessed the earthquake-triggered tsunami hazard within the Santorini-Amorgos Tectonic Zone by examining worst-case scenarios. Through simulations of tsunami wave generation, propagation, and inundation from various well-documented seismic sources, the results demonstrated significant variations in tsunami arrival times across the study areas, ranging from just a few minutes to over 40 minutes, depending on proximity to the seismic sources. The observed inundation extent and run-up values indicated localized impact, with a maximum run-up of 2.8 m recorded at Gialos (Ios) and Chora (Astypalaea), and 2.3 m at

Katapola (Amorgos) potentially affecting residential zones and the main ports of these islands. In contrast, Kamari and Perissa (Santorini) experienced a maximum observed run-up of 2.4 and 2.2 m, respectively, with the inundation extending only slightly beyond the coastline. Although earthquake-triggered tsunamis pose a potential hazard, the results suggested that these events are unlikely to lead to a disaster in the study areas.

Introduction

Milos is located at the southwestern edge of the Cyclades islands in the Aegean Sea, Greece, and is part of the South Aegean Volcanic Arc (Pe-Piper, et al., 2005). The island's geological history includes volcanic activity from the Late Pliocene to the Early Pleistocene, with the last subaerial eruption occurring around 80,000 years ago (Sonder, 1924; Fytikas, 1977; Fytikas, et al., 1986). Its tectonic background is characterized by alternating phases of extension and compression related to volcanic activity during the Pliocene-Pleistocene (Angelier, et al., 1977). The neotectonic and active faults of Milos have produced a block structure, characterized by the occurrence of specific stratigraphic formations in each block (Papanikolaou, et al., 1990). These faults have served as conduits for geothermal fluids, resulting in hydrothermal alteration of the adjacent volcano-sedimentary formations and giving birth to several exploitable ore deposits (Fytikas, 1989). The most active onshore vent fields are located in the Aghia Kiriaki area, along the eastern edge of the Fyriplaka Volcano, near the intersection of the NW-SE and ENE-WSW active faults. As for the offshore domain, extensive hydrothermal venting has been documented in Paleochori, Adamas Bay and Voudia Bay (Dando, et al., 1995; Dando, et al., 2000). Specifically, in Paleochori area, from shore up to depths of almost 500 m, hydrothermal venting is manifested through emissions of gases and high-temperature fluids, often associated with bacterial mats and/or hydrothermal mineral precipitates (Puzenat, et al., 2021).

Highly dominant tectonic features are two major fault zones bounding the central block of the Milos – Fyriplaka tectonic graben, which hosts the Fyriplaka volcanic crater and numerous vent fields both onshore and offshore (Papanikolaou, et al., 1990). Seismic activity, such as the earthquake of 5.2 ML on March 20, 1992, in the southeastern part of the graben, caused extended impacts, including structural damage on buildings, seismic fractures, variations in intensity and temperature of gas emissions, landslides, rockfalls and liquefaction phenomena (Papanikolaou et al., 1993). A recent study has confirmed ongoing seismic and ground deformation along a NW-SE, east-dipping fault on Milos Island, through microseismicity recordings, and InSAR data, showing a significant ground motion of up to 1 cm/yr across the fault (Ganas et al., 2022).

This study combines geodynamic constraints with high-resolution geophysical data to determine the influence of tectonic processes over the distribution of hydrothermal vent fields on the continental shelf around Milos as well as their evolution in relation to sea-level changes particularly since Middle Pleistocene, with the most recent lowstand averaging around 130 m in depth (Seibold & Berger, 1993), thus documenting the interconnection of hydrothermal activity associated with volcanism, tectonics and climatic fluctuations both onshore and offshore.

Data collection and Methodology

The cruise M192, conducted in August 2023 on board the RV Meteor investigated the area offshore Milos in terms of the geomorphology, geology, geochemistry and microbiology of marine hydrothermal systems in a transect from the shallow continental shelf, photic zone off Milos to the deep, offshore, aphotic zone (Bühring et al, 2024, Nomikou et al., 2025 under review). The mission was separated into 2 legs. The major aim of Leg 1 was the systematic mapping using the multibeam echosounder system of RV Meteor, the parasound system and the AUV (Autonomous Underwater Vehicle) MARUM-SEAL in expansive areas around Milos was performed during cruise M192 of R/V Meteor, 08 August – 05 September 2023. On the second leg (M192_2) the hydrothermal vent areas targeted during the first leg were systematically sampled by multicorer and identified with the ROV MARUM-SQUID.

Results and Discussion

Processing of the acquired bathymetric data revealed that the coastal zone around Milos features a distinct shelf and slope area separated by a shelf break, which varies in depth around the island (130-220m), being deeper and disrupted on the eastern side (Fig. 1). The shelf break depth varies due to tectonic deformation, from 130-150 m on the western block (consistent with pre-Holocene sea levels) to 170-220 m in the southeastern tectonic graben, reflecting active faulting. This survey also provided us with the first documentation of Hydrothermal Vent Fields (HVFs), related to volcanism in the modern Milos geothermal system, up to depths of about 220 m and confined within the continental shelf. The distribution of the discovered vent fields around Milos Island is highly selective at the SE and NW coastal zone covering a small percentage of the Milos offshore domain. The present study reveals that these vent fields illustrate a strong correlation between hydrothermal vent fields and active faults, highlighting the interplay between tectonics and geothermal activity. Some of the discovered vent fields are associated with the NW-SE Milos Gulf–Fyriplaka tectonic graben, which hosted the last volcanic eruption 80,000 years ago. Others align with E-W and WNW-ESE faults in southeastern Milos.

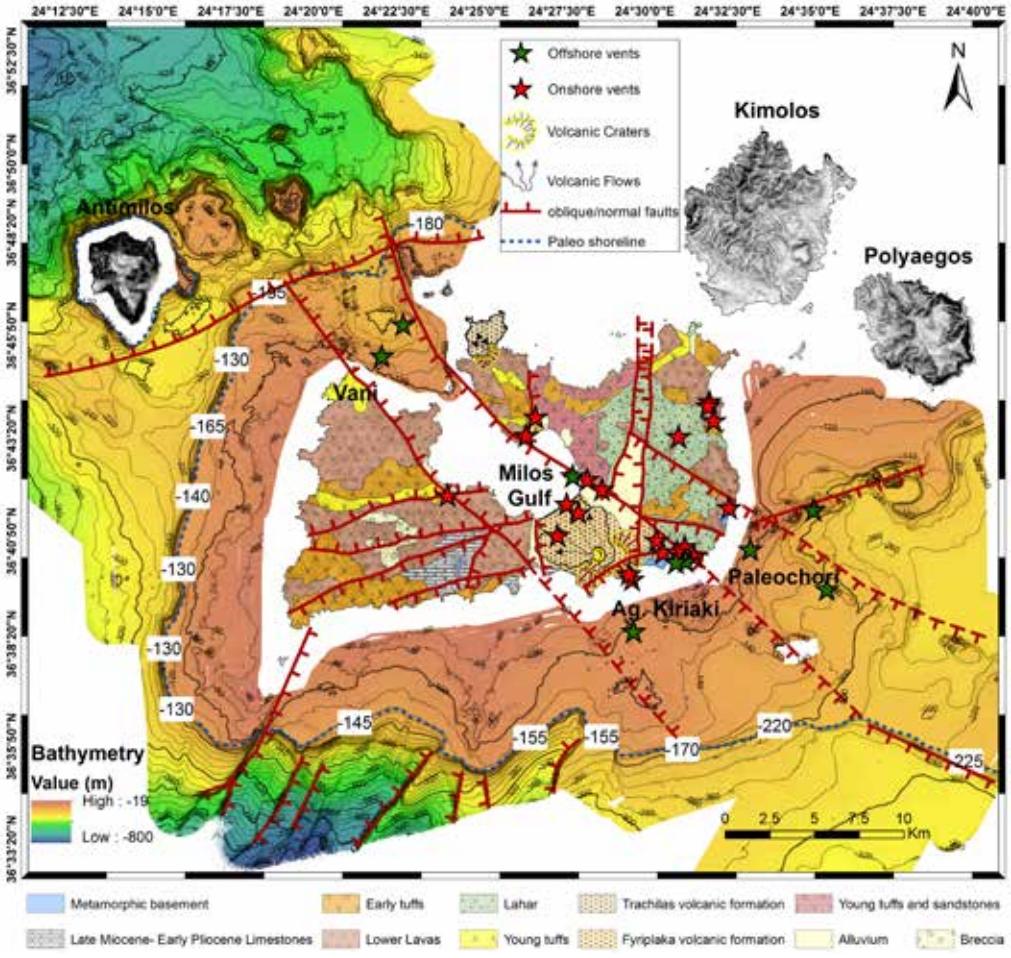

Figure 1. Synthetic tectonic map based on the swath data, the parasound seismic profiles acquired during the M192 expedition and the produced morphologic slope map. Onshore geologic map modified after Papanikolaou et al., 1990.

Two key tectonic features, the NW-SE Milos Gulf–Fyriplaka graben and the ENE-WSW fault system near Fyriplaka Volcano, separate the island's geothermal activity. The most active offshore vent fields occur at Paleochori (Puzenat, et al., 2021) along the southern coast, while Aghia Kiriaki (Fig. 1) hosts the primary onshore vent field at the intersection of active faults.

Depths of detected hydrothermal activity reveal distinct distributions varying in depth from 130 to 220 m. Despite this variation, the prevailing depth is around 110 m, with fewer hydrothermal manifestations beyond

150 m. The shelf break subsidence due to tectonic processes thus seem to strongly influence the location, depth, and activity of geothermal vent fields, with faults acting as conduits for hydrothermal fluids while leaving other regions inactive.

Notably, the E-W neotectonic faults of SW Milos and NE-SW trending faults on the SE slope do not extend onto the shelf and lack associated hydrothermal activity creating geothermal activity gaps.

Conclusions

The oceanographic research M192 around Milos, a young volcanic island in the South Aegean, revealed the offshore prolongation of the Milos major tectonic zones and their interconnection to high-temperature hydrothermal vents and continental shelf volcanism.

Hydrothermal activity has persisted beneath the Milos shelf since the Late Pleistocene, independent of active faulting, and continues today. This evolution reflects a combination of tectonic processes and climatic shifts, alternating between subaerial erosion during sea-level lowstands and submarine venting during highstands. These findings may apply to similar volcanic and geothermal systems in island arcs at convergent plate boundaries.

Acknowledgements

We are thankful to the METEOR-Berichte, Cruise M192, Pireus – Limassol, 08 August – 05 September 2023, the technical staff of the R/V METEOR, and all of the shipboard personnel for a great expedition. We also thank the member organizations of this cruise University of Bremen and MARUM for the financial aid and the supply of all the necessary equipment for preparing and completing the expedition. We would also like to acknowledge the contribution of the program IKYDA 2024: Bridging the Gap between hydrothermal biogeochemistry and Volcano-Tectonics: Exploring Synergies Along the Hellenic Arc off Milos (BITECHELL), for the promotion of the exchange and scientific cooperation between Greece and Germany.

EXTENDED ABSTRACT 032

Storm Daniel flooding of Larissa City: embankments failure the aftermath

Belesis A.[1], Tsentzos I.[1] , Belesis M.[1], Koukouvelas I.K.[2]
1.Ermogenous 6, 41447 Larissa, Greece; abelesis1960@gmail.com
2 Department of Geology, University of Patras, 26504 Patras, Greece

Introduction

Storm Daniel was a catastrophic cyclone that became the costliest cyclone outside the North Atlantic Basin. The storm caused extensive flooding in Greece, Bulgaria, Turkey, and Libya. It was initiated on September 3rd, 2023, and on September 5th, the village of Zagora received 759 millimeters of rain (Kolios and Papavasileiou 2024). The storm flooded many villages in the low-lying area of Karditsa, in the Thessaly Plain, and towns and villages were blocked by water (Dimitriou *et al.* 2024; Kalafatis *et al.* 2024; Mavroulis *et al.* 2024).

In Larissa, after rains ended on 8th of September 2023, the water continued to rise as the Pineios River overflowed to reach 9.5 m, more than twice the typical level of 4 m. The Pineios River Basin in Thessaly occupies an area of about 11,000 km2 (Kalafatis *et al.* 2024). Its hydrologic basin is drained by the Pineios River, the third longest river in Greece at 213 km. Major tributaries of the river are the Malakassiotiko, Mourgkanis, Portaikos, Lithaios, Pamissos, Enipeas, and Titarisios, which all drain extensive meteorologically and geologically heterogeneous areas (Bathrellos *et al.* 2018).

Historical data shows that the Pineios River flooding at Larissa happens approximately every 25 years, primarily during winter (i.e. Bathrellos 2005; Bathrellos *et al.* 2018). These data indicate building damage and casualties in Larissa over the last centuries. Two of the most severe flooding events devastated the city in 1883 and 1901. Thus, to prevent the town from flooding in the 1930s, the BOOT company was entrusted to construct a riverbed for water diversion outside the city. Finally, this riverbed was finished by the Ministry of Public Works sometime after 1935. After WWII, in the 1950s, part of the Pineios water was returned to the old riverbed, with a controlled flow from a dam located west of Larissa City. The reactivation of the old riverbed was related to the city's craft economy during this period. The old riverbed remains active for aesthetic reasons and as a recreational area. In previous years, the Larissa area was included in the epicentral area of the Damasi 2021 earthquake. Two strong earthquakes of magnitudes 6.3 and 6.1, on March 3rd and 4th, respectively, happened during this earthquake while a long aftershock activity was also noticed (Koukouvelas *et al.* 2021; 2023 Sarchosis *et al.* 2022). During this seismic activity, the peak ground acceleration in Larissa was 0.16 g (Sarchosis *et al.* 2022). The study area is about 20-30 km SE of the two epicenters, respectively.

This work describes the embankments during the three days of flooding in Larissa City. For this reason, we provide field examples and descriptions to understand the embankments' problems and propose some improvements to their network along the Pineios River in Larissa's territory.

Material and methods

Immediately after the Daniel storm, on the 8th of September 2023, a sector of Larissa City came under the pressure of flooding due to the river overflow reaching 9.5 m. A series of embankments along the river came under pressure. We executed repeated fieldwork in an area characterized by meanders and two riverbeds, the old one flowing through the city and the post-1935 riverbed flowing a few hundred meters north of the old one (Figure 1). During the fieldwork, we mapped overtopping, piping, seepage, and foundation defects. Furthermore, we used Google Earth scenes after the flooding to define the results of embankment failure and to measure the dimensions of the embankments approximately.

Figure 1. Google Earth scene showing the study area, showing localities of embankment problems in close proximity with the Larissa City. Inset shows the location of the study area in Greece.

Data

Five embankment sites were analyzed in detail because these localities caused severe flooding (Figure 1). Embankments, or levees or dykes, are constructed mainly from earth materials and are used to confine stream flow preventing flooding events. Five major embankment sites failed during the storm Daniel from west to east called hereinafter DEYAL, Kioski, Alkazar Stadium I and II, and Alsos (Fig. 1 and Table 1).

Table 1. Embankment dimensions and configurations

	DEYAL	Kioski	Alsos	Alkazar Stadium I and II
Embankment crest width (m)	7,00	7,00	7,00	20,00
Embankment height (m)	5,00-6,00	4,00-5,00	5,00	5,00
Embankment slope (inner and outer)	2:3	1:1,20	2:3	2:3

In the first site, the embankment problems start as seepage. However, this seepage stopped due to the immediate reaction by local authorities during the flooding accumulating earth material and the final repair of the site just after the flood (Fig. 2).

Figure 2. (a) Google Earth scene showing two failed low-height embankments. (b) Field photo of the two failed embankments. (c) The embankment at the DEYAL site was repaired immediately after the flooding. All the localities are at the west entrance of Larissa City, near DEYAL facilities.

The second site at Kioski locality is related to a severe embankment destruction that caused the flooding of large cultivated area and a block of buildings. After the flooding, a 100 m long by 50 m wide and 7 m deep erosional basin was created. This basin is probably the result of extensive water pipping before the embankment collapsed due to overtopping (Fig. 3). At present the embankment is fully restored (Fig. 3). In the same site, we also noticed the existence of small-scale slides across the embankment suggesting that the flooding caused significant problems across the Kioski embankment and the whole area needs analytic inspection. Of particular importance in the Kioski failure is a basin developed on both sites of the embankment that is interpreted as the result of flow along the structural interface of the embankment and the diffused flow through granular media below its foundation.

Figure 3. Google Earth scene showing the Kioski failure on October 2023 note on the satellite view the produced basin due to the embankment failure and the deposited material over cultivated lands. The lower left photo shows the restored embankment a few days after the flooding the photograph was taken looking west. The photograph to the right shows the basin at the south of the embankment.

The Alkazar Stadium sites I and II are two cases where initial piping was stopped by the immediate response by the authorities with the use of earth materials to stop seepage successfully (Fig. 4).

Figure 4. Google Earth scene (left) and field photo (right) of piping failure at locality Stadium just after the Pineios River flooding. The white rectangle in satellite scene show the area of field photo.

Flooding results at the Alsos embankment (Fig. 5) show its destruction for a length of 55 m. In this particular area, at the junction of old and new riverbeds, the flow of the river rise attained a maximum level. As a result, the embankment failed, and the water moved in the river's floodplain over cultivated lands to the northeast. The failure of the embankment in this area was the result of water overtopping. Overtopping phenomena were noticed for 100 m in total beyond the point of the embankment collapse. Concomitantly, the embankment destruction caused the deposition of significant thickness mud over cultivated lands (Fig. 5 blue arrow). The failure at Kioski and Alsos caused the flooding of a large area to the north.

Figure 5. Google Earth scene of the repaired embankment at Alsos locality. The blue arrow shows the flow direction and mud deposition on the cultivated lands. This embankment failure caused by extensive overtopping of the Pineios River.

In addition, second-order failures on the embankments during flooding are noticed in several places ruptures on top of the embankments (Fig. 6a). We interpret these cracks as the result of lateral spreading processes. Except for the along-strike cracks, they are mapped at several places circular to elliptical holes resulting from piping (Fig. 6b). The circular ruptures are interpreted as small-scale landslides commonly developed at the embankments.

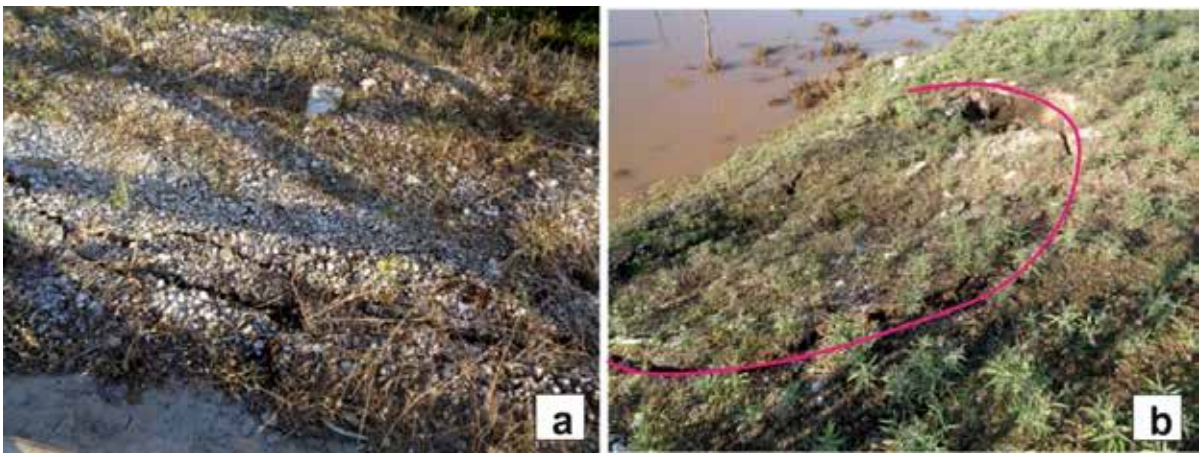

Figure 6 Second order failures of embankments.

In summary, the embankments in the study area are constructed with fine-grained materials were failed for two main reasons: the piping and overtopping. These embankments are categorized as hydrologically or seismically deficient. Notably, in 2021, the area of flooding was rocked by a strong seismic sequence that caused significant ground acceleration in the area of Larissa and their surroundings.

Overtopping manifests when the level of water is higher than the embankment crest elevation, as was the case of Kioski and Alsos. Piping failure of the embankment is caused in DEYAL, probably by the removal of soil particles through the intergranular flow within the soil mass of the embankment.

Discussion

In Greece, Daniel's severe rainfall led to flooding that caused more than two billion euros in damage, making it the costliest recorded storm for the country. Typical embankments in the study area are 80 m at their base and a height of up to 10 m. However, it has to be noticed that these dimensions vary along the entire length of the embankments. Their construction age is from 1930-1970, and their age of construction is ranging from 55-100 years old. The risk of failure of embankments that channelize a river is produced due to seepage induced by temporary and occasional impoundments taking place on the upstream side as a consequence of exceptional rainfalls is frequently underestimated. Commonly the failure of embankments results from the following factors: the flooding event, the hydraulic weakness and the embankment's geotechnical weakness or any combination of these three factors. However, the failure of embankments due to seepage and other water-related issues is often underestimated. In addition, considering climate change will have impacts on flood magnitudes and frequency in the same area we propose that the protection of the villages and cities has to be revised. In particular, for the case of Larissa and its flood hazard, the embankments need inspection after the 2021 earthquake and the 2023 flooding. However, as the area where these embankments are constructed is the Pineios floodplain it is also important to consider the processes related to the stratigraphy of the floodplain.

Conclusions

In five cases, close to Larissa City we mapped almost catastrophic types of failure by sudden, rapid, and uncontrolled release of impounded water. In three cases the emergency action of the local authorities prevents the failure.

Based on the severity of the flooding we considered the failures of the embankments in the territory of Larissa as of low hazard potential. However, given that the area was inflicted by a strong earthquake in 2021 and the flooding in 2023 we consider that a program of careful embankment inspection has to be considered as urgent.

Introduction

The Aegean Volcanic Arc, a crucial part of the Hellenic Arc and Trench System, is situated along the convergent boundary of the northward-subducting African Plate beneath the European Plate and since the Late Miocene beneath the Aegean Plate This volcanic arc has demonstrated continuous activity for at least the last 45 million years, as evidenced by various geological studies (McKenzie, 1972; Le Pichon et al., 1979; Papanikolaou, 1993; Royden & Papanikolaou, 2011). The current geodynamic structure includes the Hellenic Trench, a 1500-km-long arcuate trough extending from the Ionian Sea to the Libyan Sea, with the South Aegean volcanic arc developed parallel to it.

The Milos volcanic center comprises a cluster of islands located at the junction between the Myrtoon Basin, Cretan Basin, and southwestern border of the Cycladic plateau. This region includes Milos, Kimolos, Antimilos, Poliaigos, and smaller islets such as Akrathi and Arkadi. Antimilos is positioned 8.9 km northwest of Milos Island and is entirely composed of volcanic rocks with its highest elevation reaching 686 m (Sonder, 1924; Marinos, 1961). The volcanic deposits on Antimilos have been dated to approximately 0.32 million years ago (Fytikas et al., 1986), though this only represents a portion of its volcanic history.

Antimilos Onshore Geology

The island of Antimilos serves as the subaerial manifestation of the only composite volcano within the Milos Volcanic Field, as established by Fytikas et al. (1986) and Vougioukalakis et al. (2019). This roughly triangular island features two prominent topographic elevations: the rounded northern peak reaching approximately 686 meters, and a smaller southern peak at 435 meters. The simplified stratigraphy of Antimilos, as shown in the modified by Marinos (1961) geological map (Fig. 1a, 1b), consists of several distinct layers. Multiple dacitic domes overlying lower pyroclastic formations, with one major dome forming northern peak Sterna and other minor domes comprising Agiokastro peak and Alonia crater. Distinct eruptions have followed with new dacitic products emerging at Agiokastro peak alongside two neighboring craters and new andesitic products at Sterna peak, where thin volcanic flows extend toward eastern and western slopes from previous dacitic domes in a relatively smooth relief compared to earlier steep slopes.

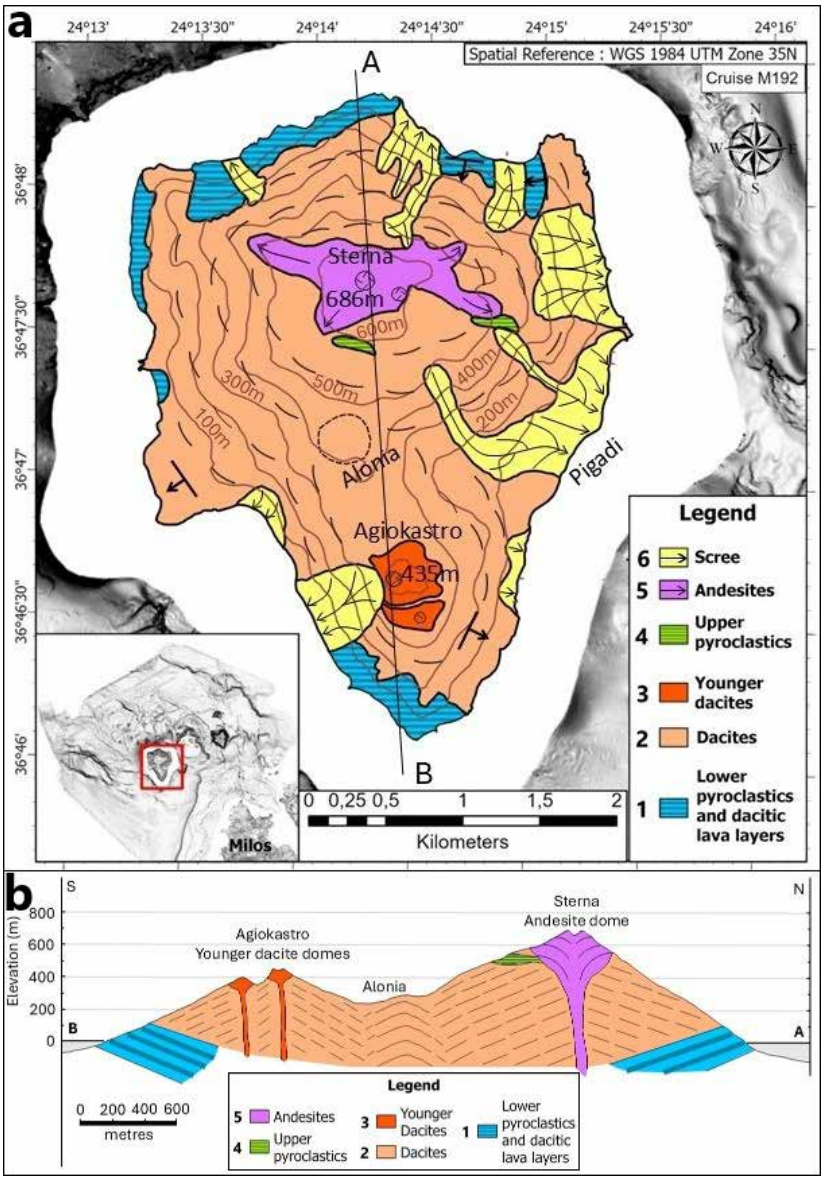

Figure. 1. (a) Geological map of Antimilos Island, modified after the geological sketch of Marinos (1961). (b) N-S Geological Profile across the Antimilos volcano.

Materials and Methods

The survey aboard R/V METEOR during cruise M192 (August 8 – September 5, 2023) utilized the EM710 multibeam echosounder for high-resolution seabed mapping. The system, operating effectively at depths of 3–2000 meters with a swath width up to 5.5 times water depth, covered areas from northern Milos southeastward. Data acquisition, managed via SIS software, integrated sound speed profiles and collected bathymetric (.all) and water column data (.wci), excluding AUV deployment/recovery phases.

Bathymetric data were processed in Qimera QPS, with manual corrections using Slice Editor and 3D Editor, resulting in a 5-meter resolution CUBE surface. Seismic profiles from the ATLAS PARASOUND P70 system provided morphological and sub-bottom data via high- and low-frequency parametric sonar.

Results

The constructed bathymetric map of the seafloor morphology around Antimilos Island reveals intricate features and distinct geological formations (Fig. 2). The analysis indicates that the seafloor morphology

transitions from the shelf zone, which extends up to approximately 140 meters in depth, down to the deeper regions of the southern Myrtoon Basin at around 1000 meters. Notably, in the transect from NW Milos to Antimilos, the Milos shelf exhibits a width of about 5 km, while that of Antimilos is significantly narrower, measuring less than 1 km. Between these two regions lies a small basin with depths ranging from 300 to 320 meters.

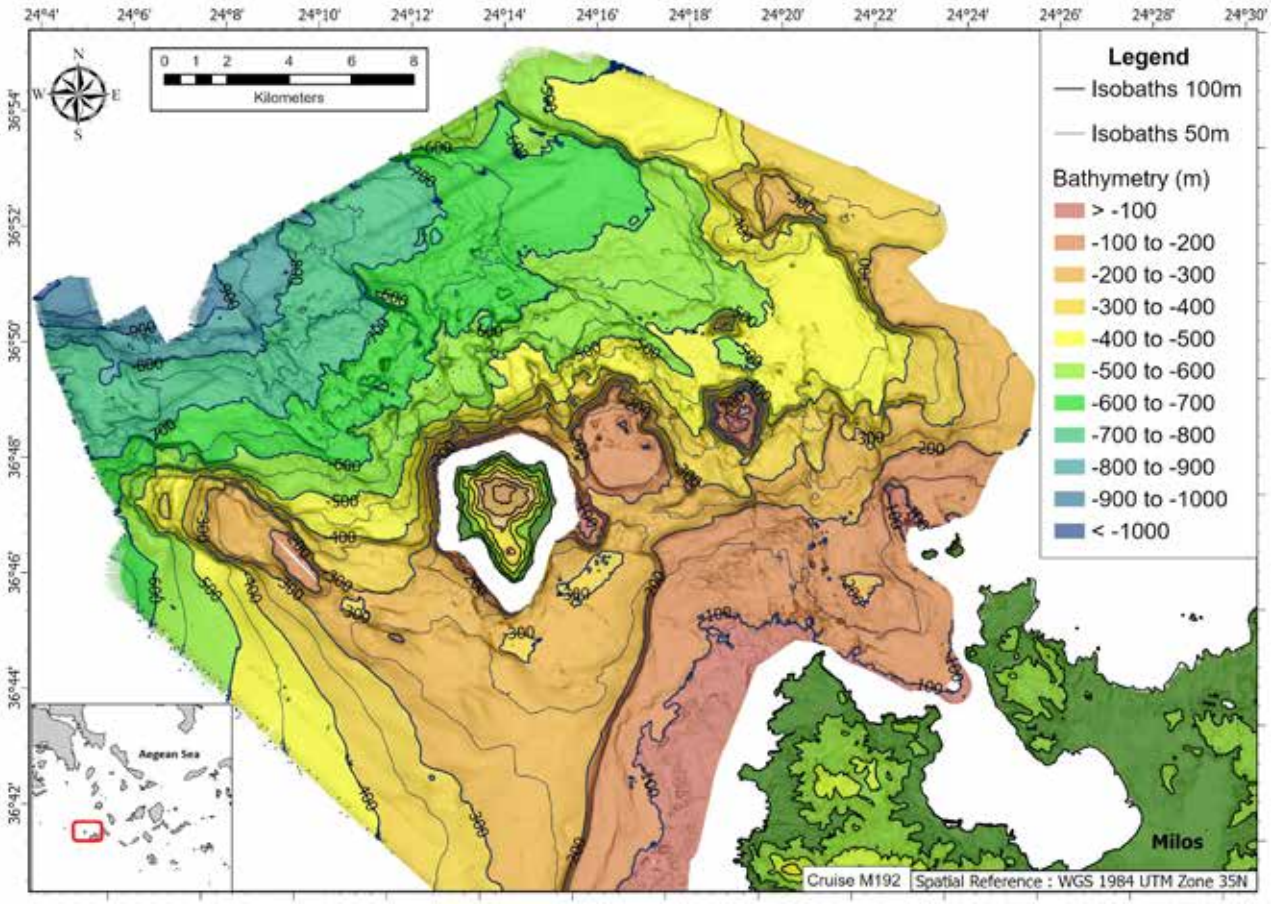

Fig. 2. Detailed swath bathymetry map of the Milos-Antimilos volcanic field (resolution 5 meters). The onshore DEM is obtained from SRTM and has a pixel size of about 30 meters resolution. The location of Antimilos is given in the inset map.

Three prominent submarine volcanic domes are identified to the east of Antimilos (Fig. 3) : Bangos cone, Shallow cone, and Deep cone. The largest of these is Bangos cone, followed by the medium-sized Shallow cone and the smaller Deep cone located further north. The NW slope hosting Antimilos and these three sea mounts is bordered by two significant NW-SE trending cliffs: one from the northeast at depths between 300 and 600 meters, marking the boundary with the Cycladic plateau, and another from the southwest at similar depths forming what is referred to as the Western Ridge. Bangos Dome stands at 349 meters tall and the summit has a flat top with a mean water depth of 140–145 meters. This flat area likely resulted from wave erosion during periods of low sea level. Shallow Cone reaches a total height of 417 meters with its summit at a depth of 58 meters. Although wave activity during the Last Glacial Maximum eroded its summit, it remains the shallowest cone among the three. A shelf has developed at depths between 130-140 meters. Deep Cone has with a total height of 226 meters and a conical shape that narrows significantly towards the summit with its peak at 293 meters below sea level. Due to its depth, it has remained unaffected by low sea level fluctuations that have impacted the other two domes.

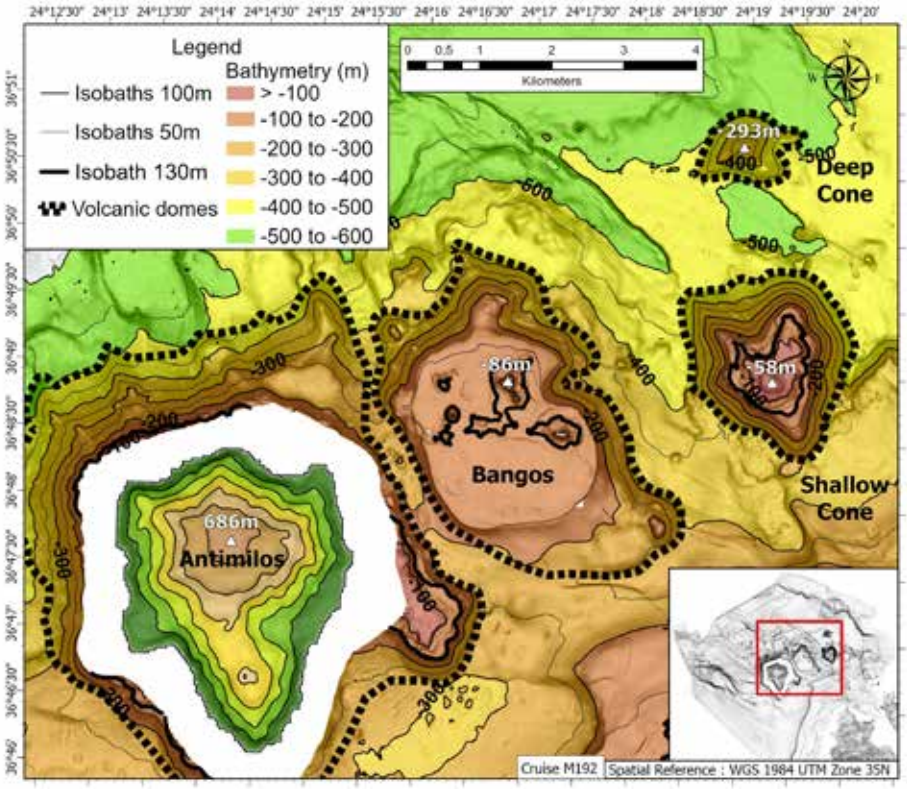

Figure. 3. Bathymetric map showing the boundaries of the volcanic domes NE of Antimilos island.

The hummocky area (Fig. 4) located offshore northwestern Antimilos is characterized by a rough, blocky terrain and has been identified as a significant Volcanic Debris Avalanche (VDA) deposit, which plays an essential role in understanding the geological processes that have shaped the area. The VDA covers approximately 72 km² and consists of numerous blocks that vary widely in size, shape, and orientation (Fig. 4). A detailed morphometric analysis was conducted on them, focusing on several key parameters such as height, area, distance from the coastline, and volume. The vertical drop-to-run-out ratio (H/L) was calculated to assess the mobility of the displaced material. The analysis revealed a total of 88 individual blocks distributed along the foot slope, extending up to 8.3 km from the coastline. Their orientation generally aligns with the slope's direction but also displays a discernible trend along a SE-NW axis.

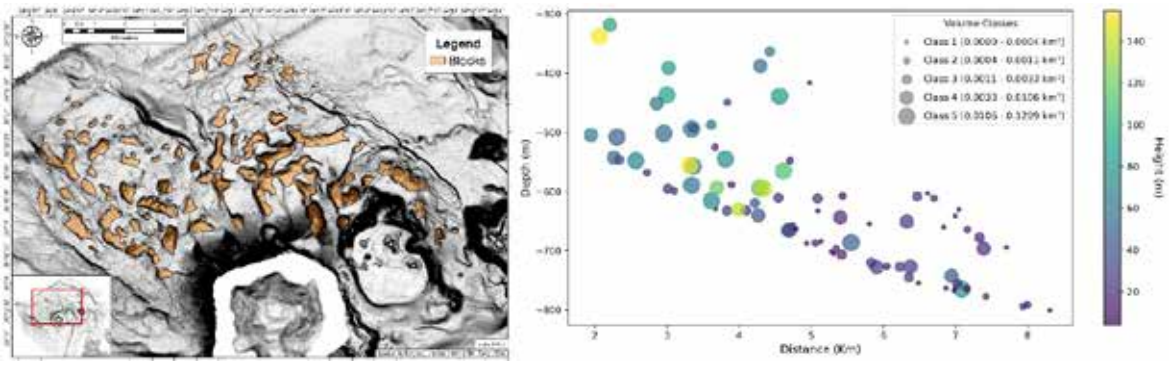

Figure. 4. VDA Blocks. (a) Gray-shaded map showing the identified blocks. (b) Scatter plot depth vs distance from the coastline of the block. The color scale indicates the height of each block.

Conclusions

The morphotectonic analysis of the Antimilos volcanic field, northwest of Milos Island, reveals four volcanic structures: the subaerial Antimilos volcano and three submarine volcanoes. The volcanic relief is 1180 m for Antimilos, 350 m for Bangos, 420 m for the Shallow and 200 m for the Deep Cone. Except for the Deep Cone the other three domes are highly affected by the climatic fluctuations, which have peneplained the Bangos dome at 140 m depth and have created a broad shelf zone at 100-140 m depth in Antimilos Island and the Shallow Cone. The available Middle Pleistocene age of 0.32 Ma indicates a pre-Holocene volcanic activity including the development of the shelf at least during the last three low stands. On the contrary, all three submarine volcanic cones are rather geometric, indicating one major volcanic phase, probably also of Middle Pleistocene age, judging from the development of the shelf in the two shallow cones.

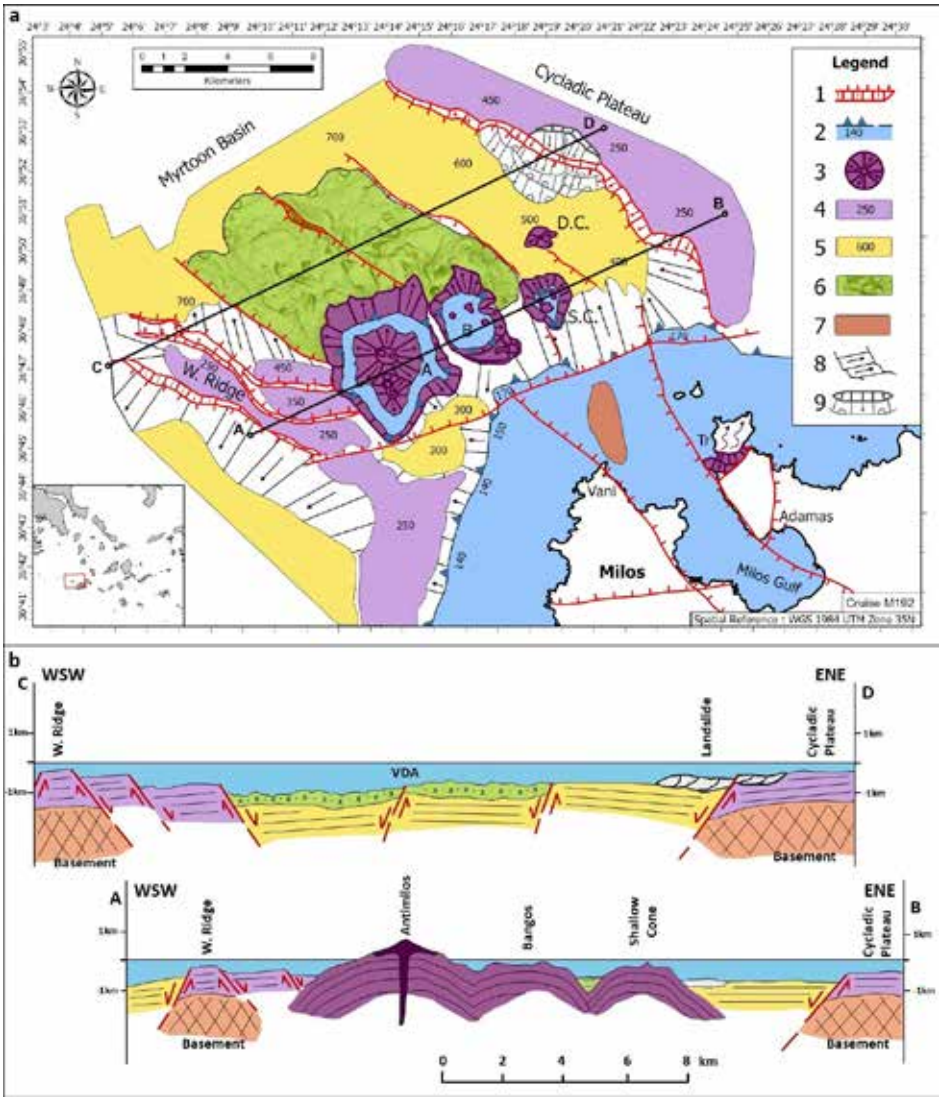

Figure 5. Morphotectonic map of the Milos-Antimilos volcanic field. Tr : Trachilas volcano, A : Antimilos Island, B : Bangos Cone, S.C. : Shallow cone, D.C. : Deep cone, 1 : Normal fault, 2 : Shelf and shelf break, 3 : Volcanic dome, 4 : Submarine Plateau, 5 : Basin, 6 : VDA – Flow direction, 7 : Distribution of flairs, 8 : Moderate morphological slope, 9 : Landslide and related fans. b) Subparallel tectonic profiles through the shallow (A-B profile at 300-500 m depth) and the deep (C-D profile at 500-800 m depth) parts of the Antimilos tectonic graben. The main elements are the three volcanic domes along the shallow profile and the VDA deposits along the deep profile.

The Antimilos group lies at the 7 km wide shallow zone extending between 250 m and 500 m depth within the 17 km long depression/tectonic graben formed to the NW of Milos, bounded by two prominent NW-SE normal faults one towards the NE from the Cycladic plateau and another from the SW from the Western Ridge (Fig. 5). Three additional NW-SE faults traverse the graben's central zone at depths of 600–900 m, confining extensive VDA deposits originating from the Antimilos and Bangos domes. This hummocky area contains volcanic blocks transported several kilometers northwest from their sources. The volcanic domes of Antimilos are located at depths of 500–250 m within the graben's shallow zone, while deeper profiles feature VDA deposits bordered by intra-basin faults. An intermediate zone (200–300 m depth) separates Antimilos from the NW Milos shelf, delineated by an ENE-WSW fault zone over 20 km long. This fault disrupts the NW Milos shelf, causing displacements of up to 30 m and delimiting the Vani hydrothermal vent field. Despite the shared NW-SE fault trend in both areas, there is no structural continuity across the ENE-WSW fault zone. The fault's 20 m Holocene displacement over 14 ka corresponds to a slip rate of 1.43 mm/year. The volcanic domes' development reflects climatic fluctuations, with low-stand periods (~100 ka) causing subaerial erosion and high-stand periods (10–20 ka) promoting marine deposition. Antimilos exhibits dacite and andesite domes with minor pyroclastic deposits, while Bangos, Shallow, and Deep Cones consist solely of volcanic domes, the Bangos Cone accompanied by two minor domes.

A vast hummocky area of VDA deposits with sliding blocks of volcanics occurs to the NW of Antimilos and Bangos domes, reaching 5-7 km distance down to 700-800 m depth, bounded by NW-SE normal faults at the central zone of the Antimilos tectonic graben. Their distribution aligns with the SE-NW trend of debris flows (Alexandri et al., 2001; Nomikou et al., 2013, 2014). The Antimilos VDA deposits shows several similarities to the VDA deposits reported from Santorini and Nisyros along the eastern part of the Aegean volcanic arc.

17th INTERNATIONAL CONGRESS of the Geological Society of Greece

BULLETIN OF THE GEOLOGICAL SOCIETY OF GREECE, SP. PUBL.

EXTENDED ABSTRACT 034

The Geoheritage as a tool to engage children with the Sustainable Development Goals in UNESCO Global Geoparks: Best practices of educational activities from Lesvos Island UNESCO Global Geopark

Konstantina Bentana[1,2], Nikolaos Zouros[1,2]
(1) UNESCO Chair on Geoparks and Sustainable Development of Insular and Coastal Areas, Department of Geography, University of the Aegean, Greece, k.bentana@aegean.gr, (2) Natural History Museum of the Lesvos Petrified Forest

Introduction

Geoheritage constitutes an excellent tool for UNESCO Global Geoparks for the teaching of many cognitive subjects as well as the education of school students of all educational levels in a series of fundamental local or global problems that our society faces (Bentana and Zouros, 2020).

At the same time, UNESCO and other international organizations have been urging educators to seek out and utilize new learning environments outside the classroom, as well as pedagogical tools such as geological heritage in UNESCO Global Geoparks, in order to engage students with issues of sustainability and environmental protection (UNESCO, 2019).

UNESCO Global Geoparks utilize all aspects of their geological heritage in combination with natural and cultural heritage to enhance the education of children and their understanding of contemporary local or global problems (UNESCO, 2016).

However, for the next generation to be able to address contemporary problems, they must know what these problems are. A good way to ensure this is by engaging children to the subjects of the Sustainable Development Goals (SDGs). At the same time, the Sustainable Development Goals help children to understand our impact on the planet, to see the bigger picture and what role we can all play in taking responsibility.

By integrating geological heritage and processes with broader environmental, cultural, and social narratives, UNESCO Global Geoparks offer immersive, hands-on learning experiences among young learners. These natural learning environments not only highlight Earth's dynamic history but also provide a unique platform to illustrate the interconnectedness of geological and natural systems with human activities. In this context, geological heritage becomes a compelling pedagogical tool for introducing children to the Sustainable Development Goals.

This paper aims to explore how geological heritage, when combined with educational infrastructure and active engagement, can effectively involve school students in learning about the UN Sustainable Development Goals. Drawing on best practices from educational activities successfully implemented by the Natural History Museum of the Lesvos Petrified Forest, management body of the Lesvos Island UNESCO Global Geopark, this paper highlights how such initiatives provide meaningful learning experiences beyond the traditional classroom setting. By using local examples and fostering international collaborations, these programs offer students a rich context for understanding global challenges and contribute to the development of informed and active citizens.

Methods

The methodology used for this paper involved a qualitative case study, focusing on the educational activities implemented by the Natural History Museum of the Lesvos Petrified Forest within the Lesvos Island UNESCO Global Geopark. This methodology included an analysis of the educational programmes, focusing on their content, target school student groups, and connections to the Sustainable Development Goals. In addition, the study included the documentation of these educational activities to demonstrate how geoheritage education is applied in alignment with the Sustainable Development Goals in practice. In this paper, we analyzed three educational programmes based on the age of the children: 5-8, 9-12 and 13-17 years old.

Results

Lesvos Island UNESCO Global Geopark offers a wealth of geosites such as the Petrified Forest, which has

been designated a Protected Natural Monument, volcanoes, hot springs, important fossiliferous sites, faults, waterfalls, coastal landforms, which constitute significant evidence of the geological history of the Aegean area and contributed to the island's recognition as UNESCO Global Geopark (Zouros *et al.*, 2015).

Geosites and the rich geoheritage of the island are the main tools that are used for educational purposes by the Natural History Museum of the Lesvos Petrified Forest, the management body of the Lesvos UNESCO Global Geopark. The Museum actively utilizes the island's unique geoheritage in its educational programmes to engage children with the subjects of the Sustainable Development Goals. The educational activities analysed demonstrate a strong connection between geological heritage and the Sustainable Development Goals, and cultivate active citizens.

The first educational programme analysed is entitled "The Deinotherium and the Animals of the Petrified Forest" and is dedicated to school students 7-9 years old.

The programme aims to help children acquire values for the protection of biodiversity and geological heritage. The educational programme focuses on the paleoenvironment of the Petrified Forest, allowing students to identify different fossilized plant species and learn about the animals that coexisted 20 million years ago. Children get to know the animals through the replica of the Lesvos Deinotherium and the Liota crocodile. A theatrical play has been designed for younger children, and the pupils embody roles from the dramatized story of the Petrified Forest (Figure 1).

Geoheritage link: The diverse fossilized flora and fauna within the Petrified Forest showcase the rich biodiversity of the past ecosystems of Lesvos. This provides a baseline for understanding current biodiversity and the impact of habitat loss and environmental change.

Connecting Geoheritage to SDG: 15 "Life on Land"

Preparing active citizens: Students participate in discussions about the need for protecting present-day biodiversity, engaging in activities like creating their school and home gardens, and returning to the Museum petrified tree trunks that they identify by accident.

Figure 1. Children embody roles from the dramatized story of the Petrified Forest.

The second educational programme analysed is entitled "Climate change: learning about the impacts by observing the Lesvos Petrified Forest" and is dedicated to school students 9-12 years old.

The aim of the educational programme is students to understand the consequences of climate change on biodiversity. At the Petrified Forest Park and at the exhibition room of the Natural History Museum of the Lesvos Petrified Forest, children analyze fossilized leaves and tree rings to understand the past climate of Lesvos (Figure 2). Children continue their research at the botanical garden of the museum and are asked to look for evidence about the climate in the modern ecosystem of the Lesvos Petrified Forest area. By observing the vegetation at the time the Petrified Forest lived and the current vegetation, they record the data they collected, process it, and draw their conclusions about the consequences of climate change in the biodiversity of the region over the last 18Ma. Children then compare their results about past climate with the current climate crisis,

discussing the accelerated rate of change and the human impact.

Geoheritage link: The Petrified Forest itself is a direct record of past climate and environmental change during the early Miocene. Fossilized plants provide evidence of a subtropical forest ecosystem and the subsequent environmental shifts caused by volcanic activity and changing climate conditions.

Connecting geoheritage to SDG: 13 “Climate Action”

The Petrified Forest of Lesvos provides invaluable records of past climate change, aiding in the scientific understanding of current and future climate trends.

Preparing active citizens: International collaborations between schools from Lesvos and schools from other UNESCO Global Geoparks around the globe are implemented, encouraging children to participate in common activities. One such activity was implemented in collaboration with Maiella UNESCO Global Geopark (Italy). School students were encouraged to join the educational action “I LOWER THE LIGHTS, LIGHT UP THE FUTURE!” where school students were encouraged to turn off the lights in their school on a specific day and to discover what they can do themselves to save energy in their everyday life at school and at home and how they can become active citizens (Figure 3).

Figure 2. Children participate in research activities at Lesvos Petrified Forest for past climate records.

Figure 3. Children from Vatousa Elementary school joined the educational action “I LOWER THE LIGHTS, LIGHT UP THE FUTURE!” and turned off the lights in their school.

The third educational programme analysed is entitled “Natural Processes on our planet. All about the earthquakes” and is dedicated to school students 13-17 years old.

The main part of the educational programme is the experiential activity of earthquake simulation on the museum's seismic simulator. The seismic simulator has been shaped like a school classroom, and children experience devastating earthquakes from Greece and around the globe. On the seismic simulator the children are trained on how to respond to earthquakes and learn about preparedness measures (Figure 4).

Geoheritage link: Lesvos is located in a seismically active region. Understanding the geological processes that lead to earthquakes is crucial for building resilient communities.

Connecting geoheritage to SDGs: 11 "Sustainable cities and communities"

Knowledge of geological hazards, such as earthquakes, is critical for developing resilient and sustainable urban and rural communities.

Preparing Active Citizens: Students become more informed about earthquake hazards and are empowered to take proactive steps for their safety and contribute to community resilience efforts.

Figure 4. Children participate in the experiential activity of earthquake simulation on the museum's seismic table and are implementing the preparedness measures in case of an earthquake.

Conclusions

Geoheritage serves as an exceptionally powerful and effective pedagogical tool for engaging children with the Sustainable Development Goals. The comprehensive educational activities developed and implemented by the Natural History Museum of the Lesvos Petrified Forest in the Lesvos Island UNESCO Global Geopark provide a robust model for how to leverage geological heritage to foster environmental awareness, promote sustainable practices, and empower young generations. By offering hands-on activities, interdisciplinary approaches and age-appropriate learning experiences, these programs aim to foster a deeper understanding of sustainability challenges and empower students to become informed, responsible, and active citizens committed to a sustainable future. The best practices and valuable lessons learned from the Lesvos Island UNESCO Global Geopark are highly adaptable and can be effectively applied in other UNESCO Global Geoparks and diverse educational settings worldwide, contributing significantly to global sustainability efforts.

EXTENDED ABSTRACT 035

Environmental controls on *Globorotalia menardii* size variability preceding the Tortonian/Messinian boundary

Besiou E.[1], Kontakiotis G.[1], Vasiliev I.[2], Antonarakou A.[1]

(1) Department of Historical Geology-Paleontology, Faculty of Geology and Geoenvironment, School of Earth Sciences, National and Kapodistrian University of Athens, Panepistimiopolis, Zografou, 15784 Athens, Greece (2) Senckenberg Biodiversity and Climate Research Centre, Senckenberganlage 25, D-60325 Frankfurt am Main, Germany

Research Highlights

Analyzing the potential drivers of *Globorotalia menardii* size variability in the eastern Mediterranean, we compare the *G. menardii* maximum diameter with the most significant regional environmental parameters during the Late Miocene. Among the examined abiotic factors, the strongest correlations were found to be with oxygen isotopic composition ($\delta^{18}O$) and sea surface salinity (SSS), while the correlations with sea surface temperature (SST) and carbon isotopic composition ($\delta^{13}C$) of planktonic foraminifera were relatively weak, suggesting that salinity had a greater impact on *G. menardii* size than sea surface temperature or primary productivity.

Introduction

Morphological changes in marine microorganisms have been of increasing interest to more and more researchers over the last decades. The size variability of species, a significant morphological parameter, can be altered by paleoceanographic changes reflecting global environmental events and/or local hydrographic changes (Schmidt *et al.*, 2004; Metcalfe *et al.*, 2015). Particularly, planktonic foraminifera are commonly preferred for morphological investigations, as they capture the abiotic environmental parameters in water masses, such as temperature, salinity, stratification and productivity (Adebayo *et al.*, 2023), but also for their abundance and global distribution (Schmidt *et al.*, 2004). Moreover, it has been observed that planktonic foraminifera can reach their maximum size under favorable conditions in the water column, while away from these areas occurred the opposite (Hecht, 1976), indicating their adaptive responses to the modified water mass structure (Friesenhagen, 2022; Besiou *et al.*, 2023). For the documentation of test size alterations, several studies have been carried out on illustration of the morphological variability of both Neogene and modern planktonic foraminifera. Particularly for the studies dealing with *G. menardii*, most of them have been performed in the Pacific, Atlantic, and Indian Oceans (Bhonsale and Saraswat, 2012; Knappertsbusch, 2016, 2022; Friesenhagen, 2022), showing that its size varies significantly over the different oceanic basins. Nevertheless, there is a gap in the morphometric study applied to the sedimentary archive of Mediterranean basin, without any evidence of size distribution patterns of *G. menardii* from this marginal subtropical setting.

Objectives

In our effort to examine how the environmental factors interplay with the observed morphological variability, we mainly attempt to investigate which environmental factor had the greatest influence on the size alterations of *G. menardii* specimens picked up from Potamida section (Crete Island, eastern Mediterranean; Fig. 1).

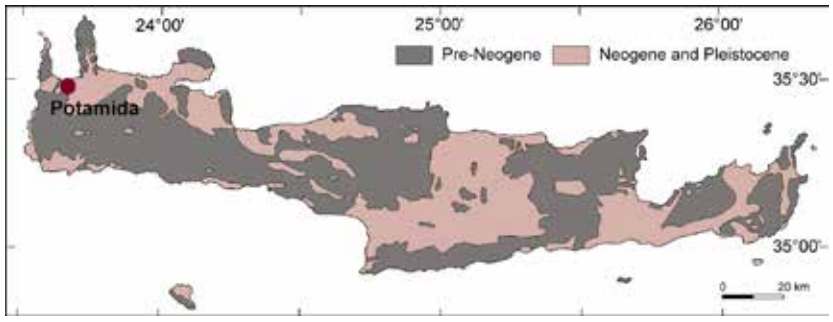

Figure 1. Geological sketch map of Crete Island, showing the Potamida section position (red circle).

On this context, the size variations of the analyzed species correlated to TEX_{86}-derived SST and SSS reconstructed values (Besiou *et al.*, 2024). Additional indices such the coiling direction and the species abundance were also evaluated as biotic measures of the foraminiferal ecological optimum conditions.

Material and Methods

The studied samples were collected from Potamida section in western Crete during the Thalys Project in 2017. Potamida section consists of blue-grey marls in the Tortonian and white-beige pelagic marls to clay limestones towards the Messinian (Agiadi *et al.*, 2017; Moissette *et al.*, 2018). The chronostratigraphic framework of the study section resulted from the combination of planktonic foraminiferal biostratigraphy, magnetostratigraphy and cyclostratigraphy published in Besiou *et al.* (2024) (Fig. 2). For size analysis, 10 specimens of *G. menardii* form 5 were handpicked from the >250 μm size fraction split per sample for the 7.36–7.24 Ma time interval. Then, the foraminiferal shells were positioned to capture the maximum diameter of each individual in the umbilical side and were photographed by a LEICA MZ16 stereo-zoom microscope supplemented by a digital camera connected to a computer. For testing the potential relationship to environmental perturbations, $\delta^{18}O$ and $\delta^{13}C$ isotopes measured on the shallow-dweller *Globigerinoides obliquus*. Moreover, SST estimates were calculated based on TEX_{86} biomarker proxy and SSS through the combined stable isotope and biomarker-based SST data.

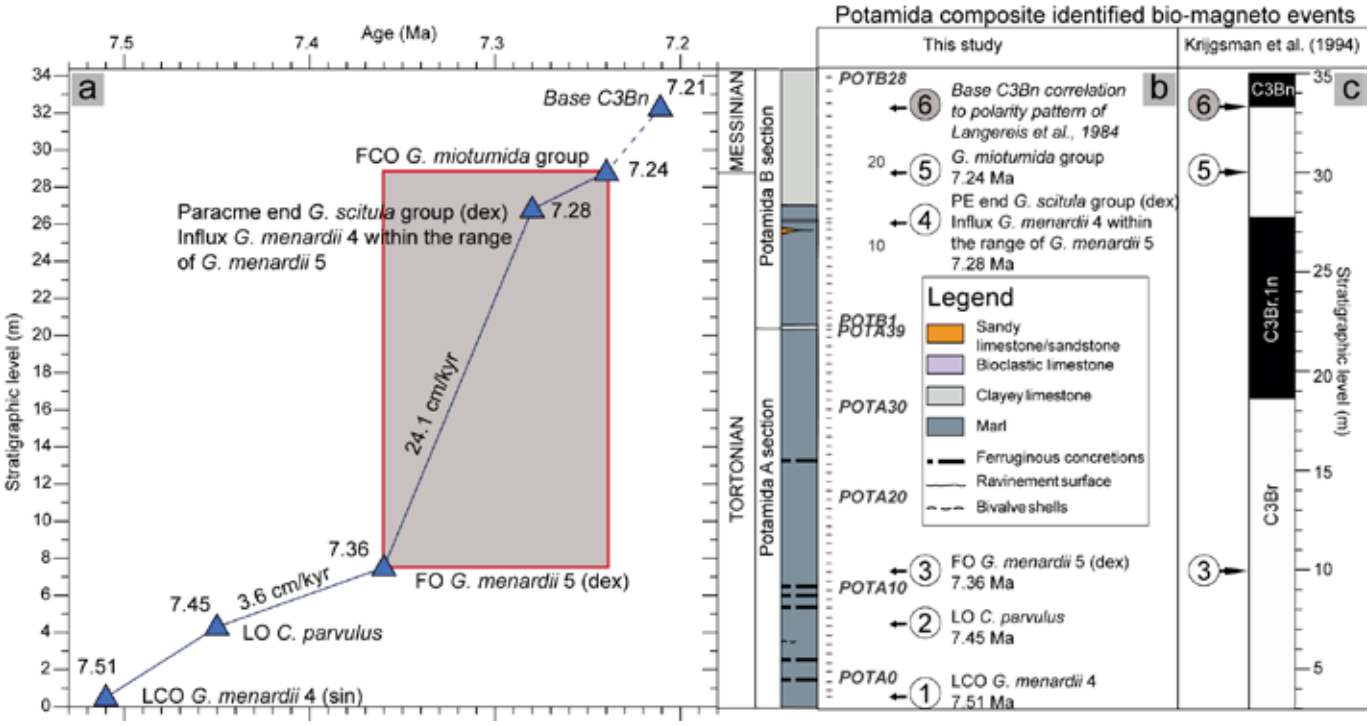

Figure 2. a) Age model of the composite Potamida section (modified by Besiou et al. 2024) with marked the studied time interval (represented by the red frame). b) The lithostratigraphy of the section along with five astronomically calibrated planktonic foraminiferal bio-events (labelled from 1 to 5) and the base of C3Bn magnetic polarity zone labeled in grey circle as event 6. c) The composite magnetostratigraphy based on Krijgsman et al. (1994).

Results

The evaluation of the existing dataset of Late Miocene Potamida section showed that optimum conditions in *G. menardii* are better inferred from its preferred environmental conditions rather than its relative abundance.

Therefore, the relative abundance may not the best descriptor of optimum growth conditions in planktonic foraminifera as the observed pattern is possibly attributed to adaptation strategies of the targeted species as a response to regional environmental forcings (Besiou *et al.*, 2023). Moreover, the coiling direction of this species within the study time interval remained constant (dextral) and not environmentally controlled. Size analysis further highlighted a quite large range of sizes between 330-450 μm (Fig. 3), consisting of small, intermediate and large specimens. These three groups of test sizes clearly reflect a biological adaptation to the significant environmental changes that took place in the Mediterranean Sea during the latest Tortonian. The distribution pattern of the average size of *G. menardii* varies significantly over the 7.36-7.24 Ma time interval. Size fluctuations are better correlated with the oxygen isotopic signal and more explicitly with the SSS reconstructions, indicating that the morphological characteristics are mostly influenced by the vertical changes of upper water column stratification in terms of salinity variations within the thermocline. This relationship is inversely proportional, with higher salinity conditions leading to smaller sizes in *G. menardii*.

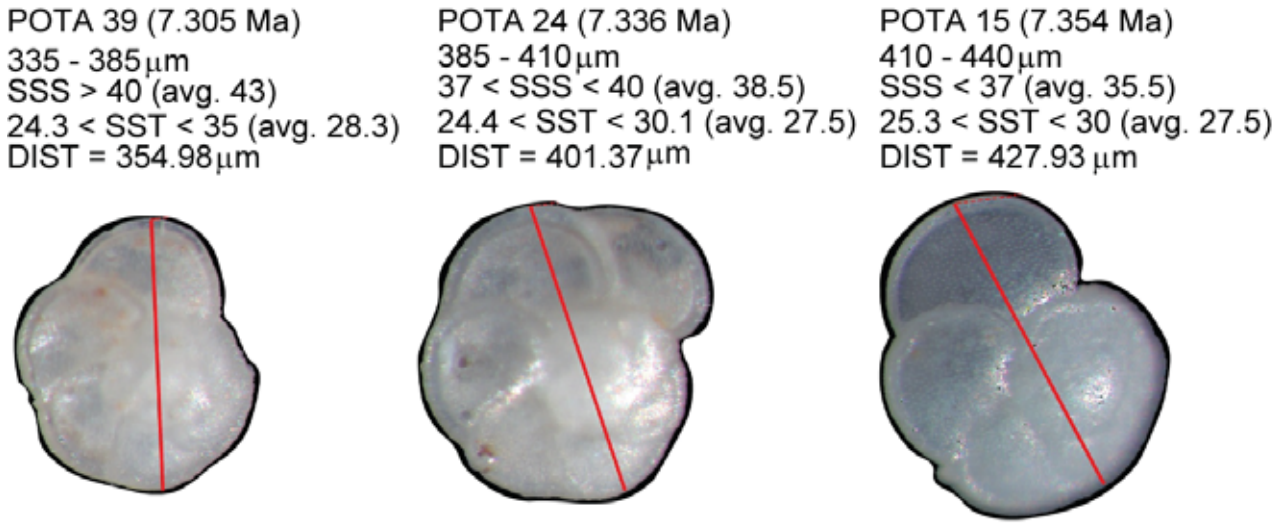

Figure 3. Images of *G. menardii* specimens separated in three maximum size groups (from the left to the right small, intermediate and large specimens).

Conclusions

The linear correlation analyses among the environmental parameters indicated that the dependence of test size on the temperature is not primary as initially thought to be, but secondary. Within such a highly evaporative stressed environment, salinity exerts a stronger influence on the size of *G. menardii* compared to sea surface temperature. Moreover, primary productivity seems to have only a minimized effect in such an ultra-oligotrophic setting as the Late Miocene eastern Mediterranean. The large size variability observed in Potamida samples corresponds to both small and large specimens of *G. menardii* (including intermediates) that were produced during colder/saltier and warmer/fresher sea water events in the lower and upper thermocline, respectively. Overall, our findings highlight the importance of analyzing species-specific paleoceanographic records around the globe by evaluating the shell size response to different environmental drivers in a regional context.

Research Highlights

- HOMEROS stands for “Harmonising Observations from Multi-hazard Environments in Research for Open Science”.
- The project aims to deliver FAIR-compliant tools and datasets to enhance disaster preparedness and resilience in high-risk regions through transparent and collaborative research.

Introduction

In today’s interconnected world, communities face a diverse range of hazards, including natural disasters like earthquakes, floods, and landslides, as well as human-induced events. To address these challenges, the HOMEROS project aims to strengthen multi-hazard assessment methodologies in seismology, geodesy, and geology (Figure 1). Leveraging technical solutions suited to the big data era, HOMEROS represents a significant advancement in standardizing research processes, promoting collaboration, and enhancing understanding and prediction capabilities for natural hazards through Open Science practices. By adhering to FAIR principles (Findable, Accessible, Interoperable, Reusable), HOMEROS ensures that its research outputs are transparent, reproducible, and universally accessible, maximizing their value for the scientific community and stakeholders. Focusing on high-risk areas in Greece with significant seismic activity, strong earthquakes, floods, and landslides, HOMEROS will compile earthquake catalogues and assess ground deformation products to provide a comprehensive evaluation of seismic hazards. Additionally, it will enhance the understanding of flood and landslide risks, vital for effective mitigation strategies.

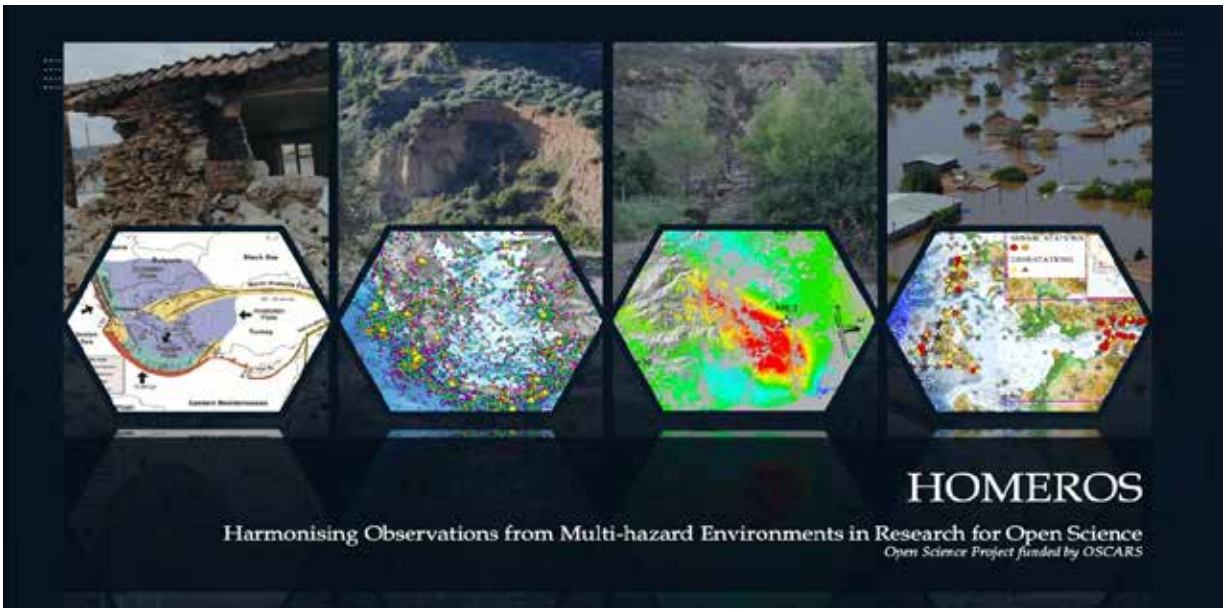

Figure 1. Official logo of the HOMEROS project, highlighting its multi-hazard focus

Objectives

The HOMEROS project addresses the critical need for robust and standardized multi-hazard assessment methodologies in a rapidly evolving risk landscape. By leveraging the power of Open Science and interdisciplinary collaboration, the project aims to advance scientific knowledge, foster data-driven decision-making, and enhance community resilience. Its objectives focus on three key pillars:

- Integration with Open Science environments: HOMEROS aims to utilize platforms such as the European Open Science Cloud (EOSC) and the Environmental Research Infrastructure (ENVRI) Hub (Adamaki & Vermeulen, 2023) to create accessible ecosystems for data sharing. This builds on prior integration efforts in ENVRI projects and promotes FAIR principles to ensure the usability and reproducibility of research outputs.
- Enhancing multi-hazard assessment: The project seeks to develop methodologies for integrating diverse datasets, including seismic, geodetic, and geological data. It will advance the understanding of earthquakes, floods, and landslides through the creation of detailed models, maps, and inventories.
- Fostering collaboration and communication: HOMEROS aspires to strengthen partnerships among research institutions, infrastructures, and projects. Results will be shared through Open Access publications, workshops, and training resources.

Multi-hazard environments - Pilot areas

The HOMEROS project focuses on two high-risk pilot areas in Greece, the central Ionian Islands and the western Gulf of Corinth (Figure 2), which represent diverse and complex multi-hazard environments. These regions have been selected due to their significant seismic activity and susceptibility to other natural hazards, such as floods and landslides. By studying these areas, HOMEROS aims to develop and demonstrate innovative methodologies for multi-hazard assessment.

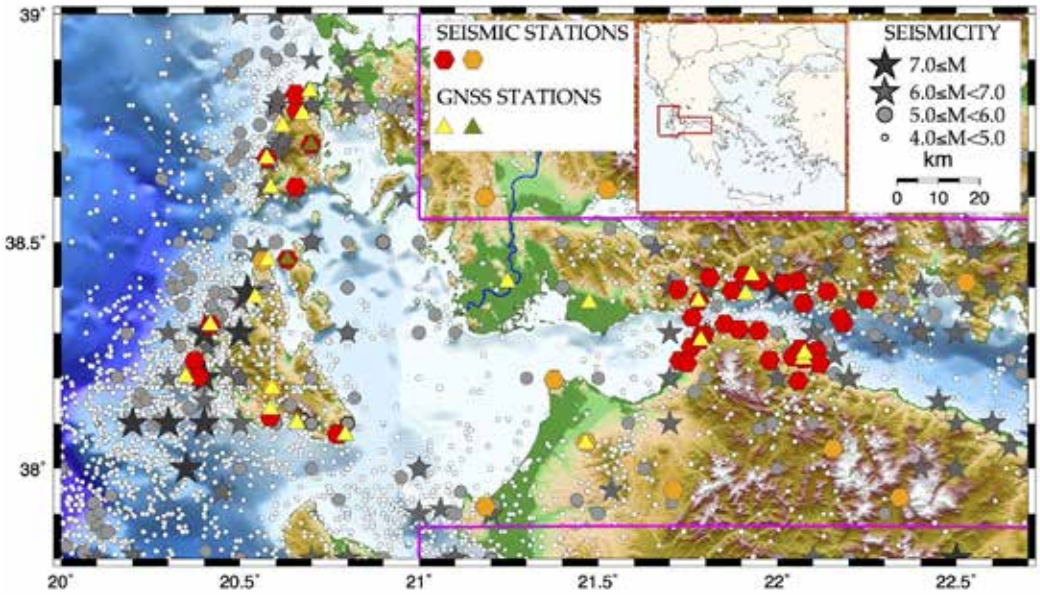

Figure 2. Map of the pilot areas encompassing the central Ionian Islands and western Corinth gulf. Different symbols denote the epicenters of all known earthquakes in the study area with magnitudes M>4.0 as shown in the upper right inset. The central inset shows the territory of Greece with the study area enclosed in the red polygon. Hexagons illustrate the positions of the seismological stations providing online access to their recordings. Yellow triangles depict the installation sites of GNSS stations in operation, whereas the olive triangles the positions where additional GNSS stations are planned to be installed in the framework of the project, collocated with already existing and operated seismological stations.

The central Ionian Islands, along with the western Gulf of Corinth, accommodate the highest seismicity in the eastern Mediterranean, exhibiting high deformation rates (Pikridas et al., 2016; Bitharis et al., 2024) and frequent occurrences of strong earthquakes (e.g., Karakostas et al., 2015; Sakkas et al., 2022). The compilation of earthquake catalogues (e.g. from the Euro-Mediterranean Seismological Centre - EMSC, the European Plate Observing System - EPOS providers as the ORFEUS infrastructure, the database of the Aristotle University of Thessaloniki - AUTh seismological center, and others), comprising historical, instrumental, and recent events, along with focal mechanism and stress field data, represent a significant contribution to the understanding of seismic hazard. Earthquakes are among the most impactful geohazards in Greece given that more than 50% of seismic energy in Europe is released in the country. A reliable seismic hazard model can contribute to seismic risk mitigation. To that end, Peak Ground Acceleration (PGA) and Peak Ground Velocity (PGV) together with a site-specific analysis (Uniform Hazard Spectra - UHS and hazard curves) in the most populated towns can provide a holistic evaluation of seismic hazard (e.g., Kaviris et al., 2022; 2024). Besides strong earthquakes, the aforementioned areas along with parts of the northern Peloponnese have experienced severe floods and landslides that resulted in loss of life and substantial loss of property, along with extensive damage to the natural and built environment and key infrastructure (Bathrellos et al., 2017; Skilodimou et al., 2018). Maps displaying the spatial distribution of flood and landslide hazards are invaluable at identifying areas at risk (Skilodimou et al., 2019; Bathrellos et al., 2024). The project will enhance the understanding of the spatial distribution of historical and recently recorded floods, along with the identification of flood – prone areas, which constitute critical input information on effective flood-risk mitigation. Regarding landslides, they are mostly observed in the mountainous part of the Gulf of Corinth, the Ionian Islands, and parts of western Peloponnese, where serious damage has been repeatedly caused to sections of urban areas and the road network. Landslide hazard assessment maps are important tools for prediction and mitigation of natural disasters. In this context, the project will work on an inventory map that includes recorded landslide events, crucial for understanding the landslide hazard.

Data and Methods

Comprehensive multi-hazard assessment requires diverse data sources and advanced methodologies to address the complexity of natural hazards. HOMEROS will integrate high-quality datasets from seismology, geodesy, and geological monitoring to provide robust and reproducible insights. Seismic data from regional networks form the basis for compiling earthquake catalogues, analyzing focal mechanisms, and studying ground deformation, all of which are critical inputs for seismic hazard assessment. Geodetic observations, including GNSS and InSAR, enhance the understanding of tectonic deformation (Bonatis et al., 2024) and enable the integration of precise ground deformation monitoring with broader hazard assessments. Flood and landslide hazards can be assessed using historical records and remote sensing data. Spatial analyses and advanced techniques, such as InSAR, help to identify flood and landslide prone areas (Aslan et al., 2020). These methods are complemented by the development of inventories that catalog historical events. A key component of the project is the harmonization of data and the application of Open Science principles to ensure all research outputs are transparent, reproducible, and widely accessible. Collaborative platforms and tools will be utilized to integrate datasets from diverse sources, fostering interdisciplinary research and promoting knowledge sharing. Reproducible workflows will enable the seamless combination of datasets and methodologies to deliver actionable insights into natural hazards.

Exploitable results

The HOMEROS project aims to deliver a range of results that will significantly advance multi-hazard assessment and enhance disaster resilience (Table 1). A primary output will be open-access datasets, including earthquake catalogues, ground deformation products, flood hazard maps, and landslide inventories. These datasets will adhere to FAIR principles and will be shared through platforms such as EPOS ERIC, ENVRI repositories, and other open repositories (e.g., GitHub, Zenodo). These data products will provide valuable resources for advancing research and fostering interdisciplinary collaboration.

Another key outcome is the development of transparent and reproducible research workflows documented through tools like Jupyter Notebooks. These workflows will demonstrate the integration of diverse datasets and methodologies, enabling researchers to replicate and adapt the processes for similar studies. This documentation will serve as a best-practice guide for future multi-disciplinary research projects.

Table 1. Summary of the key outcomes of HOMEROS

Output	Description	Impact
Open-access datasets	Comprehensive datasets including earthquake catalogues, ground deformation products (GNSS and InSAR), flood hazard maps, and landslide inventories.	Enabling improved hazard modeling, interdisciplinary research, and data-driven policy-making.
Scientific publications	Peer-reviewed articles published in Open Access journals, showcasing HOMEROS methodologies and findings.	Advancing scientific knowledge.
Training modules	Educational resources designed to teach Open Science principles, data sharing practices, and the utilization of research tools like Jupyter Notebooks and ENVRI/EOSC services.	Capacity building among researchers, students, and professionals, fostering widespread adoption of Open Science practices.
Integration demonstrators	Showcase of pathways to integrate data pipelines from diverse sources, including ENVRI and EOSC infrastructures, to highlight interoperability and scalability.	Improved data interoperability.
Policy recommendations support tools	Practical outputs such as hazard maps and risk models suited for policymakers and disaster management stakeholders.	Enhancing disaster preparedness and resilience.

Conclusions

HOMEROS represents a vital step forward in addressing the growing complexity of multi-hazard environments. By harmonizing data from diverse scientific domains and adhering to Open Science principles, the project tackles key challenges in making hazard assessment both comprehensive and accessible. It lays the foundation for more integrated and scalable approaches to understand natural hazards, from earthquakes to floods and landslides, in high-risk regions. The emphasis on FAIR principles ensures that HOMEROS outputs not only benefit current research but also provide a robust framework for future innovations in hazard modeling. The project's focus on high-risk areas, such as the Ionian Islands and the Gulf of Corinth, will demonstrate its applicability, while offering scalable solutions that can be adapted to other geohazardous regions worldwide. Lastly, the outputs including open-access data, scientific publications, and training modules, will serve as valuable resources for academia, policy-making, and disaster management, fostering a safer and more resilient society.

Research Highlights: **Development of an index-based equation and methodology for assessing coastal vulnerability in Greece at a national scale**

Introduction

Coastal areas are one of the most vulnerable environments and due to their continuously growing population, their protection is of great importance for society and economy. Moreover, climate change can increase the intensity of climate related coastal hazards, especially coastal erosion and sea level rise, whose adverse impacts on coastal zones are expected to be significant even under the most optimistic emission scenario (IPCC 2022). Against these rising threats, different risk and vulnerability assessment methodologies have been developed to understand the processes underpinning coastal hazards. More specifically, the assessment and calculation of coastal vulnerability, focusing on coastal erosion processes, is accomplished with the following methods: (a) methods based on a specific vulnerability index, (b) methods based on a sequence of indicators, (c) methods based on geographical information system (GIS)-based decision-making systems and (d) methods based on dynamic computational model (Ramieri et al. 2011).

In the present study, the use of a method based on a specific vulnerability index, and more specifically the Coastal Vulnerability Index (CVI) approach was chosen to assess vulnerability along the Hellenic coastlines and for this reason it was named HCVI. The CVI is a very productive, low-cost and effective tool for mapping and managing coastal risks. In this way, it provides an initial identification of coastal vulnerability to facilitate local and regional authorities in preparing coastal management and protection plans, coastal zone regulation and adaptation strategies against erosion.

However, despite the effective application of the CVI index, there are limited publications in the literature addressing its use at the national scale. Furlan et al. (2021), developed a modified CVI index (MDim-CVI) for Italy, incorporating four different sub-indices: a) Coastal Forcing, b) Environmental, c) Social and d) Economic. In addition, López Royo et al. (2016), estimated coastal vulnerability for the entire coastal zone of Spain again using a modified CVI index, which was calculated for 4 different future climate models (RCPs) of sea level rise, based on IPCC future projections.

The aim of this project is the creation, implementation and presentation of the Hellenic Coastal Vulnerability Index (HCVI) for the assessment of vulnerability along the Hellenic coastlines and the creation of a national scale vulnerability map.

Methodology

For the calculation of coastal vulnerability at a national scale, the classic vulnerability index CVI (Coastal Vulnerability Index) was chosen, with the following variables: 1) Geological resilience, 2) Coastal Slope, 3) Historical shoreline change, 4) Significant wave height, 5) Sea level rise and 6) Tidal range.

The calculation of CVI for the Hellenic coastlines was carried out using the equation proposed by (Gornitz (1991) according to which the result is equal to the square root of the product of the variables divided by the number of variables. For the calculation of the CVI, the coastline of Greece was divided into coastal segments of 100 meters, precisely at the same locations where transects were created for calculating

the historical shoreline change using the DSAS software (Digital Shoreline Analysis System version 6) (Himmelstoss et al., 2024).

The equation for calculating HCVI is presented below:

$$HCVI = \sqrt{\frac{a * b * c * d * e * f}{6}}$$

where a: Geological resilience, b: Significant average wave height, c: Coastal slope, d: Historical shoreline change, e: Average tidal range, f: Sea level rise (SLR).

The initial step before calculating the Coastal Vulnerability Index is to determine the range values of each variable to classify them with a specific vulnerability value, for example, from very low to very high vulnerability. The five (5) ranges of vulnerability classification values used in this project are presented in Table 1.

Table 1. Vulnerability classification ranges for each of the variables used in the HCVI calculations.

Variables	Very Low (1)	Low (2)	Moderate (3)	High (4)	Very High (5)
Geological resilience	Limestones, plutonic and metamorphic rocks	Flysch, evaporites, igneous and semi-metamorphic rocks	Neogene deposits (hard soils- soft rocks)	Quaternary loose materials with a higher percentage of coarse-grained materials (sand, gravel and pebbles)	Quaternary loose materials with a higher percentage of fine or mixed phase deposits (silts and sands)
Significant Wave Height (m)	<0.3	0.3–0.6	0.6–0.9	0.9–1.2	>1.2
Coastal Slope (%)	>12	12- 9	9 – 6	6 – 3	<3
Historical Shoreline Change (m/y)	>(+1.5)	(+1.5)–(+0.5)	(+0.5)–(-0.5)	(-0.5)–(-1.5)	<(-1.5)
Average Tidal Range (m)	<0.2	0.2–0.4	0.4–0.6	0.6–0.8	<0,8
Sea Level Rise (mm/y)	<1.8	1.8 - 2.5	2.5 – 3.0	3.0 – 3.4	>3.4

Geological resilience is one of the most important variables in the equation of HCVI as it assesses the resistance of any geological formation to erosion. The more resistant the formation is to erosion, the lower the vulnerability class corresponds to. Based on this principle, the data of the geotechnical map of Greece, published by EAGE, which includes 28 engineering-geological units at a scale of 1:500,000, were used. Subsequently, the units were grouped into five vulnerability classes, according to the guidelines for the European coastal zone of the EUROSION programme (EC 2004), as presented in Table 1.

Wave height is the main hydrodynamic force, which causes sediment transport leading to erosion. Therefore, vulnerability is higher as wave height increases, while it decreases with lower wave height. Therefore, in CVI applications, wave height is included as an indicator of wave energy, influencing the coastal sediment balance. For the calculation of the significant wave height, data produced through ERA5 reanalysis from 2001 to 2017 (Copernicus database) were used (https://cds.climate.copernicus.eu/datasets/sis-ocean-wave-indicators?tab=overview).

A coast characterized by a gentle slope is considered more vulnerable to erosion than a coast with a steeper slope during an inundation event (Boumboulis et al. 2021). As a result, the coastline is classified as low vulnerability on steep coasts and as high vulnerability in gentle coasts. The coastal slope variable for Greece was determined by processing the Digital Elevation Model (DEM) (5X5 m) of Greece for a range of 8 km from coast to land. More specifically, after the creation of the DEM, it was processed to calculate the coastal slope, expressed as a percentage,

based on the distance between the 10m elevation contour and the coastline of Greece.

For the calculation of the historical shoreline change, multi-spectral satellite images of Greece from 1984 to 2024 as derived from the satellite system of Landsat and processed with ArcGIS Pro were used in order to extract the shoreline in various time periods. The evolution or rate of change of the shoreline is an important variable that indicates the deposition/erosion regime in an area. In this work, the extracted shorelines of 1984 and 2024 were used for the calculation of the rate of change from 1984 to 2024, while the DSAS software was used for the statistical visualization and estimation of the rate of change of the shoreline by calculating the end point rates (EPR). The EPR is calculated by dividing the distance of coastlines (between the oldest and more recent coastlines) by the number of years between their captured dates.

According to Gornitz (1991), macro-tidal environments (high tidal range) are vulnerable to erosion, because they can create stronger currents and cause larger sediment transportation in comparison with the micro-tidal environments. The Greek coastline has low vulnerability to erosion due to the prevailing micro-tidal regime so in the present study, this hypothesis was adopted. The data used for the calculation of tidal range was retrieved from Copernicus and confirmed Greece's low tidal range (https://cds.climate.copernicus.eu/datasets/sis-water-level-change-indicators-cmip6?tab=overview).

SLR is the annual mean increase or decrease of water elevation measured at tide gauges, and is the sum of eustatic, hydro-isostatic and tectonic factors. In this specific research, sea level rise data derived by the Copernicus platform are used, which are attributed to time series based on historical records of sea level changes (https://cds.climate.copernicus.eu/datasets/sis-water-level-change-timeseries-cmip6?tab=overview).

Results

The spatial distribution of the HCVI along the Hellenic coastlines, calculated using the equation proposed in the methodology, is illustrated in the map in Figure 1, highlighting two specific areas identified as having high and very high vulnerability. In particular, the Northwestern Peloponnese and a significant part of Northern Greece were identified under the regime of high and very high vulnerability.

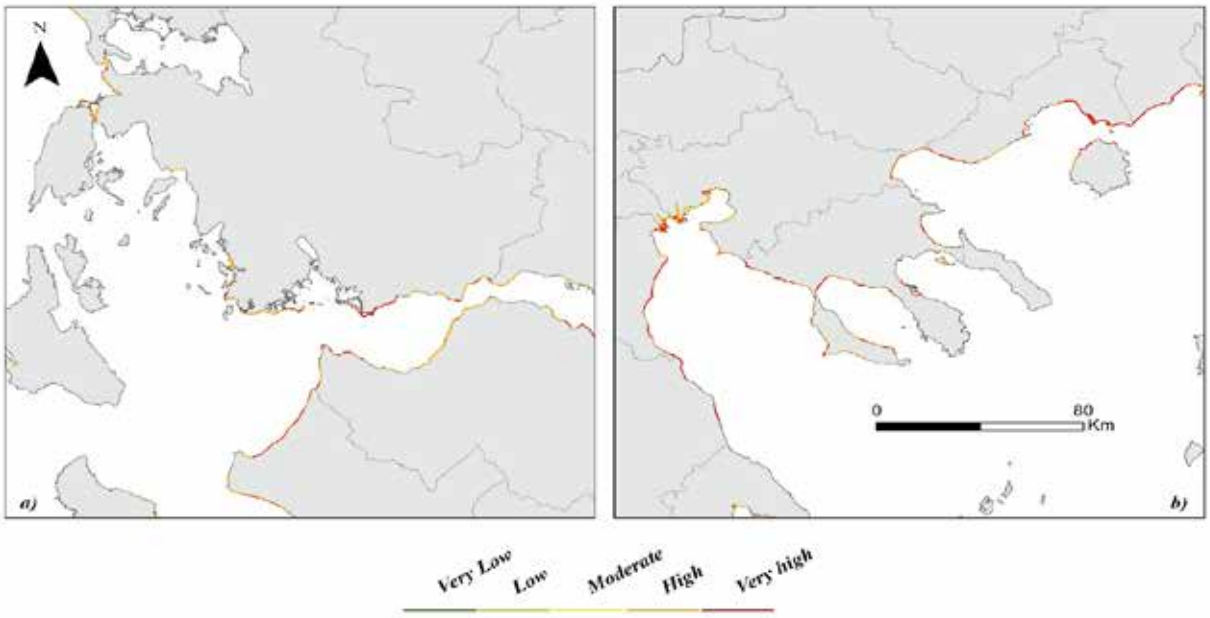

Figure 1. Spatial distribution of high and very high vulnerability classes in a) Northwestern Peloponbese and b) Northern Greece.

More specifically, a large part of the northern Peloponnese (northern and southern part of the Gulf of Patras, southern part of the Gulf of Corinth) is under a high and very high vulnerability regime. Similarly, under the regime of high to very high vulnerability is also the western part of the Peloponnese (Gulf of Kyparissia

and the shoreline from Kalogria to Kyllini) (Figure 1a). The rest of the Peloponnese is characterized by low and moderate vulnerability, with only small areas exhibiting high to very high vulnerability, notably in the Messenian and Laconian Gulfs.

A significant part of the coastline extending from the Regional Unit of Larissa to the Kassandra Peninsula is characterized by high to very high vulnerability due to the presence of gentle slopes and geological formations of low resistance to erosion (Figure 1b). Similarly, a significant part of the coastline of the Regional Unit of Kavala, as well as the entire coastline of the Regional Units of Xanthi and Evros, are characterized by high to very high vulnerability.

Most of the country's islands are in a very low to low vulnerability regime, as they are composed of rocky geological formations and steep slopes. Exceptions are the islands of Rhodes, Limnos, Lesvos, Corfu and Crete, where a large part of their coasts are in a high and very high vulnerability regime.

Conclusion

Among a variety of other indexes and methodologies, the Coastal Vulnerability Index (CVI) was chosen as a method for the estimation and calculation of vulnerability as low-cost and effective tool for mapping and managing coastal risks at a national scale. It is important to note that the coastal vulnerability assessment methodology used in this study was implemented for the first time on a national scale in Greece. Therefore, the application and the produced results can inform national strategic decisions regarding the impacts of climate related hazards on coastal zones.

However, the HCVI results presented in this study are preliminary and are expected to be further improved by incorporating additional variables into the final model, drawing on indicators identified in existing methodologies from literature. This could lead to adjustments of the index and improvements of the findings on the vulnerability of the Greek coasts.

Despite the presence of high percentage of High and Very High vulnerability classes in the study area potential future climate projection was not included in the model, which means that the vulnerability regime could be increased in the future with severe impacts for the entire coastline of Greece.

Acknowledgements

The current research was funded by the Onasis Foundation in the framework of the project "Vulnerabilty of Greek coasts due to climate change" ("Initiative 1821-2021" - Protovoulia 21).

ABSTRACT

Mytilene is the capital of Lesvos, the largest island in the North Aegean. The region of North Aegean is a geotectonically complex area because its geodynamic status is directly affected by the North Anatolian Fault Zone. The seismic activity negatively impacts the material and technical infrastructure and, by extension, social and economic life. This fact makes mitigation of negative impacts of seismic events imperative. This paper describes the development of a web-based GIS for disaster response in Mytilene, Lesvos (Greece), urban area through the ArcGIS Online application (https://www.esri.com). WebGIS technologies provide a wide range of solutions for fault mapping, data analysis, and publication of results. The completion of this project contributes to the improvement of methodologies and applied technologies and the proposal and development of new ones, indicating the direction for the implementation of similar research projects and the introduction of new geographic information technologies in seismic risk management.

Keywords: Earthquakes, emergency management, GIS, Web-based

1. Introduction

An earthquake is a highly challenging natural phenomenon to forecast, making each occurrence essential for advancing research (Darzi et al., 2022). Geographic Information System (GIS) can support disaster management as a powerful tool for collecting, storing, analyzing, modeling, and displaying large amounts of data. Online GIS combines the advantages of both GIS and the Internet. The WebGIS is addressed to a broad target of end users and supports the implementation of seismic risk mitigation strategies. Web GIS is one of the most widely used technologies for the propagation of open data for multiple purposes. WebGIS technologies have also been widespread for natural risk assessment and communication (*Daud et al., 2024; Vinueza-Martinez et al., 2024*). Web GIS and geodatabase technologies have been used to advance interactive tools for defining seismic hazard scenarios and risk analysis (Pessina & Meroni, 2009; *Aye et al., 2015*). The ArcGIS Online application (https://www.esri.com) helps create interactive maps.

An Earthquake Information Management System (EIMS) is a system that records, collects, keeps, retrieves, and analyzes inputs, produces reports and required information for earthquakes, and informs the responsible stakeholders. The information does not comprise an end but contributes to better decisions in policy design, disaster planning, management, monitoring, and evaluation of disaster plans and damage reduction (*Ajami & Fattahi, 2009; Kirschenbaum et al., 2017).*

Earthquake Information Management Systems (EIMS) use ArcGIS (Geographic Information System) to map and visualize ground vibration, the pattern of damaged buildings, and demographic information about a community (*Cao et al., 2023)*. Once the location and magnitude of an earthquake have been determined, the EIMS will assess the distribution of ground vibrations, building failures, casualties, transmission system failures, power, and water outages, population displacement, and the cost of repairing potential faults (Ajami et al., 2008; Cao et al., 2023). In this study, we developed a Web GIS for earthquake management and monitoring in the urban area of Mytilene, Lesvos (Greece). Decision-makers and the general public can use our Web-based GIS model.

2. Materials and methods

2.1. General description of the analyzed area

Lesvos is the third largest island of the Greek Islands, with 1.632 square kilometers in extent. It is located in the northeastern Aegean Sea. Mytilene is the capital of the island of Lesvos and the Prefecture of Lesvos. The geology can be summarized as a basement composed of Alpidic and pre-Alpidic metamorphic rocks, which were covered later by post-Alpine formations, mainly Miocene volcanic rocks and Neogene marine and lacustrine deposits (Soulakellis et al., 2006). The island was characterized by high seismicity hazards and had been affected many times by powerful, devastating earthquakes. Mytilene is the capital of Lesvos and is located in the eastern part of the island. The altitude fluctuates from 0 to 100 m, and it is a smooth relief.

2.2. Methodology

The steps of the methodology include:

1. Microtremor measurements and processing

Microtremor measurements have been conducted to study the site effect and the site ground response in case of an earthquake in the urban area of Mytilene. The Horizontal-to-Vertical Spectral Ratio (HVSR) technique has been applied to ambient noise measurements (Nakamura's technique). The Nakamura technique is helpful for subsurface soil structure and site response studies (*Araque-Pérez, 2024*). The microtremor HVSR method has been widely used in seismic micro-zonation and site effect studies.

Ambient noise measurements have been performed in Mytilene from May 2012 to February 2013. One hundred measurements of ambient noise have been conducted throughout the city. The measurements were carried out from Monday to Friday from 23:00-02:30. A global Positioning System (GPS) module localizes the spatial position of each measurement point (Hatzopoulos & Hatzopoulos, 2024). The sampling rate was 200Hz, and the recording duration was 30 minutes. These data are acquired according to guidelines proposed by Duval et al. (2004). The sites of microtremor recordings were selected to cover all the different geological formations of the area. Figure 1 shows the locations of measured points in the urban town of Mytilene.

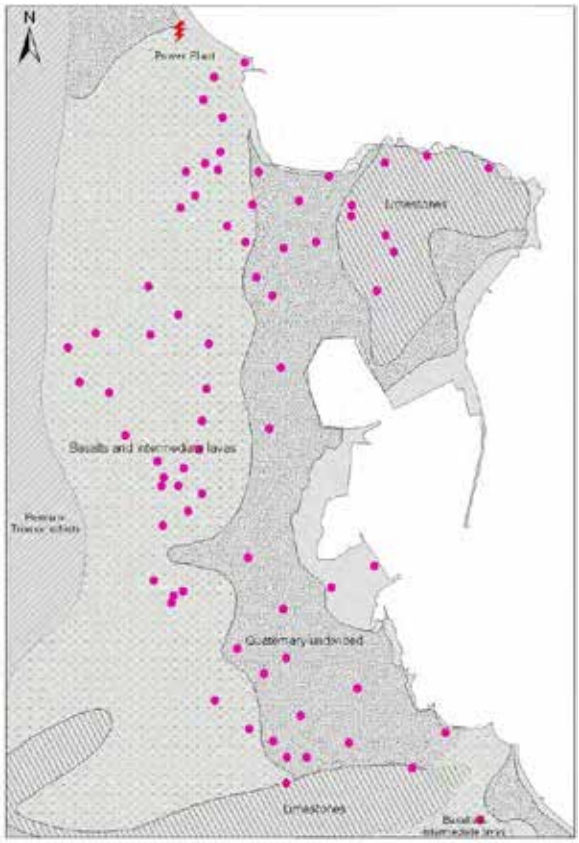

Figure 1. Position map of microtremor measurements in the urban area of Mytilene

2. Deployment of temporary strong motion network

A strong motion sensor network was deployed in the three different geological formations to provide valuable information for the region (Fig. 2). A total of 198 seismic events were recorded from December 15, 2014, to July 20, 2015, for the study area.

Figure 2. One of the three stations. The accelerograph is on the left, and the GPS is on the right.

The spatial distribution of the strong motion parameters, such as the Peak Ground Acceleration (PGA), Peak Ground Velocity (PGV), and Peak Ground Displacement (PGD) observed at the urban area of Mytilene are presented with the use of a Geographic Information System (GIS) environment (Figures 3, 4, 5). The results provide valuable information on earthquake hazards before and after detrimental seismic events to supply systems supporting civil protection decisions for prevention and emergency response.

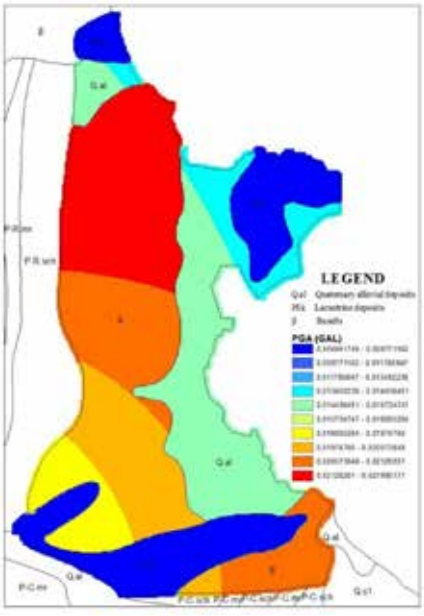

Figure 3. Spatial Distribution of PGA

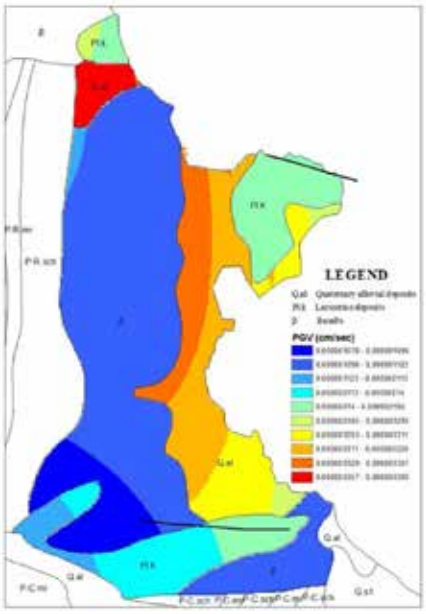

Figure 4. Spatial Distribution of PGV

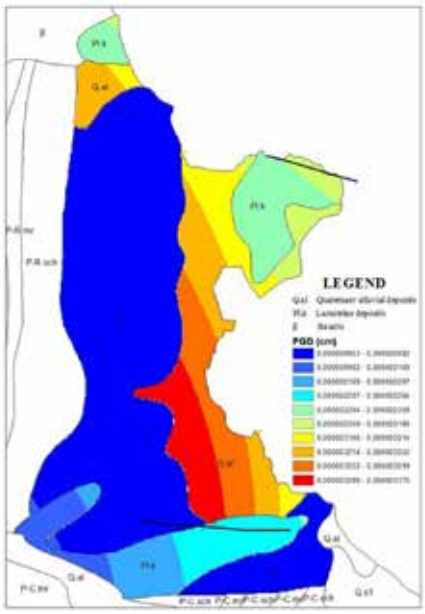

Figure 5. Spatial Distribution of PGD

3.

3. Development of a Web-based interface for earthquake management and monitoring

Finally, dynamic seismic hazard maps were created for the urban complex of Mytilene. Dynamic maps enable the user to manage geoinformation via the Internet. Creating a dynamic map requires the use of a network GIS. (web GIS). This is a GSP that can work and be used on the Internet. Using the ArcGIS Online application (https://www.arcgis.com/home/), the corresponding dynamic maps of maximum ground acceleration (PGA), maximum ground speed (PGV), and maximum ground shift (PGD) were created. The application allows the creation of custom cartographic compositions with user data and the ability to select a background.

3. Results and Discussion

The pilot strong-motion network comprises three stations, which were, however, strategically positioned to represent distinct geological formations. The objective was not to achieve full spatial coverage, but rather to evaluate the potential for site-specific, geology-dependent ground response. This approach serves as a foundation for the future expansion of the network. The correlation of recorded motion data with subsurface characteristics provides valuable insights into the spatial variability of seismic site effects.

WebGIS is constantly gaining ground in decision-making and spatial planning applications, as it enables researchers and stakeholders to benefit from the visualization, exchange, and evaluation of geospatial data with minimal effort and cost. Both scientific staff and stakeholders having access to the correct data at the right time can make the right decisions to mitigate the effects and address the risks of an impending earthquake. Thus, an online GIS can be a powerful tool in all phases of a disaster management cycle. The proposed platform distinguishes itself through its focused application at the local scale, effectively integrating in-situ microtremor measurements with real-time strong-motion data. A key innovation lies in its capacity to generate dynamic seismic hazard maps and offer interactive tools designed to serve both technical experts and the broader public, thereby enhancing accessibility and practical utility in risk communication.

The generated maps of maximum ground acceleration (PGA), maximum ground velocity (PGV), and maximum ground displacement (PGD) can give an idea of the magnitude of the damage that an earthquake can cause depending on the existing local soil conditions. Assessing the effects of an earthquake enables preparedness and immediate response to the crisis in the event of an earthquake. The dynamic maps that are created can be shared via a link. Following the link below gives the user direct access to dynamic maps: http://arcg.is/1QIlj1X (Fig.6).

Figure 6 is a screenshot of the application and illustrates the interface of the WebGIS application, showing the PGA map, where users can interactively explore areas of maximum ground acceleration based on different parameters. The map highlights the spatial variation of PGA across the region, helping stakeholders prioritize high-risk zones.

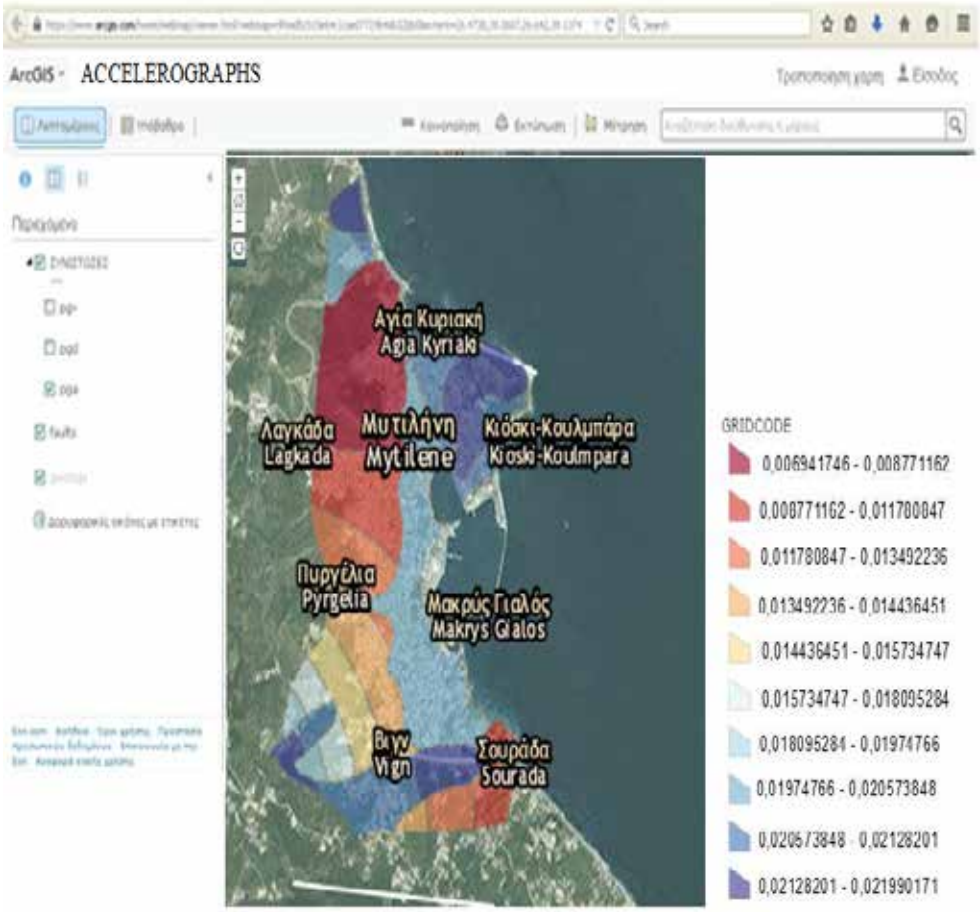

Figure 6. Screenshot of application

The analysis conducted in this study highlights the criticality of using WebGIS tools for earthquake preparedness and disaster management. For the city of Mytilene, the generated maps indicate specific areas that are more vulnerable to seismic activities due to local soil conditions. In particular, zones with high PGA and PGV values should be given priority in terms of preventive measures and resource allocation. These high-risk areas can guide city planners and emergency response teams to implement targeted interventions that mitigate potential damages.

Moreover, the findings suggest that immediate attention should be focused on zones with critical infrastructure and dense populations in an earthquake. Prioritizing these areas ensures residents' safety and essential services' functionality. The application of WebGIS in identifying and visualizing such zones proves invaluable for proactive planning and efficient disaster response. By integrating real-time data and dynamic maps, stakeholders can make informed decisions that enhance the resilience of Mytilene to seismic hazards.

The obtained results can be a valuable tool for the rational management of seismic risk as they can be applied at any stage of disaster management (mitigation, preparedness, response, rehabilitation). In the future, as far as the online GIS is concerned, this will mainly be addressed to experts and the general public. For this reason, a mechanism could be created to offer solutions to non-skilled people, such as making a discussion forum. Developing an application using open-source or free software could also be addressed to any user, enabling the general public to participate in decision-making processes.

The developed WebGIS system demonstrates strong potential for future scalability and functional

expansion. One of its most promising directions lies in the integration of additional datasets, such as detailed building inventory information—including structural typology, construction year, and height—as well as socio-economic indicators like population density, age distribution, and social vulnerability indices. Incorporating such multidimensional data would enable the generation of more sophisticated and realistic seismic risk scenarios, tailored to both the physical and human dimensions of urban environments. Furthermore, the integration of Building Information Modeling (BIM) technologies with the WebGIS framework could pave the way for a unified risk management platform, combining geospatial intelligence with structural-level detail. This holistic approach would significantly enhance the capacity for pre-event planning, impact assessment, and post-event response in earthquake-prone areas. Finally, registering building stock data in an electronic database would make it possible to create seismic risk scenarios, which would be a helpful guide for the relevant services.

4. HELPE Upstream S.A., Hellenic Energy Holdings S.A., 8ª Chimaras str., 15125 Marousi Athens, Greece.

This research involves the integrated sedimentological and paleontological analysis of the Neogene tidal deposits in the eastern parts of the Hellenic Fold and Thrust Belt, in South Kefalonia (Paliolinos - Avithos coast) and in NW Corfu (Arillas coast) islands. The study of tidal is supported by illustrative outcrop photographs, with a particular emphasis on two synthetic outcrops. Sedimentary logs were generated to document detailed bed-by-bed measurements, descriptions, and identification of sedimentary structures. Additionally, over 75 samples were chosen for age determination and paleoenvironmental analysis. Micropaleontological analysis encompassed 52 samples from South Kefalonia and 23 samples from NW Corfu and the results point to an Upper Miocene time interval. The sedimentological examination revealed sixteen distinct sedimentary structures within the studied deposits. The study results indicate for NW Corfu that the deposition displays fluctuations between low and high energy episodes, predominantly representing a tidally-influenced continental shelf (Figure 1a); whereas in the South Kefalonia deposition took place in a back-barrier restricted basin and highly active margins (Figure 1b). The different tidal environments, in the two studied regions, were related with the different tectonic conditions. When the tidal environment in a basin mostly controlled either by transfer or strike-slip faults, open shelf tidal environment could be formed; whereas when the major influence is the normal or the thrust faults then a tidal back-barrier environment could be formed.

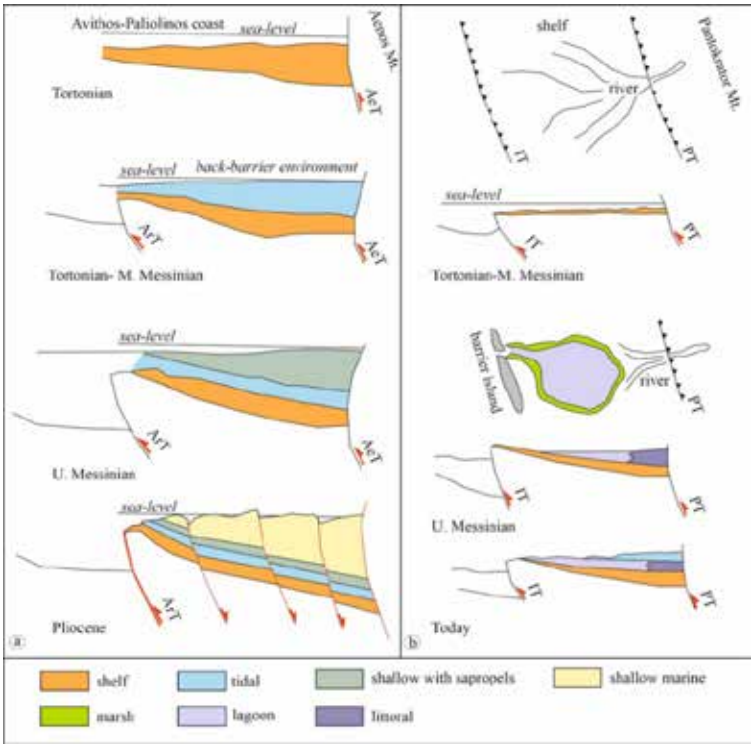

Figure 1. Evolutionary models for two studied areas.

Tsunami modelling for a potential earthquake between Santorini and Amorgos (Greece)

Bufféral S.[1], Briole P.[1], Dupont A.[2], Escartin J.[1], Heinrich P.[2]
(1) Laboratoire de Géologie, ENS-CNRS, UMR3538, PSL University, Paris, France - simon.bufferal@ens.fr

Highlights

The seismic swarm that struck northeast of Santorini Island (Greece) in February 2025 highlights the critical need to assess tsunami hazards in this historically vulnerable region. Using Okada's model for seafloor displacement and subsequent tsunami simulations, we discuss hypothetical tsunami scenarios from shallow normal faults identified around the recent swarm. Our simulations suggest that a potential tsunami could impact the eastern coast of Santorini in as little as 6 minutes and reach the surrounding islands within 25 minutes. For a magnitude Mω = 6.3–6.5 earthquake, heights along nearby coastlines could range from 0.1 to 0.6 meters, with localized amplification possible in closed bays. Based on these scenarios, we propose a strategic placing of tide gauges at Agios Nikolaos Port (Anafi) and Agios Andreas (Astypalaia) to enhance tsunami detection and improve regional early warning capabilities.

Context

A volcano-tectonic unrest has been active since late 2024 in the surrounding area of the Santorini volcano, in the Aegean Sea (Greece), peaking with a significant seismic swarm during the first half of February 2025, along a fault zone that ranges between Santorini and Amorgos islands. This region is characterized by both significant volcanic and seismic hazards, as it lies along the volcanic arc associated with the Hellenic subduction zone and an active rift likely related to the Anatolian extrusion. Historically, the area has experienced destructive tsunamis, notably a volcanic-induced event after the Minoan eruption at Santorini around 1600 BC (McCoy and Heiken, 2000; Friedrich *et al.*, 2006; Manning *et al.*, 2006; Goodman-Tchernov *et al.*, 2009) and an earthquake-triggered tsunami after the 9 July 1956 earthquake along the eastern coast of Amorgos (Galanopoulos, 1957; Ambraseys, 1960; Okal *et al.*, 2009; Leclerc *et al.*, 2024). The 2025 seismic crisis has been occurring in the southwestern continuity of the 1956 earthquake zone, underlining the need for a reevaluation of the seismic and tsunamigenic hazards in the area.

Potential for seismic rupture

The seismic crisis began in September 2024 within the Santorini caldera, then migrated northeast of the island starting on 27 January 2025. During February 2025, approximately 200 earthquakes with magnitudes Mω ≥ 4.0 and 8 events with Mω ≥ 5.0 were recorded[1]. At the time of writing (March 2025), seismic activity has been slowing down, although earthquakes exceeding Mω ≥ 4.0 continue to occur intermittently. With geodetic modelling indicating a total slip in the middle to lower crust of an equivalent seismic moment of $2 \cdot 10^{19}$ N·m, i.e., over an order of magnitude greater than the cumulative moment released seismically, the possibility of a stronger earthquake triggered by elastic loading of the upper crust cannot be ruled out. Independent studies have found that the observed surface deformation is consistent with a slow-slip event occurring on a low-angle, southeast-dipping plane initiating below 7 km depth (Briole *et al.*, *in review*). Assuming a listric geometry, this segment would intersect the surface at the mapped location of the West Ios Fault, according to the NOAfaults database (Ganas, 2024; see Table 1 and Figure 1). The present study explores the possibility of rupture on the shallow, locked portion of that fault, and the tsunami that would follow. We model such a scenario by simulating a shallow earthquake producing 0.8 m of slip on a fault measuring 22 km in length and 11 km in width, with an average dip of 50°, consistent with a moment magnitude of Mω = 6.5. This scenario is compared with two additional candidate faults from the NOAfaults database (see Table 1), each approximately 14 km long and 9 km wide, with a dip of 60°. A slip of 0.8 m on such a fault would correspond to a moment magnitude of Mω = 6.3. The focal mechanism for a hypothetical rupture on the Ios West Fault (GR2691) is presented in Figure 1.

1 https://bbnet.gein.noa.gr/HL/databases/database

Table 1. Characteristics of the two candidate faults considered.

Fault Code	Name	Length	Width	Centroid (°E, °N, Depth)	Azimuth	Dip	Slip Type
GR2691	Ios West fault	22.0 km	11 km	25.51, 36.72, 5 km	N054°	50° SE	Pure normal
GR3219	Anhydros Fault	14.6 km	9 km	25.71, 36.52, 7 km	N045°	60° NW	Pure normal
GR3222	SAF-SW Branch	13.5 km	9 km	25.55, 36.58, 7 km	N222°	60° SE	Pure normal

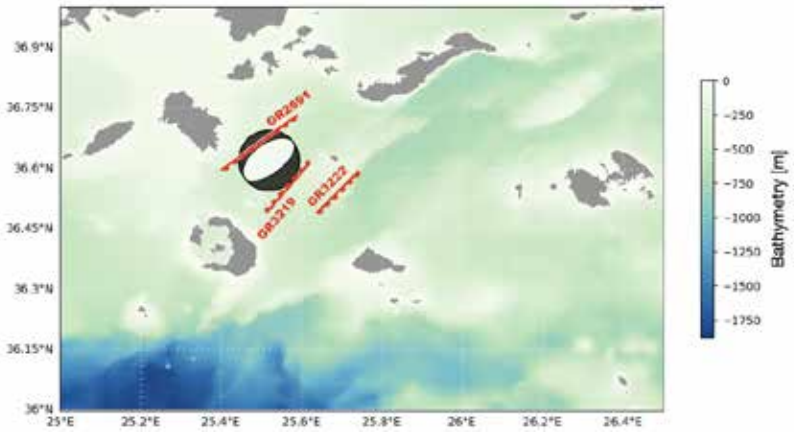

Figure 1. Focal mechanism of a hypothetical rupture on Ios West Fault (GR2691): N054°, 50°SE, pure normal slip.
Simplified surface traces of faults GR3219 and GR3222 are also represented.

Tsunami simulations

We use Okada's equations (Okada, 1985) to calculate the seafloor displacement induced by potential ruptures on the main faults surrounding the 2025 seismic zone (see Table 1 and Figure 1). The Glimsdal transfer equation (Glimsdal *et al.*, 2013) is then applied to evaluate the initial water surface deformation (Figure 2). Finally, tsunami propagation is modelled using the Taitoko code, developed by the Commissariat à l'Énergie Atomique (CEA, France), based on shallow-water wave equations (Heinrich *et al.*, 2021; Heinrich *et al.*, 2024). These calculations use bathymetric data from the European Marine Observation and Data Network (EMODnet[2]), with a grid resolution of 110 meters.

Figure 2 illustrates the initial water surface displacement for an instantaneous and homogeneous normal slip of 80 cm on fault GR2691, with its upper edge located at 1 km depth.

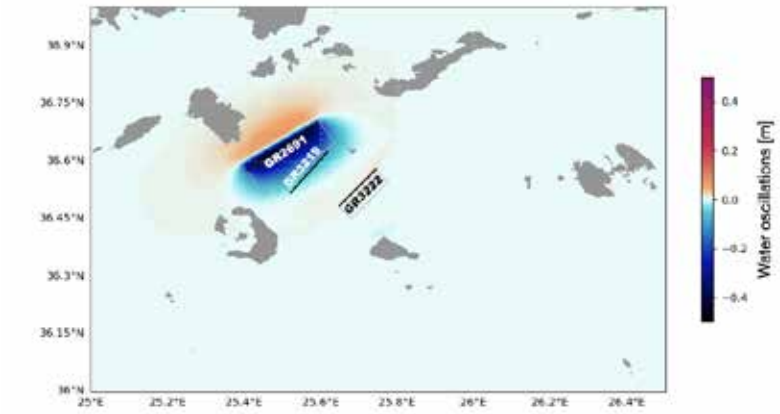

Figure 2. Initial water displacement for 80 cm homogenous normal slip stopping at 1 km depth on Ios West Fault (GR2691). Surface projection of the rupture patch is represented with a rectangle. Potential rupture areas on faults GR3222 and GR3219 are also drawn.

2 https://emodnet.ec.europa.eu/en

Figure 3 shows the wave position after 10 minutes of propagation for the same model. One of the key results of our simulations is that, if an earthquake were to occur in the zone of unrest, the first wave would reach:

- the eastern coast of Santorini in 6 to 15 minutes, depending on the fault location and dip direction;
- Agios Nikolaos Port (Anafi Island) in 11 to 16 minutes;
- Katapola Port (Amorgos Island) in 20 to 25 minutes;
- Chora Port (Ios Island) in 20 to 27 minutes.

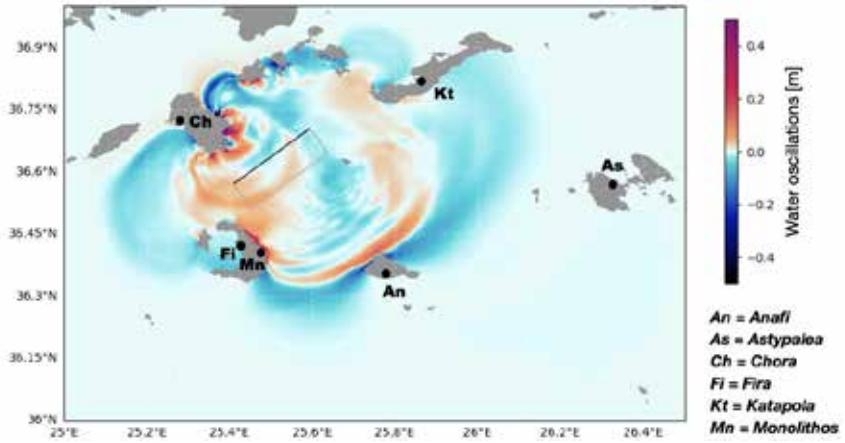

Figure 3. Location of the wave after 10 minutes of propagation for the scenario of a rupture with an 80 cm normal slip stopping at 1 km depth on fault GR2691. The locations of the main harbors are indicated.

Figure 4 presents these arrival times for key ports and coastal areas for a rupture on fault GR3222. These short arrival times emphasize the critical need for early anticipation to ensure an effective response for at-risk populations.

According to our simulations, a tsunami generated by such ruptures would produce wave heights between 0.2 and 0.5 m along the coastlines of nearby islands (Figure 5). The precise wave height depends on the depth and location of the rupture. While these heights may seem moderate, they represent a significant volume of displaced water and high wave energy upon coastal impact, as observed in Samos in 2020 (Kalligeris *et al.*, 2022), with potential risks to people and infrastructure. Due to their geomorphological configuration, bays and inlets are particularly vulnerable to wave amplification, making coastal flooding highly likely in the most pessimistic scenarios.

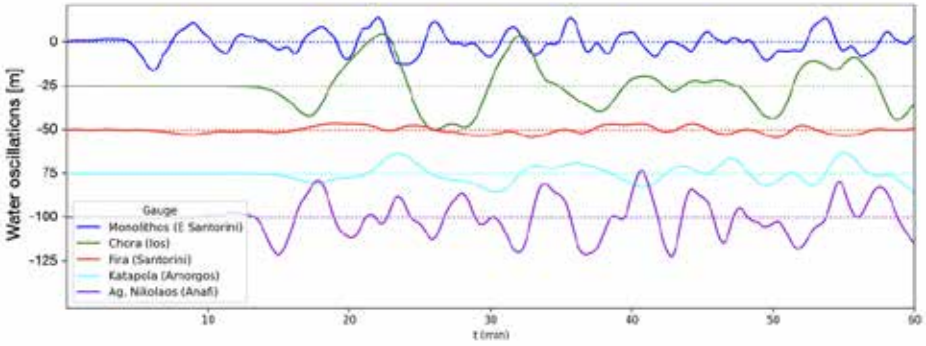

Figure 4. Arrival times at nearby harbors relative to the earthquake origin time for 80 cm normal slip stopping at 3 km depth on fault GR3222.

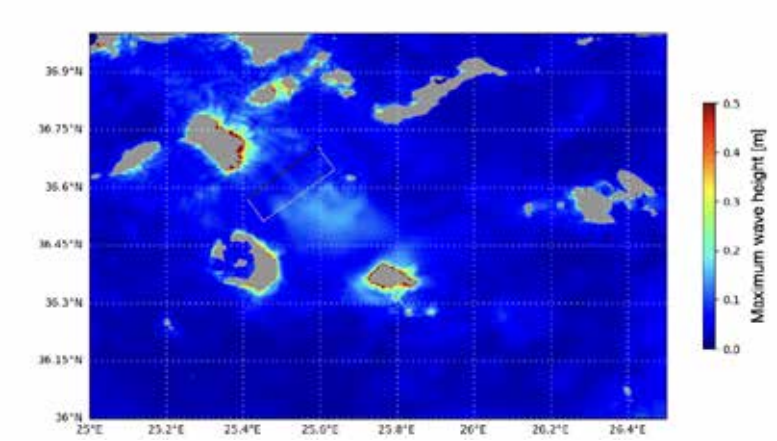

Figure 5. Maximum wave height for 80 cm normal slip stopping at 1 km depth on fault GR2691. These large-scale results do not take into account further local wave amplification phenomena in bays and inlets.

Figure 6 shows the water movement in Chora Bay (Ios Island) for two fault locations:

- GR3219: northwest dip, southwest of Anhydros Island.
- GR3222: southeast dip, south of Anhydros Island.

The upper edge of the rupture is tested at 1 km, 3 km, and 5 km depth.

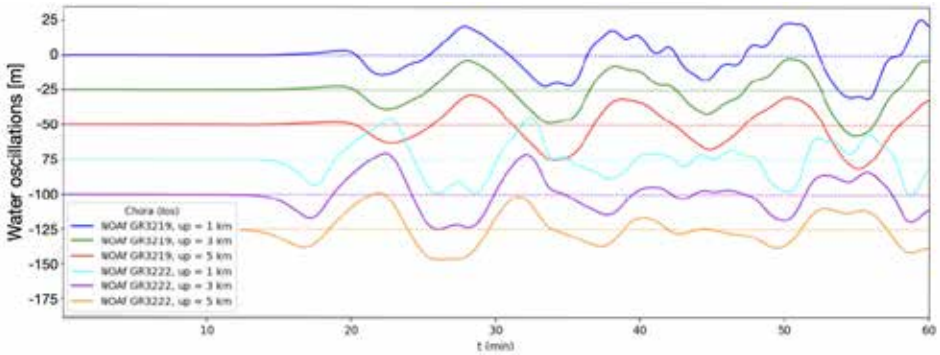

Figure 6: 1-hour water oscillations in Chora Bay (Ios) for two faults and three upper rupture depths.

Our simulations indicate that, in this configuration with several closely spaced islands, the rupture location is the primary factor influencing both wave arrival times and wave attenuation or amplification, depending on interactions with headlands, islands, or underwater obstacles. For instance, shifting the hypocenter 15 km north significantly reduces the wave amplitude reaching Chora Bay (Figure 6). Unlike lower-magnitude earthquakes, whose effects are quickly dampened by upper-crustal layers, the depth of the upper fault edge appears to play a secondary role, provided it remains within realistic values for the region. As shown in Figure 6, variations in depth have a negligible impact on tsunami amplitude, with a maximum discrepancy of only a few centimeters. The azimuth and dip angle of the fault also have limited influence on tsunami morphology, as any normal fault generates an initial water surface depression with a relatively consistent shape. This is confirmed by tests made using the same fault location but opposite fault dips.

Comparison with the 1956 Amorgos Tsunami

On 9 July 1956, a magnitude Mω = 7.1–7.8 earthquake struck south of Amorgos Island, just a few dozen

kilometers north of the current seismic swarm. This event generated an exceptionally large tsunami, with waves reaching up to 20 meters in height in Astypalaia, causing three direct fatalities on Kalimnos Island and several injuries and severe coastal damage in the nearby islands (Ambraseys, 1960).
For a long time, the unusual size of this tsunami was attributed to a submarine landslide (Galanopoulos, 1957; Okal *et al.*, 2009), which was believed to have displaced a large volume of water, producing a wave of exceptional intensity. However, recent studies have failed to find clear evidence of such a landslide, shifting the focus to the hypothesis of a co-seismic displacement of approximately 10 meters as the primary cause (Leclerc *et al.*, 2024).
Given the steep submarine slopes in the region, which show evidence of past landslides, a similar scenario cannot be ruled out for the ongoing seismic crisis, potentially leading to a much stronger tsunami. This study does not specifically address this less likely hypothesis.

Implications for a useful monitoring of future tsunamis

In response to recent tsunami events, studies that used local high-resolution bathymetric data digitized from nautical charts demonstrated that incorporating finer (e.g., ~10 m pixel resolution) bathymetric grids into models significantly modifies tsunami waveforms, potentially doubling wave amplitudes at the coastline (Zahradník *et al*., 2022; Alfonsi *et al*., 2024). It is therefore highly problematic that, despite the existence of numerous high-resolution bathymetric datasets in the Aegean Sea, none are freely accessible. This situation introduces significant reliability issues for tsunami modelling and poses a critical risk to civil safety, as emergency preparedness scenarios may be underestimated, leading to inadequate hazard assessment.
It should also be noted that environmental factors, such as tidal conditions and atmospheric pressure, can intensify the impact of tsunamis. These key parameters call for continuous monitoring of sea level heights and coastal subsidence in the region. In this framework, as part of the ongoing GNSS deployment aimed at monitoring, among others, the Santorini magma chamber inflation, a priority should be given to co-located GNSS and tide gauge stations.
Based on our simulations, closed bays such as the Santorini Caldera, where sub-meter amplitude waves either do not arrive or arrive with a significant delay, should be avoided. Instead, we recommend the maintenance and continuity of instruments on the east coast of Santorini (e.g., NOA-99[3]), where waves arrive quickly with minimal interference or attenuation.
Our results highlight the need for more tide gauges in the region, to monitor water movements in the event of a tsunami, to better constrain climate-change-induced sea level rise, and, ideally, to provide early warning if the gauges are positioned at strategic locations along possible wave paths. High-frequency sampling (~1 Hz) is advised to ensure a rapid and accurate tsunami alert. In the framework of the current instrumentation of the Santorini region, we suggest two more locations for additional tide gauge installation:
● Port of Agios Nikolaos, on the island of Anafi. This harbor appears to be a strategic location for early warning. Simulations show that waves always reach it quickly due to the deep waters offshore. It is not located in an enclosed bay, and the coastline is relatively smooth, minimizing the effects of wave interference. From a broader regional perspective, southern Anafi is an optimal monitoring site as it would be among the first coasts to be hit by a tsunami arriving from the south, particularly likely given the seismic hazard in Crete, which hosts both the Hellenic subduction zone and active normal faults.
● Port of Agios Andreas, on the north coast of the island of Astypalaia. Given the high amplitude of the waves that reached this coast after the 1956 earthquake (Ambraseys, 1960), the harbor of Agios Andreas, on the north coast of Astypalaia, appears as a suitable location for studying large-scale wave propagation in the region.

Conclusions

● The possibility of a tsunami triggered by volcanic or seismic events in the highly active southern Aegean

3 http://antares.gein.noa.gr/TAD_Server/SensorData.aspx?id=53

Sea is significant and must be taken into account. Local populations and tourists should be adequately prepared, particularly by being informed about potential wave propagation scenarios resulting from such events. Civil protection authorities should also be ready to issue tsunami alerts rapidly.

● Accurate knowledge of wave trajectories and arrival times is crucial for enhancing preparedness and improving tsunami early warning protocols. Tsunami wave modelling allows for identifying the most suitable observation sites, whether for post-event analysis to understand tsunami processes or for real-time monitoring to support early warning systems. It also helps distinguish less strategic locations, such as enclosed harbors, where waves tend to be delayed and are less representative of regional tsunami impacts.

● Additional tide gauges are needed to better constrain tsunami models and support the development of early warning capabilities. Moreover, sea-level sensors serve as valuable tools for monitoring broader phenomena, such as climate change-induced sea-level rise, underscoring the need for long-term installations capable of producing reliable time series with minimal influence from local effects like coastal subsidence.

● The critical lack of publicly available coastal bathymetric data introduces significant uncertainties into tsunami modelling, putting people's lives at risk. Addressing this urgent issue by ensuring the existence of comprehensive and accessible coastal bathymetric datasets is, therefore, of paramount importance.

The broader Aegean Region, including the Southern Balkans, is among the most tectonically active areas of the Mediterranean realm and has the highest seismicity both in terms of frequency of events and magnitudes. The principal aim of this note is to present the new release of the Greek Database of Seismogenic Sources (GreDaSS) corresponding to version 3.0 systematically revised in terms of sources and seismotectonic parameters and largely improved both qualitatively and quantitatively (Figure 1).

Background

The importance of a complete repository for active faults in the Aegean Region became clear since the late 1990's; however, the first efforts were primarily focused on tectonic structures associated to pre-instrumental and instrumental seismicity (e.g. Ambraseys and Jackson, 1998; Papazachos et al., 1999) and thus based almost entirely on historical and seismological data. This approach can be successful in studying recently activated seismogenic sources, but becomes inappropriate for sources without any seismological record (neither pre-instrumental nor instrumental) and characterized by a long recurrence period. The 13 May 1995 Kozani earthquake (Ms = 6.5; e.g. Pavlides et al., 1995; Meyer et al., 1996; 1998a; 1998b; Chiarabba and Selvaggi, 1997; Clarke et al., 1997, 1998; Hatzfeld et al., 1997; 1998) and the 7 September 1999 Athens earthquake (Mw = 6.0; e.g. Kontoes et al., 2000; Voulgaris et al., 2001; Ganas et al., 2004; Atzori et al., 2008; Foumelis et al., 2009) are emblematic examples of ruptures occurred in areas considered till that moment as aseismic or associated with low seismic activity. Although the subsequent works managed to include the geological records in the source identification process, most of them resulted to be too much descriptive, lacking in quantitative parameters information (e.g. Mountrakis et al., 2006; Pavlides et al., 2007; Karakaisis et al., 2010).

For these reasons, in the late '90ies on the track of the European FAUST Project and the Italian DISS, the GreDaSS Project was thus launched initially at the University of Basilicata and then permanently developed at the University of Ferrara (copyright owner) with an international working group. The financial support of this initiative was primarily provided by the Italian Ministry of University and the University of Ferrara.

The principal aim of the GreDaSS Project was indeed i) to overcome the above described critical issues , ii) to provide a complete and accurate repository of fully parametrized seismogenic sources and not simply, for example, a 2D map of (active) fault traces (Papazachos et al., 2001; Pavlides et al., 2008) and iii) to contribute to better and more realistic Seismic Hazard Assessment (SHA) analyses.

Since its beginning, GreDaSS was obviously populated by seismicity-related sources, but the preferred approach was intrinsically multidisciplinary (e.g. Caputo and Helly, 2008; Caputo et al., 2015) giving emphasis and exploiting as many as possible different sources of information digging any geological, structural, morphotectonic, geodetic, palaeoseismological, historical, archaeoseismological, geophysical, etc. data available in the literature or specifically collecting new data by the research group.

During the years and becoming a reference database for SHA analyses, the products of GreDaSS were included in several European projects, like the European Seismic Hazard Model (ESHM13; Woessner et al., 2015) and more recently the European Fault-Source Model 2020 (EFSM20; Basili et al., 2024).

Since its almost 30 years of research activity, the working group of the GreDaSS Project evolved in time and saw the collaboration and contribution of several PhD students, like Valkaniotis (2009), Sboras (2012), Maggini (2020) and Russo (2025) and colleagues. The authorship of this note is limited to the contributors of the new entirely revised and updated version 3.0 of GreDaSS, which is the object of the present note.

Method

For our purposes we used the well tested, time-proof, worldwide acknowledged database structure and method proposed by the Istituto Nazionale di Geofisica e Volcanologia (INGV) for the Italian Database of Individual Seismogenic Sources (DISS), which represents the result of almost twenty years research experience of its Working Group (Valensise and Pantosti, 2001). The DISS uses many basic levels of data that can be either independent or directly related. Among the most important ones are the Individual Seismogenic Sources (ISS), the Composite Seismogenic Sources (CSS) and the Subduction Sources (SDS); see also Basili et al. (2008) for a more detailed description of the informatic framework.

- "Individual Seismogenic Sources" (ISS) are obtained from geological and geophysical data and are characterized by a full set of geometric (strike, dip, length, width and depth), kinematic (rake) and seismological-palaeoseismological parameters (average displacement per event, magnitude, slip rate, return period) and by a rating of the associated uncertainties. ISSs are assumed to exhibit "characteristic" behaviour with respect to rupture length/width and expected mean and maximum magnitude. They are tested against worldwide databases for internal consistency in terms of length, width, average displacement and magnitude. This category of sources favours accuracy of the information supplied over completeness of the sources themselves. As such, they can be used for deterministic assessment of seismic hazard, for calculating earthquake and tsunami scenarios, and for tectonic and geodynamic investigations.

- "Composite Seismogenic Sources" (CSS) are still obtained from geological and geophysical data and characterized by geometric (strike, dip, width, depth) and kinematic (rake) parameters, but their length is more loosely defined and spans two or more Individual Sources. They are not assumed to be capable of a specific earthquake, but their potential can be derived from existing earthquake catalogues. A CSS is essentially inferred on the basis of regional surface and subsurface geological data, that are exploited well beyond the simple identification of active faults or youthful tectonic features. Opposite to the previous case, this category of sources favours completeness of the record of potential earthquake sources over accuracy of source description. In conjunction with seismicity and modern strain data, CSSs can thus be used for regional probabilistic seismic hazard assessment and for investigating large-scale geodynamic processes.

- "Subduction Sources" (SDS) are designed to include a simplified model of this complex tectonic environment. They represent the dipping slab at mantle depth, the interface between the two plates at crustal depth, and the detachment at the base of the accretionary wedge. In map view, a set of depth contour lines depicts the geometry of the subducted slab. At the upper end of the slab, a fault trace marks the boundary of the two plates. A set of basic parameters relative to the tectonic behavior, the possible segmentation of the Wadati-Benioff surface and the net convergence direction and rate are also added in the corresponding layers of information. This type of reconstruction is typically performed using data from geology, exploration geophysics, seismicity distribution, and seismic tomography.
The details about how faults are graphically represented in the database and what are the attributes of every information field can be found in the paper of Basili et al. (2008).

Informatic platform

Different from version 2.0 that is available as a Google Maps version or a downloadable KMZ version, Gredass 3.0 is hosted on "SEISMOFAULTS.EU" IT infrastructure (Basili et al, 2022) that provides access through standard web services protocols such as the Web Map Service (WMS), Web Feature Service (WFS), or Web Coverage Service (WCS), developed by the Open Geospatial Consortium (OGC; https://ogc.org). Through the OGC web services, data can also be downloaded as CSV (Comma-Separated Values), SHP (Esri shapefile), KML (Keyhole Markup Language), GeoJson, and many others.
The last release of GreDaSS (version 3.0) is also publicly available through a web GIS interface (Figure 1). Since the database structure remains consistent, we have chosen to adopt the same web interface designed and developed by DISS Working Group of INGV for the most recent version of Italian Database of Individual Seismogenic Sources (DISS Working Group, 2021). This interface is developed in JavaScript language, using the open-source library OpenLayers for mapping data directly querying the web services made available by the "SEISMOFAULTS.EU" infrastructure.

Results

Within the investigated area, we have already recognized, characterized and parametrized numerous CSSs and

ISSs. All ISSs show evidence of Late Pleistocene-Holocene activity and sometimes also the occurrence of past 'linear morphogenic earthquakes' (sensu Caputo, 2005) as inferred, for example, from palaeoseismological trenches, archaeoseismological investigations or detailed morphotectonic mapping. In some cases, a moderate to strong earthquake has occurred in the last few decades, therefore allowing us to investigate the re-activated fault with a great detail, based on a modern scientific approach, and especially exploiting a rich seismological information associated with the mainshock. In particular, available instrumental data commonly provide crucial constraints about focal depth, magnitude, focal mechanism (i.e. strike, dip and rake) and aftershock distribution. This additional 'co-seismic' information is obviously not available for all the other geologically-derived seismogenic sources (ISSs) where no historical or instrumental earthquakes have been recorded. Accordingly, these faults represent a crucial test for the database and especially for its possible applications in seismic hazard assessment analyses. They have been independently investigated according to the two approaches, in one case the available 'co-seismic' constraints of the principal seismotectonic parameters have been ignored and mainly the cumulative effects of Late Quaternary morphogenic events have been considered; in the other case this additional co-seismic information has been included (Caputo et al., 2015).

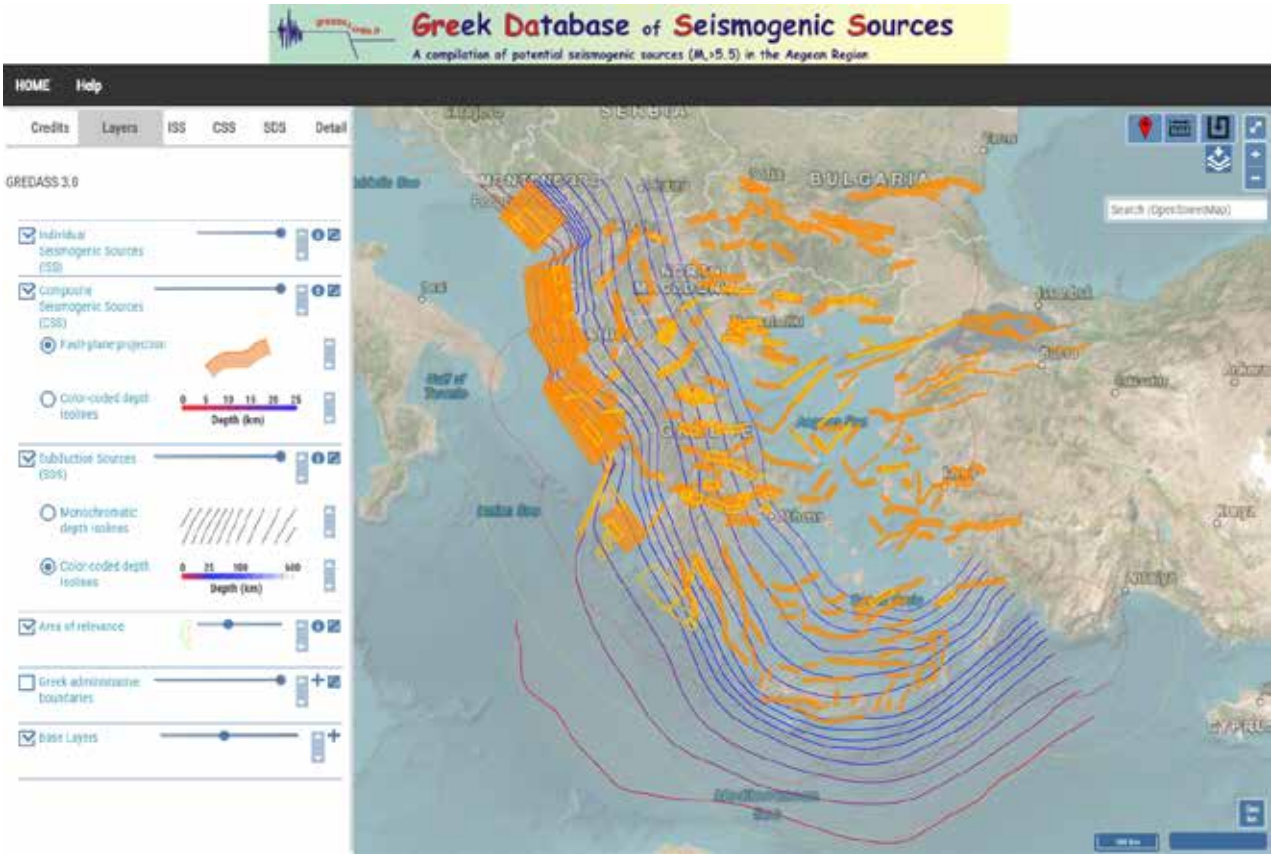

Figure 1. Screen capture of the last release of GreDaSS (version 3.0) available through the new web GIS interface.

It is worth noting that relative to the previous one (release 2.0; Caputo and Pavlides, 2013) the new version of GreDaSS (release 3.0) has been largely improved both qualitatively and quantitatively. In particular, all seismotectonic parameters have been systematically revised and most of the numerical fields have been completed and/or compiled where missing. This work produced an overall rough increase in the order of +70% of the information contained. It is worth noting the significant improvement that was achieved in better constraining the seismogenic layer all over the investigated area by applying the results of the 3D thermo-rheological model recently produced for the broader Aegean Region (Maggini, 2020; Maggini and Caputo, 2020; 2021; Maggini et al., 2023). Based on this model, a set of crucial seismotectonic parameters, like maximum depth, width, dip-angle and maximum credible magnitude of the seismogenic sources, have been systematically revised and/or better quantified.

Crustal faults (i.e. CSSs and ISSs) included in the database are at present 277 (instead of 267) and 117 (108), respectively. As concerns the other two informative layers (the graphical one and the relevant literature), the number

of figures associated with the sources are now 1667 (916) and references 853 (679), showing in both cases an important step forward the completeness and improvement of the database especially if compared to version 2.0.
When a seismogenic source is associated with secondary effects, especially liquefaction features, because of a recent or historical event, this information taken from DALO (Papathanassiou et al., 2010) has been systematically included in the descriptive layer of the new GreDaSS release.
A further major difference of the last release is represented by the reconstructed and modelled Wadati-Benioff zones that were not included in the previous version of GreDaSS. In version 3.0, they are actually two, the Hellenic Subduction Zone and the Adriatic Continental Collision (Figure 1), therefore better defining the seismotectonics of the active accretionary wedges surrounding the southern Balkan peninsula.
As a final comment, we want to stress the fundamental and intrinsic difference of GreDaSS with respect to other apparently similar catalogues and/or databases available or under construction for the broader Aegean Region. Indeed, GreDaSS with its philosophical approach, its informatic structure and especially the choice of including some crucial parameters is the only one that could be directly exported and easily used for performing seismic hazard assessment analyses, like for example, in the Seismic Hazard Harmonization in Europe Project (SHARE; http://www.share-eu.org/) or the TAP Project between the Greece-Turkey border and southern Italy (Slejko et al., 2021; Moratto et al., 2021).

Acknowledgements
We acknowledge the financial contribution provided by INGV and the EPOS Italia Project and the multi-decennial support of the University of Ferrara. We also thank R. Basili for the continuous discussions and exchanges of ideas and the contributors to the previous release of the database.

Introduction

The "Rio do Peixe Dinosaur Valley" comprises four sedimentary basins: Sousa, Triunfo (also called the Uiraúna-Brejo das Freiras basin), Pombal, and Vertentes. Located in the western part of the Brazilian Paraíba State, these areas are intracratonic basins that developed along preexisting structural trends of the basement during the origin of the South Atlantic Ocean. The age of these basins, based on microfossils, is characteristic of the Rio da Serra (Berriasian to Hauterivian) and Aratu (early Barremian) local stages (Lima and Coelho, 1987; Regali, 1990; Sousa *et al.*, 2019). Deposition is the result of tectonic activity, and it is represented by alluvial fans at the faulted borders, changing to an anastomosing fluvial system more distally, and by meandering fluvial system with a wide floodplain, where perennial and temporary lakes developed, in the central region of the basins (Carvalho, 2000; Fig. 1).

Especially in the Sousa Basin footprints and trackways, mainly of large theropods, sauropods, and ornithopods are common, as well as invertebrate ichnofossils, such as traces and burrows (Fernandes and Carvalho, 2001). Body fossils are represented by ostracods, conchostracans, plant fragments, palynomorphs, fish scales, and bones of crocodylomorph and dinosaurs. The abundance of dinosaurian ichnofaunas represents an extensive Lower Cretaceous megatracksite (Viana *et al.,* 1993; Carvalho, 2000; Leonardi and Carvalho, 2000, 2002) established during the early stages of the South Atlantic opening. In this area, 42 sites and approximately 96 individual stratigraphic levels preserve occurrences of more than 636 individual dinosaur trackways and isolated footprints, as well as rare tracks and traces of the vertebrate mesofauna (Leonardi and Carvalho, 2021). To date, the four basins of "Rio do Peixe Dinosaur Valley" show together the following dinosaur trackmakers for the corresponding trackways or isolated footprints: 38 graviportal ornithopods (Fig. 2A); one ankylosaur; one small quadrupedal thyreophoran; two small ornithopods (altogether, 42 ornithischians). Then, 447 individual theropods (Fig. 2B-C) and 90 sauropods (altogether, 537 saurischians) were identified. In total, the number of classifiable individual dinosaur tracks is 579; and the total number of dinosaur footprints and trackways, including the indeterminate tracks, is 636. This last number includes also four possible dinosaur tail impressions.

The meso-ichnofauna, very rare in these basins, is represented by just one set of batrachopodid prints, some crocodilian traces and tracks, one lacertoid footprint, perhaps a poor specimen of mammal tracks, and a very large number of small chelonian swimming tracks (Leonardi, 1989, 2021; Leonardi and Carvalho, 2021, 2024).

It is noteworthy that the large number of theropods represented is impressive, compared to the number of herbivores, which is quite common in the whole world. This phenomenon seems to be contrary to the biomass pyramid theory. It can be explained, however, considering that carnivores probably had a higher level of mobility and therefore printed more tracks and footprints daily. It is also quite remarkable that the ankylosaur hand-foot set (specimen SOES 7, from the Serrote do Pimenta, Sousa), discovered in 1979 (Leonardi, 1984, 1989, 1994), represents the first record of the presence of this clade of Thyreophora in the South American continent.

The diversity of dinosaur tracks: an insight into the Early Cretaceous ecosystems

The dinosaur footprints in the Sousa Basin occur in at least 42 localities, in clastic deposits within all the formations of the Rio do Peixe Group (Antenor Navarro, Sousa and Rio Piranhas formations). At least 636 individual trackmakers are recorded in the Rio do Peixe basins (Carvalho and Leonardi 1992; Leonardi, 1984, 1994; Leonardi and Carvalho, 2021, 2024), and many others in a widely distributed set of track localities named the Borborema Megatracksite (Viana *et al.*, 1993). This megatracksite expands to the neighboring basins of Icó, Iguatu, Malhada Vermelha, Lima Campos (Leonardi, 1989; Leonardi and Spezzamonte, 1994), Cedro (Carvalho *et al.*, 1993), Araripe (Carvalho *et al.*, 1994, 2019, 2024; Carvalho and Leonardi, 2021, 2024), and can also be extended to encompass the region of the Cameroon Basin (Africa) as suggested by Jacobs *et al.* (2024).

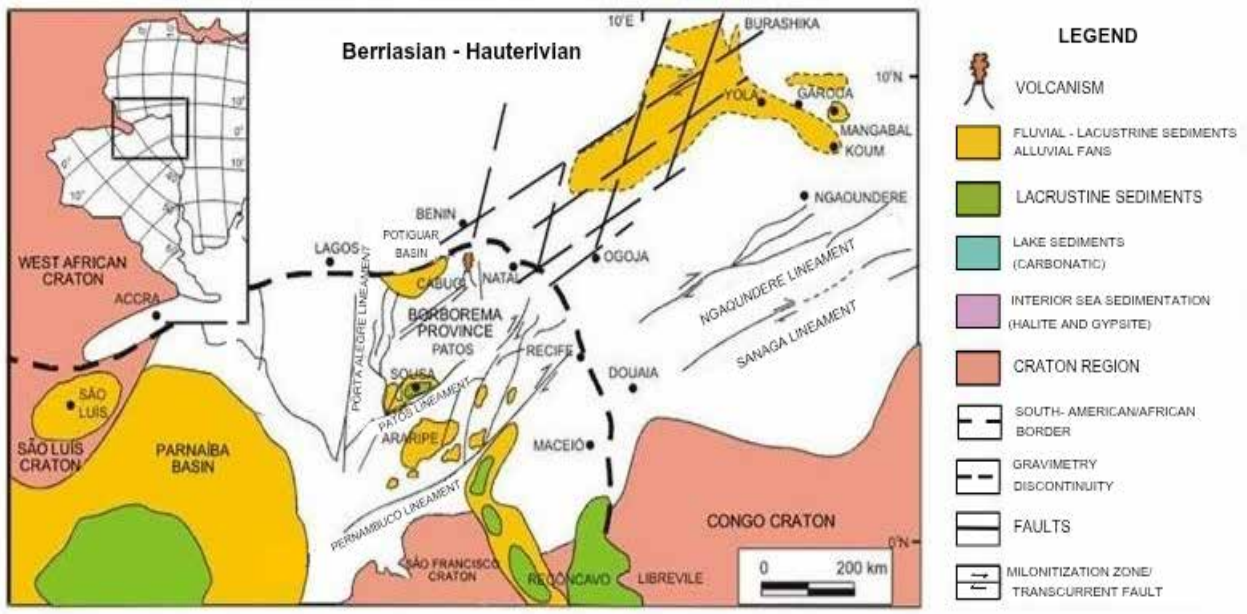

Figure 1. Geological context of Sousa Basin, northeastern Brazil during the Barremian-Hauterivian. The dinosaur footprints from the Sousa Basin were formed in the environments established during the first stages of South America – Africa drifting (modified from Popoff, 1988).

The set of footprints is indicative of the high diversity of dinosaurs in the terrestrial ecosystems, despite the few osteological remains. Footprints are rare in the Antenor Navarro and Rio Piranhas formations as they are preserved only in fine sediments that accumulated as subaerial sandy bars in alluvial fans and anastomosing rivers close to the basin margins. In the Sousa Formation, the sediments of finer grain sizes are more suitable for track preservation. This last unit is interpreted as deposited in lacustrine, swampy, and meandering braided fluvial environments (Leonardi and Carvalho, 2024; Fig. 2).

The Dinosaur Valley and its Influence in the Sousa Community

The town of Sousa is undeniably the "capital" of the "valley of the dinosaurs" of western Paraíba. The Sousa municipality has a territory of 842 km² located in the region of the Alto Sertão da Paraíba, in the semi-arid belt of Paraíba State. The municipality of Sousa has 67,259 inhabitants (IBGE, 2022).

The influence of the scientific studies concerning dinosaur tracks in the region allowed new economic perspectives. After one hundred years of research (beginning with Moraes, 1924), dinosaur footprints became a popular aspect of the local culture. The main occurrence and most accessible ichnosite is located at Passagem das Pedras (Ilha Farm) in the Sousa municipality. In December 1992 (Diário Oficial do Estado da Paraíba, Decree nº 14.833, December 20th, 1992), through a state act, the area was defined as a natural monument and named "Dinosaur Valley Natural Monument" (Monumento Natural Vale dos Dinossauros). Since then, the influence of the dinosaur theme on a variety of community activities has been incontestable, reflecting the improvement of science knowledge in the municipality.

Over the last fifty years, the region, previously known mainly for its cotton agriculture, acquired a new identity as a result of the regular presence of researchers, undergraduate and graduate students, and the media's diffusion about the dinosaur tracks in Sousa County. In the downtown area of Sousa city references to dinosaurs progressively invaded different aspects of community life, from sports to commercial and social activities, which shows the way that the people of Sousa connect to the dinosaur tracks recorded in their municipality, considered to be a heritage that deserves to be preserved (Fig. 3).

It is possible to preserve any geological heritage through public policies, but the main way to preserve it is the reconnaissance by the community about their importance and economic relevance. The tourism in the Sousa region, the local museum, a national identity based on the soccer team (Green Dinosaurs from Sertão, Sousa Futebol Clube), and the continuous support of scientific research allowed the engagement of the local population to the preservation of their ichnofossils. They are recognized as important objects to the economy and social development (Carvalho and Leonardi, 2007; Fernandes and Carvalho, 2007; Santos *et al.*, 2016, 2019), a fundamental condition for safeguarding their physical integrity.

But the ichnofossils of Sousa are exposed to risks of non-anthropic origin that call for new approaches to the issue of in-situ preservation of this type of heritage. Although the best way for educational and economic purposes is the preservation of the footprints in the natural outcrops, the environmental conditions to which they are currently subject can destroy them. Many of the

track-bearing surfaces will be worn out by natural erosion, especially where the tracks occur in surfaces nearside the temporary rivers. Besides the traditional methodology of documentation, it is also necessary to digitally reconstruct the ichnosites and their footprints (Falkingham *et al.*, 2014, 2018) as they are subject to destruction by erosion and in some rare cases to vandalism. In these cases, the removal and subsequent storage in museums, universities and research centers is the best solution to an ex-situ preservation of the paleontological heritage. Given the relevance of these ichnofossils to the population of Sousa, it would be necessary to consider replacing the original footprints with replicas, as happened within prehistoric cave paintings like Lascaux and Chauvet in France, or Altamira in Spain, a non-consensual management strategy but generally well accepted by tourists (Hughes *et al*., 2021). Other geoconservation issues of technical nature include expanding signage and improving accessibility to ichnosites, and enlargement of the Visitor Center with upgrade of the exhibition space on the theme of fossil footprints and dinosaurs of Sousa. Tormey (2019) refers to several ways of communicating geoheritage with people who are visiting protected areas or who are looking at a distance from the traditional to the most innovative social media platforms around the world which may inspire local authorities (Sousa municipality) and state authorities (Pernambuco State).

Figure 2. The great diversity of dinosaur tracks in the region of the Sousa Basin allows the reconstruction of terrestrial Cretaceous ecosystems. A. Iguanodontid footprints, the longest trackway (57 m) found in Sousa Basin, Passagem das Pedras ichnosite; B. Theropod footprints after excavation on mudstones with mudcracks, Passagem das Pedras ichnosite; C. Theropod footprint on coarse sandstones from Serrote do Letreiro ichnosite.

Figure 3. References to dinosaurs and their tracks in the emergence of a new identity for the region: A. Sousa Radio (Progresso AM); B. Sousa Sport Club, the main soccer game from the Sousa city, Paraíba State; C. A small inn located in the downtown; D. A market and bakery; E. A veterinary drugstore.

Geoconservation practitioners, researchers, and all the geoscience community need to enhance the engagement of the Sousa community with its geoheritage. This requires communication strategies targeted to different publics, such as local communities, local entrepreneurs and stakeholders, media, scientific community, tourists, politicians and policymakers around an ambitious geotourism plan to boost economic activity in the region and improve the social

conditions of the population, without jeopardizing the conservation of the paleontological heritage.
Future actions to promote the economy and social development of Sousa should include establishing guidelines by the State of Paraíba to stimulate private initiative aimed at tertiary sector activities geared towards employability around scientific tourism. At the same time, it is necessary to establish education programs that focus on the geoheritage value of Sousa ichnosites, which play a major role in raising people's awareness of their territory's paleontological heritage (Santos *et al*., 2019). On the part of the academic community, it will be important to maintain a continuous program of excavations and prospecting for new localities with fossil footprints, to guarantee a continuous flow of scientific publications and dissemination about Sousa's paleontological heritage.

Introduction / Background

The present work focuses on mapping the relief of the pre-volcanic basement on the Island of Lesvos, by interpreting the Bouguer gravity anomalies map using a 3D inversion scheme. Although the resulting model is not yet optimal, it nevertheless reveals the magnitude of the volcanic activity experienced by the area, as well as its relationship with the observed tectonic grain.

Lesvos, along with the region of the north-central Aegean, is part of a wider area that extends to northwestern Turkey, which has exhibited shoshonitic-type volcanism as part of the volcanic arc that has operated since during the Upper Oligocene – Middle Miocene periods. The volcanic rocks occupy almost the entire central and western part of Lesvos. (Hecht, 1972-1976; Pe-Piper et *al*., 2019).

Outcrops of the pre-alpine and alpine basement through which the volcanic formations were emplaced are mainly seen in the southeast part of the island; only minor occurrences exist at the western extremity of the island. In terms of age, the lithological formations of the basement cover the period from the Carboniferous to the upper Triassic, while there are also post-alpine formations of the Oligocene epoch.

The volcanic activity on Lesvos lasted for almost 6.0 Ma. Volcanic rocks are mainly shoshonitic in composition. A few calcareous andesites are placed at the beginning (Eressos area, 21.5Ma) and the end (Mytilene area, 16.5Ma) of volcanic activity.

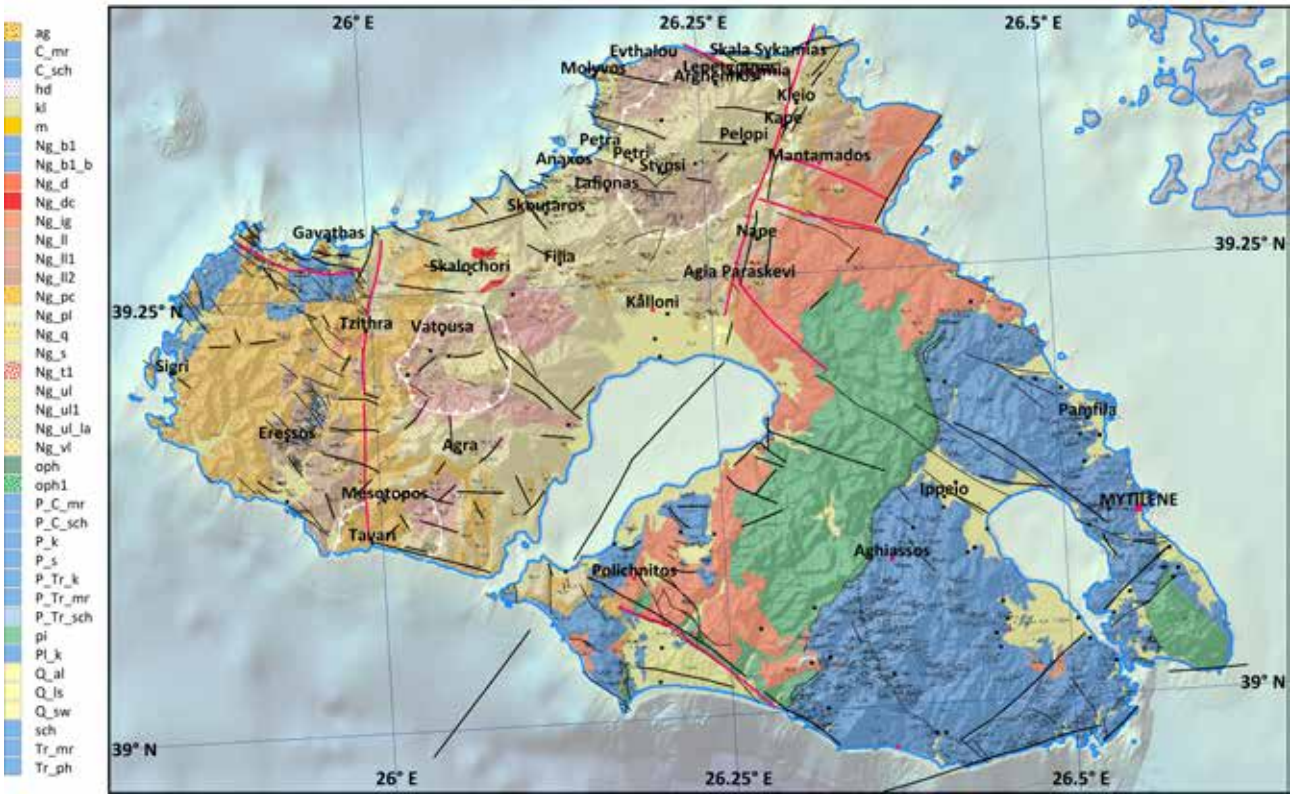

Figure 1. Geological map of Lesvos digitized from Hecht (1972-1976). The tectonic lines are from various sources

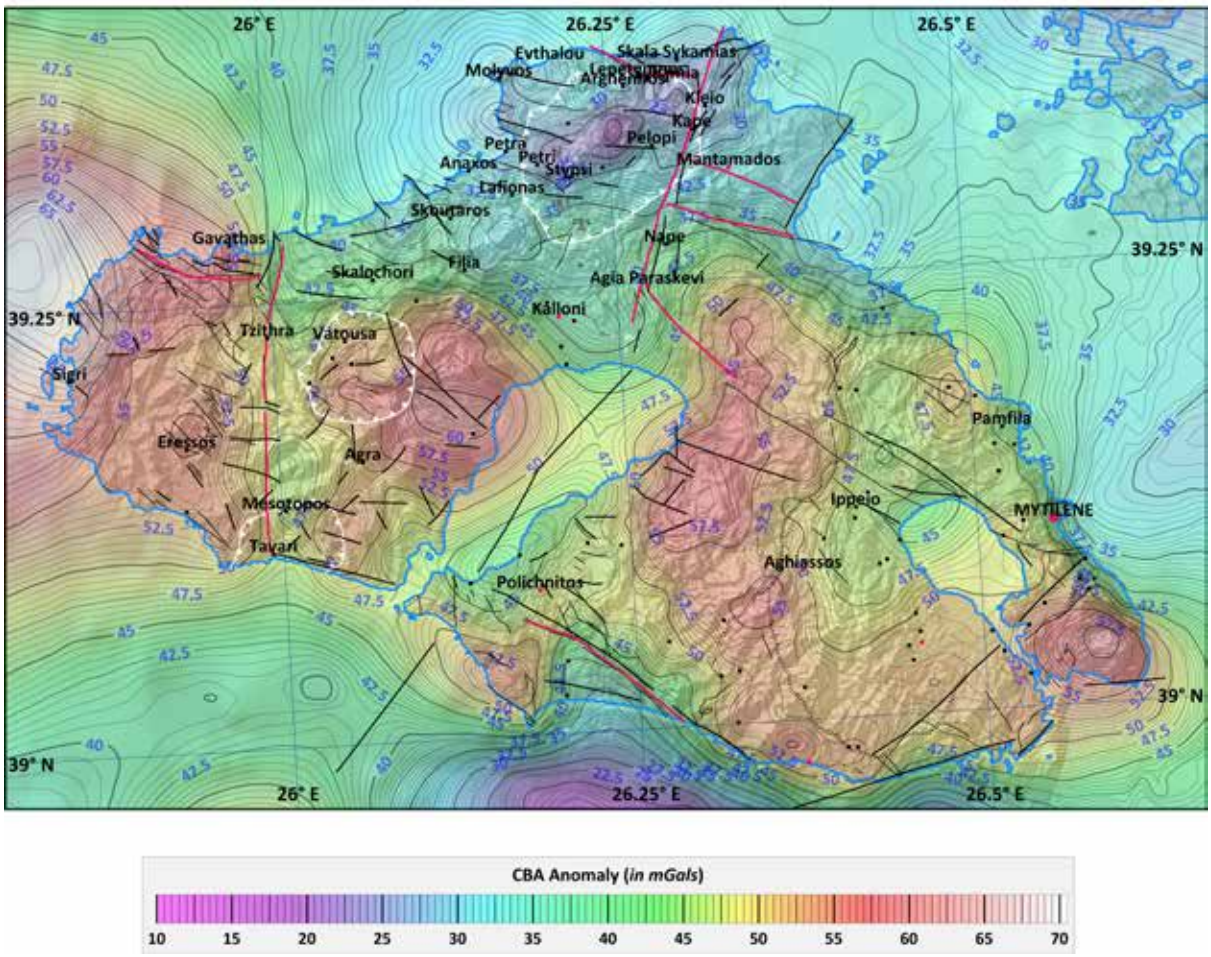

Figure 2. Bouguer Gravity Anomaly Map

The stratigraphy of the volcanic formations presented below is summarized from the work of Pe-Piper et *al*. (2019) and was based on the 1:50,000 geological maps of Hecht (1972–1976) and paleomagnetic and radiometric datings by Pe-Piper (1980) and Pe-Piper and Piper (1993). At 21.6 ± 0.5 Ma (new radiometric dating from Nissiopi Island is giving 23.3 ± 0.5 Ma) for the first andesitic-dacitic domes to break through and cover the basement at the Eressos area of western Lesbos (*Eressos Formation*). This, together with the Gavathas formation, was overlaid by the *Sigri Pyroclastic Formation* of several hundreds of meters thickness in western Lesbos and comprises principally tuffs. A prominent welded ignimbrite approx. 25 m thick is interbedded in the upper Sigri Pyroclastic Formation to the west of Antissa. In turn, the Sigri Pyroclastic Formation is covered by the *Skoutaros Formation* consisting of basaltic and andesitic flows. Some younger andesites and dacites are also included in the formation. The *Polychnitos Ignimbrite Formation* in eastern Lesbos comprises seven widespread welded ignimbrite units, each 30–50 m thick (Pe-Piper, 1980b). They appear to be contemporary with the upper part of the Skoutaros Formation. Pe-Piper (1977) suggests two different centers for its origin: a caldera near Lepetymnos for the older units and the caldera at Vatoussa for the younger (deposited in the southeast of the Gulf of Kalloni). The *Skalohorion* (eastern Lesvos) *and Sykaminea* (northern Lesvos) formations, consisting of younger andesitic and dacitic lavas, were paleomagnetically dated to between 17.0 – 17.6 Ma; these were followed by younger (16.8 Ma) minor basalts and andesites of the *Mytilene Formation* (Pe-Piper and Piper, 2002). Several sets of dykes run in different directions through the above formations. A significant stage of the geological evolution of the western Lesvos is the main volcanic phase, dated to around 17 Ma; in this, an increase in the tempo of volcanism is observed in the central volcanic chain, resulting apart from the eruption of the Polichnitos ignimbrites to the formation of the Lepetymnos and Vatoussa calderas.

As remnants of the volcanic activity, significant surface hydrothermal alterations have been mapped. These are distributed in two major groups, each collocated with one of the two calderas. The alteration ranges from argillic to pyritic and to silicic and is associated with veins whose length varies from several meters to a few kilometers and whose formation was controlled by the then active faulting.

The gravity anomaly map

The Bouguer Gravity Anomalies Map

A complete Bouguer Gravity (CBA) anomaly map of Lesvos was compiled on the basis of the Gravity Data Bank of the Department of Geophysics of NKUA (Lagios et *al.* 1995,1996). Gravity measurements (stations) are evenly distributed over the island, with a spatial density of approximately two stations per 5 km^2. The data has been referred to the IGSN71 datum and has been subject to complete Bouguer correction up to a radius of 166 km around each station. This allows the generation of gravity anomaly grids with 1km spacing. In the offshore area, the sparsity of gravity measurements, together with the absence of data from the gulfs of Kalloni, Gera and Edermit (Turkey), do not allow for any reliable representation of gravity anomalies in these areas; the contours shown in Fig. 2, 3 and 4 are only results of extrapolation.

The final CBA (Fig. 2) allows for the analysis of the gravitational signatures, not only of the volcanics as a whole, but also of individual volcanic formations with sizes comparable to the distances between stations, and of the main fault zones. Gravity anomaly amplitudes range between 10 and 70 mGal; they generally trend to the North with the highest values observed over areas of outcropping alpine and pre-alpine basement, while the lowest values are observed at the northernmost parts of the island.

Regional – Residual Anomalies Separation

To isolate gravity anomalies due to the geological structure of the area, we proceeded with the determination and reduction of the long wavelength anomalies from the Bouguer anomaly map. The resulting long wavelength (regional) anomaly map is presented in Fig. 3 and the residual Bouguer anomaly map, after subtracting it from the CBA, is presented in Fig. 4 (on top of the Geological map).

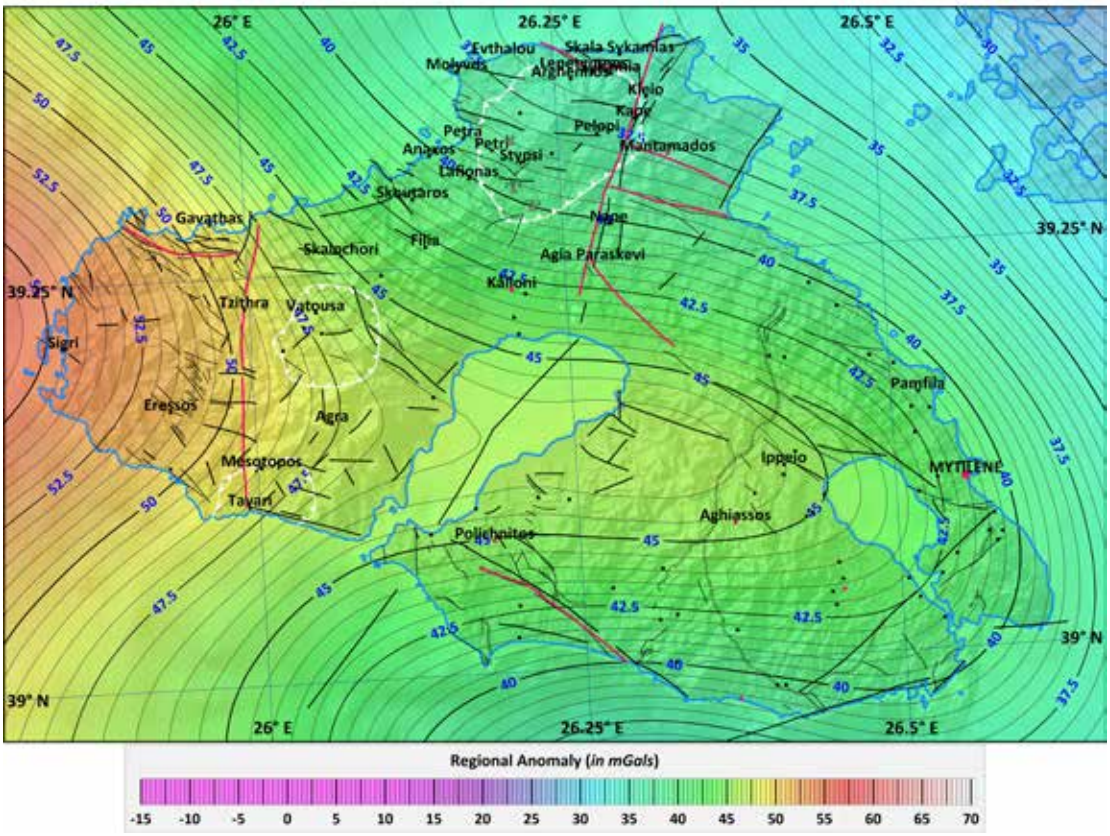

Figure 3. Regional Gravity Anomaly Map.

In the western part of Lesvos, the morphology of the residual anomalies correlates with the geology of the area. It displays a high over the area where the allochthonous basement is exposed on the surface, which is attributed to the high densities of the peridotitic rocks and the metamorphic sole. In the eastern and central parts of the Island, the presence of volcanics is evident in the comparatively lower anomaly amplitudes. Since the only extensive formations with unambiguously “low” density appearing in the area are the Sigri pyroclastics in the west, and the ignimbrites surrounding the ophiolites in the east, the low values in the rest of the area should probably be attributed to volcanic structures that extend in depth. A pronounced positive local anomaly between Vatoussa and Kalloni, not related to the exposure of an apparent high-density geological formation, requires further investigation. The presence of the

lower lavas in the area, east of Agra at an altitude of 500 meters (Fig. 1), in combination with the anomaly, points to the possibility of the generally small thickness of the volcanics in that area. Considering also the amplitude and width of this anomaly, we tentatively conclude that it could be attributed to the presence of the allochthonous basement.

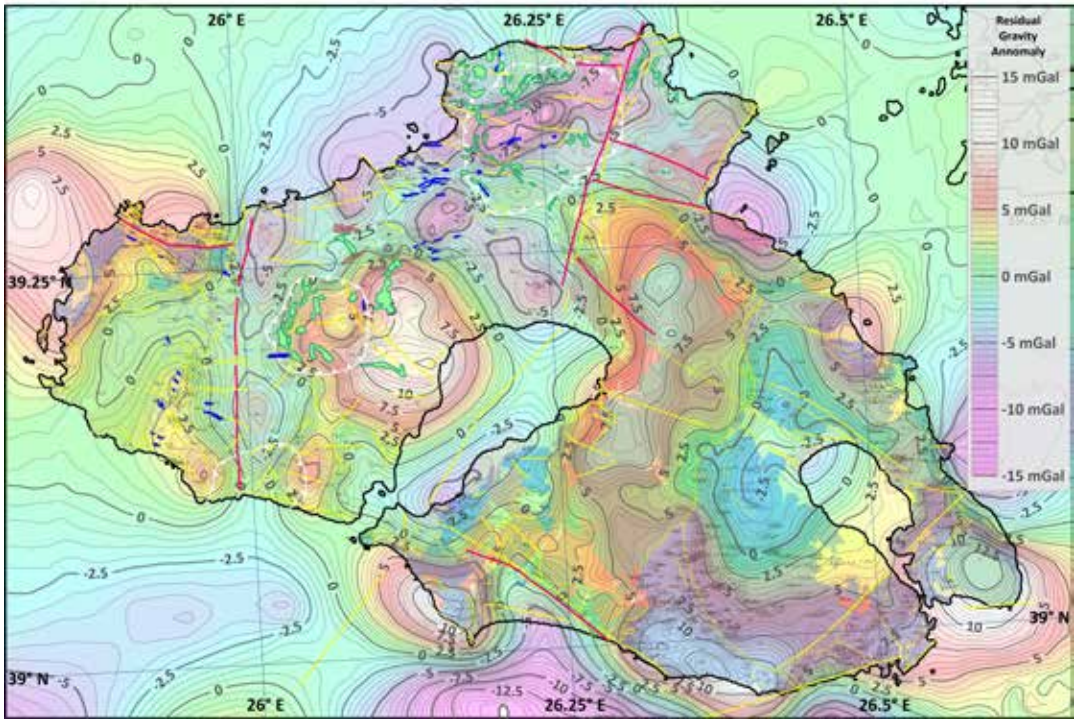

Figure 4. Residual Gravity Anomaly Map (overlaid on the geological map)

The gravity signals of Lepetymnos and Vatoussa calderas (expected to present low anomalies) seem to exist but neither of them is as clear as they were expected to be. The Lepetymnos caldera shows a significant elongate gravity low, delimited though in the area covered by the upper lavas (*Ng_ul* in the geological map). The gravity effect of the lower lavas (*Ng_ll2*) that are in contact with Ng_ll and extend to the north of the caldera, and to the south up to the trace of the caldera, seems to be unaffected by the formation of the caldera. The caldera of Vatoussa shows a more complicated figure. The caldera itself is located at the top of the topography. The gravity anomalies within the boundary of the caldera exhibit lower amplitudes with respect to the adjacent gravity high.

Inversion and Modeling

The modelling was performed with an unpublished algorithm developed by S. Chailas. In this approach, buried three-dimensional geological bodies are approximated by polyhedra of polygonal cross-section and their gravity effect is calculated by the method of Radhakrishna Murthy et *al*., (1989, 1990). Because any polyhedron can be defined by an upper and a lower boundary surface, the shape of any geological body can be determined by using prior information to fix one of the surfaces while adjusting the other. Surface topography, boreholes, other geophysical surveys and surface geology are some obvious sources of prior information.

The adjustment of the boundary surface(s) is automated by an iterative procedure derived from Bott (1960). Letting $\hat{\mathbf{g}}$ denote the matrix of observed gravity anomalies, $\mathbf{g}(k)$ the matrix of calculated gravity anomalies at the k^{th} iteration and $\Delta\mathbf{g}(k) = \hat{\mathbf{g}} - \mathbf{g}(k-1)$ the corresponding residual anomalies, the adjusted boundary surface $\mathbf{Z}(k)$ is modified according to the scheme

$$\mathbf{Z}(k) = \mathbf{Z}(k-1) - \frac{\Delta\mathbf{g}(k)}{2\pi G\Delta\rho} \circ \mathbf{W}_Z, \qquad k = 2,3,\ldots$$

where G is the universal gravitational constant, $D\rho$ is the density contrast across $\mathbf{Z}(k)$, $\mathbf{W}_Z$ is a matrix of weights and ◦ denotes the Hadamard product. The iterative procedure aims at minimizing the objective function

$$\sum\sum\left(\hat{\mathbf{g}} - \mathbf{g}\right)^2 \circ \mathbf{W}_G ,$$

where $\mathbf{W}_G$ is a matrix of weights. The elements of $\mathbf{W}_Z$ and $\mathbf{W}_G$ are either 0 or 1. Thus it is possible to keep $\mathbf{Z}(k)$ fixed wherever prior information exists and to isolate and study specific gravity anomalies.

In the present analysis and based on the data of Section 3.2.1 and Table 1, we have assumed that the volcanic rocks and Quaternary sediments on one hand, and the pre-alpine basement on the other, have a uniform density contrast of -0.25gr/cm^3. Accordingly, the analysis entailed the stripping of the gravity effect of the volcanic layer from the residual Bouguer anomaly. The upper boundary surface $\mathbf{Z}_U^{(1)}$ represents the actual topography and bathymetry (elevation) and was therefore fixed, while the lower boundary surface $\mathbf{Z}_L^{(1)}$ was allowed to vary. The thickness of the volcanic layer is $\mathbf{Z}_U^{(1)} - \mathbf{Z}_L^{(1)}$ and was kept fixed and equal to zero at the outcrops of the pre-volcanic basement. The final surface $\mathbf{Z}_L^{(2)}$ was taken to represent the topography of the pre-volcanic basement.

The adopted density contrast of -0.25 gr/cm^3 is plausible, as it represents the average value of lava densities. Note though that using a common average density for all the volcanic formations may introduce a degree of upward or downward bias to the thickness of the volcanics in localities where local densities deviate significantly from the average. For example, this may occur in areas where the cross-section of the low-density Sigri Pyroclastics is very thick. Nevertheless, it is expected that the resulting model of the volcanics layer is sufficiently representative of geological reality.

The elevation of the lower surface of the volcanic layer, i.e. the topography of the basement, is shown in Fig. 7 in both shaded relief and contour map forms. It exhibits an intricate pattern of structural features. An explanation of the more significant of these features is attempted below.

Discussion and Conclusions

The pre-volcanic basement exhibits a relief that appears to correlate with the older tectonism of the region and is only partly modulated by contemporary active tectonics. In western Lesvos, the basement is relatively shallow (-500 to –900 m) to the west of the currently active tectonic zone of Antissa, but plunges abruptly to the east, reaching elevations of -900 to -1250 m.

The Sigri formation, which extends to the orange dashed line, appears to have covered a preexisting basin (**B$_1$**) and an elongated morphological trough (**B$_2$**), possibly related to past tectonism. Along the orange line, which passes through the center of the Vatousa caldera, a sharp morphological change is observed in the basement, running from coast to coast subparallel to the Antissa fault and parallel to the active zone of Agia Paraskevi. On either side of the southern part of the Gulf of Kalloni, the morphology of the basement indicates the possible existence of an older basin (**B$_3$**). Further north, the area of Kalloni appears to be the southern end of basin **B$_4$**, which has a NW-SE oriented axis at the deepest point of which the Agia Paraskevi fault terminates.

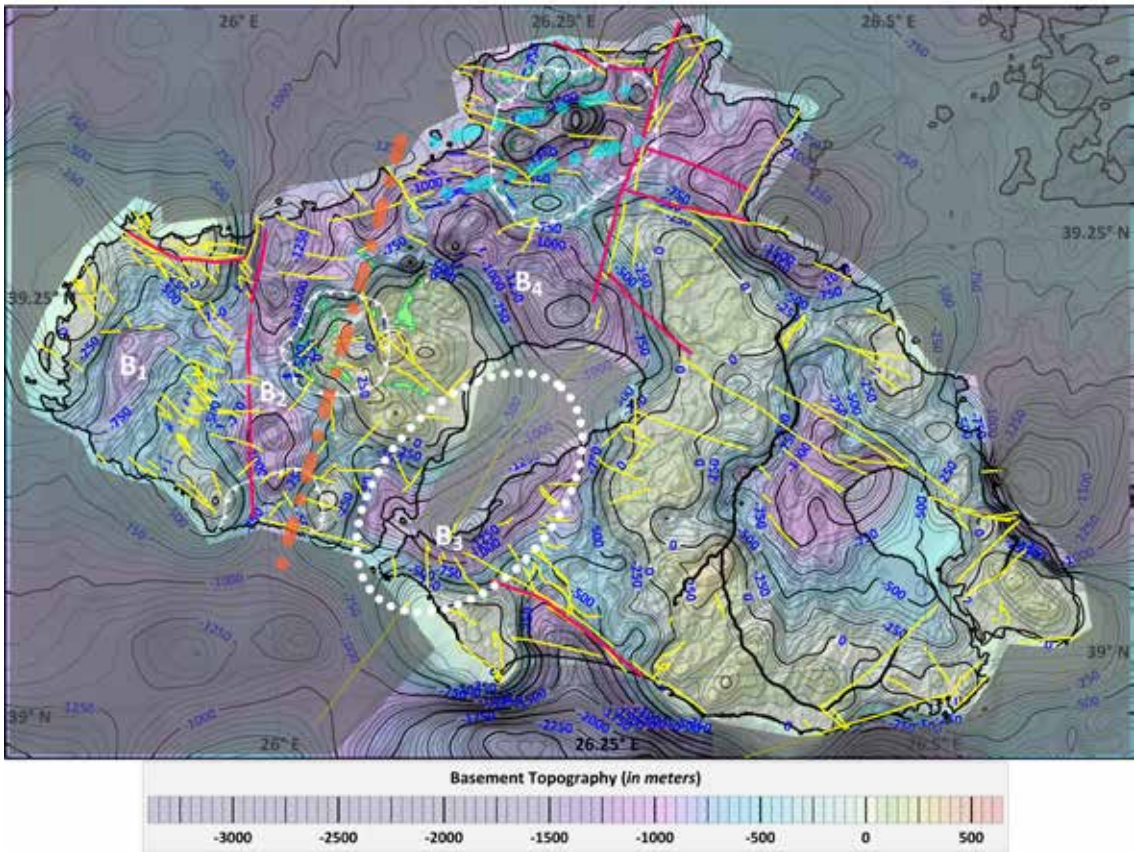

Figure 5. Model of the relief of the pre-volcanic basement

In the caldera of Lepetymnos, a significant NE-SW depression can be observed in the basement, which may be the result of density reduction through chemical alteration by hydrothermal activity facilitated by (past?) active faulting. Finally, in southern Lesvos, the model indicates a structural connection between the Vrissa – Vatera area and the submarine Lesvos basin, with the former feature appearing to fuse smoothly into the latter.

EXTENDED ABSTRACT 044

Sediment dynamics in the Sperchios river basin and their influence on stevia cultivation

Chantzi P.[1], Doani, S.[1], Albanakis K.[1]
(1) Department of Physical and Environmental Geography, Aristotle University of Thessaloniki, Thessaloniki, Greece, pchantzi@geo.auth.gr

Introduction / Background

The purpose of this study was to conduct sedimentological analyses at selected stations within the Spercheios River basin, corresponding to specific sampling locations in stevia cultivation fields found in the area. The sediments, formed through rock weathering and erosion, transported downstream and deposited within the Spercheios basin, 2) the tectonic structures that determine the available space for sediment deposition, 3) the type of the Spercheios River, which defines the types and forms of deposited sediments, and 4) the lithological differentiation which influence the geochemical characteristics of the sediments, collectively define the cultivation environment. The simultaneous action of these mechanisms creates a unique geological identity for the sedimentary basin of the Spercheios River, framing the cultivation background. Consequently, this geological identity is reflected in the products grown in these specific fields. The focus of the study was to understand the variations between different agricultural areas in terms of their sedimentological identity and to explore the mechanisms driving any observed differences.

Methods

A sedimentological analysis was undertaken in the Laboratory of Sedimentology, Department of Physical and Environmental Geography A.U.Th. More specifically, grain size analysis was conducted on 12 samples from the first sampling period in 2023 (Figure 1). Particles larger than 2 mm were analyzed using the mechanical sieve method and a set of sieves at half-phi (ϕ) intervals. Following the removal of organic matter with a 10% H_2O_2 solution (Trautmann et al., 2000a, b), the finer fractions were analyzed through laser diffraction with a Malvern Master Sizer Hydro 3000.
The grain size statistical parameters were computed using Gradistat software (Blott & Pye, 2001), applying the Folk and Ward (1957) method. The granulometric indices, Mean grain diameter (M_z), Skewness (Sk_I), Sorting (σ_I), and Kurtosis ($K._I$), were also calculated, and the grain size distributions were visualized through cumulative and frequency curves.

Figure 1: First sampling period in 2023 in the cultivated areas in the Sperchios River basin

Results

The sedimentological analysis of 12 samples from the Spercheios River basin highlighted a variety of grain sizes, textural groups, and granulometric characteristics that reflect diverse sedimentary conditions within the stevia cultivation fields. The mean grain size ranged from coarse-grained material (e.g., gravel) to finer materials (e.g., mud). The samples were categorized into different textural groups, including “Muddy Gravel,” “Muddy Sandy Gravel,” “Gravelly Mud,” and “Sandy Mud,” indicating diverse depositional environments ranging from fluvial to mixed settings. Figures 2 and 3 show the varying percentages of gravel, sand, and mud in the samples. Samples such as Stev1, Stev2, Stev3, and Stev10 exhibit higher gravel percentages (above 40%), indicating coarse-grained sediment deposits. The highest gravel content is observed in Stev10, suggesting proximity to higher-energy conditions, such as active river channels or areas affected by strong fluvial transport. Conversely, Stev7 and Stev8 have significantly lower gravel percentages, indicating deposition in relatively lower-energy environments. Sand content varies moderately across the samples, generally falling within 10% to 30% in most cases. Samples like Stev5 and Stev6 show balanced amounts of sand, suggesting areas where medium-energy conditions persist during sediment deposition. Stev7 shows relatively higher sand content compared to others, but the dominance of mud remains significant in this sample. Stev7 and Stev8 are dominated by high mud content (~60% to 80%), indicating deposition of fine particles. Most other samples, particularly Stev1, Stev2, and Stev10, have lower mud percentages.

Table 1. Results of the grain size statistical parameters: Mean grain size, Sorting, Skewness, Kurtosis; in phi scale, Folk and Ward method (φ).

Sample	Mean (M)	Sorting (σ)	Skewness (Sk)	Kurtosis (Ku)	Textural Group
Stev1	1.515	3.847	-0.103	0.659	Muddy Gravel
Stev2	1.595	3.749	-0.143	0.675	Muddy Gravel
Stev3	1.265	3.880	0.179	0.697	Muddy Gravel
Stev4	0.507	3.130	0.894	0.471	Muddy Sandy Gravel
Stev5	1.858	3.370	0.158	0.718	Muddy Sandy Gravel
Stev6	1.610	3.683	-0.031	0.684	Muddy Sandy Gravel
Stev7	5.148	1.923	0.100	0.933	Sandy Mud
Stev8	2.579	4.141	-0.381	0.614	Muddy Gravel
Stev9	2.555	3.431	-0.255	1.004	Gravelly Mud
Stev10	2.880	3.603	-0.235	0.656	Gravelly Mud
Stev11	0.204	3.484	0.512	0.698	Muddy Sandy Gravel
Stev12	2.101	3.864	-0.273	0.655	Muddy Gravel

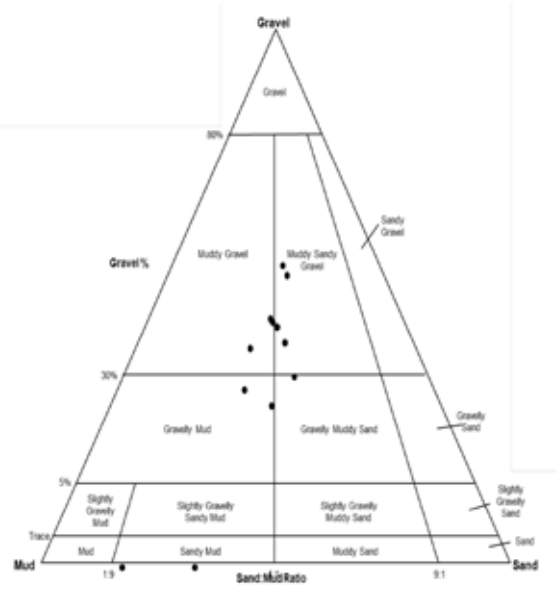

Figure 2. Gravel Sand Mud Diagram for all samples.

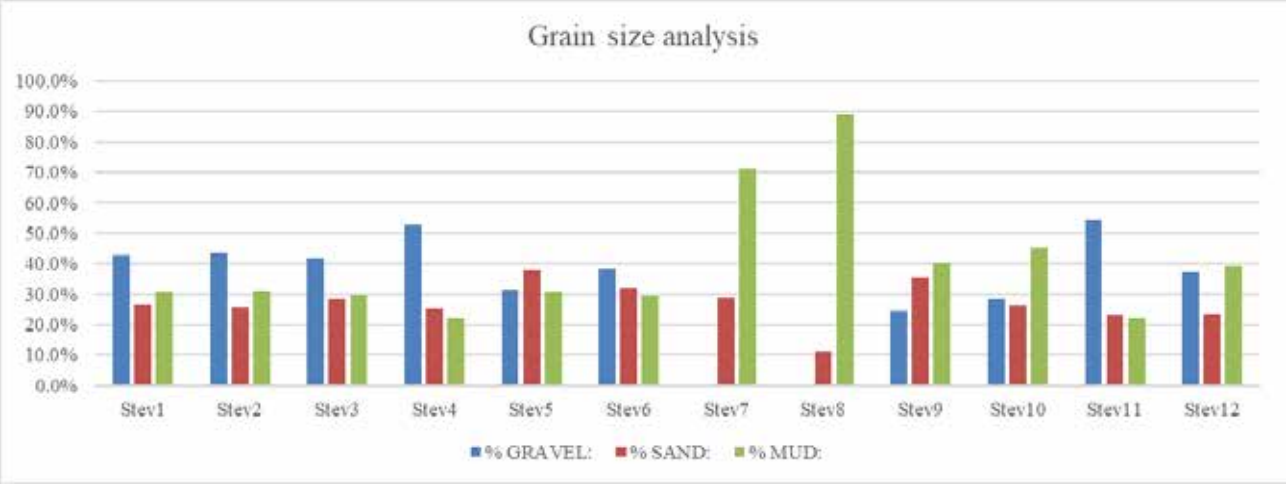

Figure 3. Gravel (%)"; the percentage of gravel fraction, "Sand (%)"; percentage of sand fraction, "Mud (%)"; percentage of silt and clay fraction, for all samples.

Conclusions

The Spercheios River basin exhibits considerable spatial variability in sedimentological characteristics, highlighting the complexity of sediment transport, deposition, and weathering processes within the region. The differences between samples can be attributed to local lithological variations and fluvial dynamics shaping sediment deposition patterns. Fields dominated by finer sediments (e.g., "Sandy Mud") offer higher water retention, potentially benefiting stevia growth, while coarser sediments (e.g., "Muddy Gravel") could enhance drainage but limit moisture availability. Poorly sorted and negatively skewed samples reflect dynamic depositional conditions, likely influenced by periodic floods or sediment influx from upstream erosion. These characteristics may lead to variable nutrient availability and soil fertility across the cultivation areas.

EXTENDED ABSTRACT 045

Sustainable Practices for Resilient Hydrosystems at a Municipal Level: Insights from the Greek Island of Chios

Angelos Chasiotis[1], Elissavet Feloni[2], Panagiotis Nastos[1]

(1) Laboratory of Climatology and Atmospheric Environment, Department of Geology and Geoenvironment, National and Kapodistrian University of Athens, University Campus 15784, Athens, Greece; a.chasiotis@geol.uoa.gr

(2) Department of Surveying and Geoinformatics Engineering, University of West Attica, 28 Ag. Spiridonos, 12243 Egaleo, Athens, Greece

Abstract

Ensuring sustainable water resources management is crucial for the long-term resilience of municipal hydrosystems, particularly in Mediterranean island communities where water scarcity, aging infrastructure, and climate variability pose significant challenges. The island of Chios, located in NE Aegean, as many other areas in Greece faces high non-revenue water (NRW) losses, seasonal demand fluctuations, and over-reliance on groundwater abstraction, making it essential to implement innovative and sustainable interventions. This study explores smart water monitoring technologies, nature-based solutions (NBS), and modernized wastewater management to enhance the system's water efficiency, quality, and security. By integrating IoT-enabled leak detection, digital twin modeling, and automated pressure regulation, the island can reduce NRW losses by up to 40%, improving network performance and cost efficiency. Additionally, infrastructure modernization, including pipeline replacements and wastewater treatment upgrades, will enhance water reuse potential and minimize environmental impacts. Finally, studies have demonstrated that digital twin models can optimize network efficiency and reduce NRW losses significantly. The proposed interventions align with EU water management directives and climate adaptation strategies, ensuring resilience to future water challenges. With technological innovation, policy support, and community engagement, Chios has the potential to become a leading example of sustainable island water management, ensuring secure and equitable access to water resources for future generations. These findings align with broader EU climate adaptation policies, reinforcing Chios' commitment to a sustainable water management strategy that remains resilient and adaptable to future challenges.

Keyword: Sustainable water management; Mediterranean islands; Non-revenue water (NRW) losses; Smart water monitoring; Digital twin modeling; IoT-enabled leak detection; Climate adaptation strategies

Introduction

Water scarcity, exacerbated by climate change and increasing population pressures, presents a significant challenge for Mediterranean islands. The Greek island of Chios, like many coastal and insular regions, experiences high non-revenue water (NRW) losses, seasonal demand fluctuations, and heavy reliance on groundwater abstraction, raising concerns over long-term sustainability. Effective water resource management in these environments requires a combination of technological innovation, policy interventions, and nature-based solutions (NBS) to ensure resilience against hydrological variability and climate-induced risks.

Recent studies highlight the effectiveness of GIS-based water management strategies and hydrological modeling techniques in mitigating water resource vulnerabilities in Mediterranean regions. Additionally, nature-based solutions, such as rainwater harvesting, aquifer recharge, and wetland restoration, have been identified as promising approaches to enhance water sustainability while reducing reliance on energy-intensive desalination systems (Monokrousou et al., 2024). However, limited infrastructure investments and governance challenges continue to hinder the adoption of such measures.

Chios offers a unique case study for implementing smart water technologies and decentralized management strategies. By integrating IoT-enabled leak detection, digital twin modeling, and automated water distribution systems, municipalities can significantly reduce NRW, enhance operational efficiency, and ensure equitable access to water resources. Moreover, coastal aquifer conservation and groundwater quality monitoring are critical for protecting the island's freshwater supply from saline intrusion, a growing threat due to over-extraction and rising sea levels.

This study aims to explore sustainable water management interventions tailored to Mediterranean island hydrosystems, with a focus on Chios. The proposed framework leverages smart water governance, digital water technologies, and community-driven conservation strategies to enhance efficiency, resilience, and long-term sustainability. The findings will contribute to EU climate adaptation policies and regional water management frameworks, supporting efforts to

build climate-resilient hydrosystems for future generations.

Proposed Interventions for Sustainable and Resilient Hydrosystems

Water sustainability in municipal hydrosystems requires a multifaceted approach that integrates smart water technologies, nature-based solutions (NBS), and data-driven governance models. This section outlines a series of proposed interventions aimed at enhancing water efficiency, mitigating non-revenue water (NRW), and strengthening climate resilience in the municipal water infrastructure of Chios, a Greek island facing significant water challenges. Recent studies highlight the crucial role of digital water management and decentralized hydrological governance in addressing water scarcity and quality issues (Wendling et al., 2019). By adopting these innovations, Chios can transition toward a more resilient and sustainable water management framework.

One of the primary challenges for municipal hydrosystems is the high level of NRW, which results from leakage, inaccurate metering, and unauthorized water consumption. Implementing IoT-based smart leak detection systems and digital twin models can significantly enhance real-time monitoring and predictive maintenance (Kumar et al., 2023). The deployment of IoT sensors throughout the distribution network enables the identification of leaks and anomalies in real time, potentially reducing water losses by up to 40% (Mounirou et al., 2025). Additionally, digital twin models, such as those employed in EPANET simulations, facilitate scenario testing and infrastructure optimization, allowing municipalities to predict system failures and improve water distribution efficiency (Breil et al., 2022). Alongside these technologies, smart water metering solutions, including Advanced Metering Infrastructure (AMI), play a crucial role in improving monitoring accuracy. These systems allow for real-time tracking of household and commercial water usage, providing behavior-driven insights that help consumers reduce waste. Furthermore, automated billing and demand-based pricing strategies encourage conservation efforts by promoting more responsible water consumption practices (Rodríguez et al., 2021). By integrating these advanced monitoring and metering technologies, Chios can enhance the efficiency and sustainability of its water management system, while ensuring long-term resilience to climate variability and growing water demand.

Expected Outcomes: Reduction in NRW and Cost Savings

The implementation of smart water management technologies is expected to lead to significant reductions in non-revenue water (NRW) and generate substantial cost savings for Greek municipalities. By integrating decentralized water management and nature-based solutions, municipalities can reduce their reliance on traditional water sources while enhancing sustainability (Table 1).

Table 1: Expected Outcomes from Smart Water Management Technologies

Technology	Expected Water Savings (%)	Energy Savings (%)	Reduction in Operational Costs (%)	Estimated Reduction in Maintenance Costs (%)
IoT-Based Leak Detection	30	10	20	25
Smart Water Meters	25	8	15	20
Automated Pressure Management	20	12	18	22
Decision Support Systems (DSS)	15	5	12	18
Nature-Based Solutions (NBS)	10	4	8	10

One promising approach is rainwater harvesting combined with managed aquifer recharge, which offers a low-energy alternative to desalination for securing freshwater supplies (Monokrousou et al., 2024). Key interventions in this area include the installation of green rooftops and permeable pavements that help reduce stormwater runoff and replenish groundwater reserves (Wantzen et al., 2022). Additionally, wetland restoration can naturally filter pollutants while promoting biodiversity (Lewandowski et al., 2019), further supporting water quality and ecosystem health. Urban green infrastructure, such as bioswales and retention basins, also plays a crucial role in enhancing water management. These features reduce urban flood risks by absorbing and storing excess rainfall, improve water purification by filtering runoff before it enters water reservoirs (Meerkhan et al., 2021), and help mitigate the urban heat island effect, which is a growing concern under climate change (Hachem-Vermette, 2024). These solutions not only contribute to water conservation but also enhance urban resilience and adaptability.

Furthermore, the integration of digital water governance through Decision Support Systems (DSS) offers municipalities

tools for optimizing water distribution, energy use, and emergency responses (Jakovljević et al., 2021). Machine learning algorithms can be employed to forecast water demand based on climatic conditions (Chang et al., 2021), while geospatial mapping can help track and prevent groundwater depletion (Zounemat-Kermani et al., 2020). Finally, community-based water conservation programs play a vital role in driving long-term behavioral change. Public engagement through educational campaigns, digital water consumption dashboards, and municipal reward programs can encourage citizens to adopt water-saving practices and reduce domestic water consumption (Majumder and Kale, 2021).

The combined impact of these smart water management interventions is expected to significantly reduce NRW, lower operational costs, and foster more sustainable and resilient water systems, as demonstrated by similar successful practices in other municipalities across Greece (Table 2).

Table 2: Reduction of NRW Losses in Greek Municipalities with Smart Water Management

Municipality	Baseline NRW Losses (%)	Expected NRW Reduction (%)	Estimated Water Savings (m³/year)	Estimated Cost Savings (€/year)	Number of Beneficiaries
Aigio	48	35	600,000	21,000	20,422
Argos	54	40	1,200,000	42,000	22,209
Paramythia	72	50	600,000	20,000	3,032

(Data from: Chasiotis et al. 2023a; 2023b)

Case Study: Insights from the Island of Chios

Chios, a Greek island in the Aegean Sea, faces significant water management challenges due to seasonal variability, climate change, and high non-revenue water (NRW) losses. As a semi-arid island, Chios experiences long, dry summers and short, intense rainfall periods, which result in frequent water shortages and inefficient groundwater recharge. The municipal water system primarily relies on groundwater abstraction from local aquifers, limited rainwater harvesting, and seawater desalination to meet growing urban and tourism-related demand. However, these sources are increasingly vulnerable to climate variability, saline intrusion, and over-extraction, posing a threat to the island's long-term water security. The Municipal Water and Sewerage Company of Chios oversees the island's water supply and wastewater infrastructure (Table 3), drawing water from over 100 groundwater wells and boreholes, 160 natural springs, and 15 reservoirs, such as the Psaropetra Dam, which stores water during wet seasons. Additionally, four seawater desalination plants supplement supply, particularly during peak demand periods. Despite this diverse water network, Chios struggles with high NRW losses, reaching up to 50% in some areas due to aging pipelines, leaks, and unauthorized consumption. Outdated infrastructure, including asbestos cement and PVC pipes, requires urgent replacement, while the island's limited surface water storage capacity heightens its dependence on groundwater, leading to aquifer depletion and saline intrusion.

Table 3: Major settlements in Chios and their water supply characteristics

Municipal District	Main Water Sources	Challenges
Chios City	Groundwater, desalination, Psaropetra Dam	High seasonal demand, aging infrastructure
Kambos	Wells, springs	Overextraction, groundwater depletion
Mastichochoria	Reservoirs, springs	Insufficient supply during summer months
Volissos & Northern Chios	Springs, boreholes	High NRW losses, insufficient infrastructure
Oinousses Island	Desalination plant	Energy-intensive water production

(Data provided by the Municipal Enterprise for Water and Wastewater of Chios)

The water supply system serves both urban and rural settlements, each facing distinct challenges. Recent efforts to modernize infrastructure, such as replacing outdated asbestos cement pipes with high-density polyethylene (HDPE) alternatives, aim to improve water quality and reduce system inefficiencies. However, three primary challenges continue to impact Chios' water management. First, NRW levels remain high, with system inefficiencies caused by

aging pipelines, leaks, and inaccurate metering contributing to financial and operational losses. Second, climate change and rainfall variability have led to a 20% decline in annual precipitation over the past 30 years (Monokrousou et al., 2024), while rising temperatures and prolonged droughts increase reliance on groundwater, exacerbating the risk of saline intrusion in coastal aquifers. Third, tourism-driven demand surges place additional stress on the system, with water consumption increasing fivefold during peak summer months (Wendling et al., 2019).

The adoption of sustainable water management strategies offers significant environmental, social, and economic benefits for Chios. Environmentally, reducing groundwater over-extraction can help prevent saline intrusion, while minimizing water losses ensures efficient resource utilization. Improved wastewater treatment will further protect marine ecosystems by reducing coastal pollution. Social benefits include securing a continuous and safe water supply, enhancing climate resilience, and promoting water conservation awareness within the community. Economically, modernizing infrastructure and reducing NRW can lower operational costs, while improved water services and environmental sustainability can boost the island's attractiveness as a tourist destination. Additionally, investments in smart water technologies and infrastructure development can create new local employment opportunities.

By implementing smart leak detection systems, automated pressure regulation, expanded wastewater treatment capacity, and increased desalination and rainwater harvesting, Chios can enhance its water security and sustainability. The European Environment Agency in 2021 emphasized that digital water governance frameworks can significantly improve municipal decision-making, further supporting these interventions. Collectively, these measures could lead to a 30–40% reduction in NRW losses, strengthening the island's long-term water resilience. The success of these strategies depends on strong municipal governance, stakeholder collaboration, and sustained investment in digital water solutions, ensuring that Chios becomes a model for sustainable island water management.

Table 4: Expected Impact of Sustainable Water Interventions in Chios

Intervention	Expected Water Savings (%)	Energy Savings (%)	Cost Reduction (%)
Pipe replacement (HDPE)	20	10	25
Smart leak detection	30	8	20
Wastewater treatment upgrades	15	12	18
Rainwater harvesting	10	5	10
Desalination efficiency improvements	25	15	30

Conclusions

Ensuring a sustainable and resilient water management system in Chios requires a holistic approach that integrates technological innovations, nature-based solutions (NBS), and participatory governance. The combination of smart water technologies, such as IoT-enabled leak detection and digital twin modeling, with green infrastructure and adaptive governance frameworks presents a comprehensive strategy to mitigate non-revenue water (NRW) losses, enhance climate resilience, and secure long-term water availability for both residents and seasonal visitors.

The adoption of IoT-based monitoring systems and advanced metering infrastructure (AMI) has already demonstrated its potential in reducing water losses and improving operational efficiency. Simultaneously, investments in rainwater harvesting, managed aquifer recharge, and wetland restoration contribute to natural water retention and purification, reducing dependency on costly and energy-intensive solutions like desalination. These integrated solutions not only optimize water use but also promote ecological sustainability by restoring natural hydrological cycles.

However, for these interventions to achieve their full potential, a strong governance framework is essential. Aligning local policies with EU water management directives, promoting community engagement in conservation efforts, and fostering regional cooperation among Aegean islands will be crucial in ensuring long-term water sustainability. Effective governance will also support the scalability of these solutions and facilitate access to financial and technical resources.

Looking ahead, future research should focus on expanding smart water infrastructure, particularly through the development of digital twins and AI-driven demand forecasting, to optimize resource allocation and emergency response. Additionally, scaling up nature-based interventions can further enhance groundwater recharge and flood mitigation while reducing reliance on non-renewable water sources. Exploring funding opportunities through EU sustainability programs will also be key to supporting large-scale implementation and ensuring the financial viability of these initiatives.

By embracing an integrated and forward-thinking water management approach, Chios can serve as a model for other Mediterranean islands facing similar climatic and hydrological challenges. Sustainable water governance, combined with technological innovation and nature-based solutions, will not only safeguard the island's water security but also enhance its resilience to climate change and environmental pressures, ensuring a sustainable future for generations to come.

Acknowledgements
Authors would like to thank the Municipal Enterprise for Water and Wastewater of Chios for the provision of available data regarding the local water resources and water distribution network.

Kentavros pluton (Thrace, Greece): Geochemistry and Petrogenesis

Chatzakou T.[1], Tsiri A.[1], Koroneos A.[1], Gerontidou I. [1], Drakoulis A. [1]

(1) Department of Mineralogy-Petrology-Economic Geology, Aristotle University of Thessaloniki, Thessaloniki, Greece, theodxat@gmail.com , atsirib@geo.auth.gr , koroneos@geo.auth.gr , ioangero@geo.auth.gr , alexdr@geo.auth.gr

Introduction

Rhodope massif is characterized by the extensive magmatism of Eocene - Miocene age. There are many plutonic rocks intruding the two units (Sidironero and Pangaion) of the Rhodope massif (e.g. Xanthi pluton, Kavala pluton, Vrondou pluton etc.) and most of them have been thoroughly studied (Christofides *et al*., 1998 and references therein). There is one pluton though, the pluton of Kentavros, which has not been petrologically and geochemically studied up to now. The pluton of Kentavros is located 26 km NNE of Xanthi city near the village of Kentavros. The pluton intrudes gneisses and gneiss-schists, marbles and occasionally amphibolites of the Sidironero unit, causing locally contact metamorphic phenomena (Fig.1) (IGME 1973). Liati (1986) using K-Ar method on hornblende gave a Late Eocene - Early Oligocene age (38±1 Ma) for the Kentavros pluton, similar to the age of Xanthi pluton which is 34±0.5 Ma (Christofides *et al*., 2012). The aim of this study is to present for the first time petrological, mineralogical and geochemical characteristics of the Kentavros pluton, to provide evidence on the origin of it as well as to compare it with the nearby Xanthi pluton of similar age.

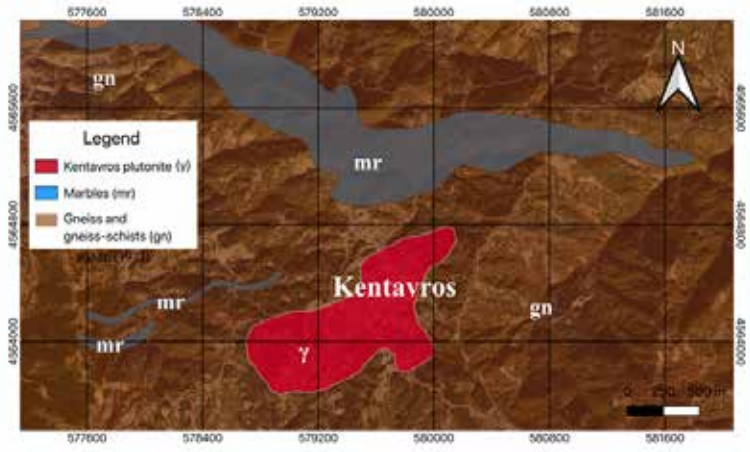

Figure 1: Geologic map of Kentavros area. (IGME, 1973 with modifications using QGIS.3.34, QGIS.org, 2023).

Geological Setting

The Rhodope massif is a thick (10-20 km) continental crust. It extends from southern Bulgaria to Thrace, Thassos, and eastern Macedonia. It is believed to originate either from the Eurasian plate or to be an ancient continental fragment of Gondwana, which was detached and incorporated into Eurasia (Mountrakis, 2021). Its western boundary is the Strymon fault, where it is separated from the Serbomacedonian massif, while to the east it is in contact with the Circum Rhodope zone. The Rhodope massif is divided into two units by Papanikolaou & Panagopoulos (1981): the Upper Tectonic Unit (Sidironero Unit) and the Lower Tectonic Unit (Pangaion Unit). The units were separated by the NE-SW trending and southwest-vergent Nestos thrust, from Xanthi to the Bulgarian border (Christofides *et al*., 2001). The Rhodope massif is intruded by igneous rocks, both plutonic and volcanic, with composition ranging from granitic to gabbroic (Christofides *et al*., 1998). The magmatism ranges from Eocene to Miocene in age and is related to an active continental margin (Mountrakis *et al*., 2006). According to Krohe & Mposkos (2002), Kentavros pluton is an intrusion into the upper Unit Sidironero Complex, which has been exhumed before 50-30 Ma. It is also associated with the Xanthi detachment system. Around the Kentavros pluton there is limited plastic elongation and rotation recrystallization of quartz. The pluton appears highly sheared and it is a syn-detachment intrusion into the Upper Sidironero Complex.

Analytical Methods

The laboratory research includes the determination of the mineralogical and chemical composition of the rocks. Regarding mineralogy, 11 thin sections were prepared and examined under a polarizing microscope. For the chemical analyses, 11 pressed pellets were prepared. The samples were ground to fine powder and mixed with a commercial cellulose based

binder (CEREOX®) at a ratio of 4 parts sample to 1 part binder. The final mixtures were then subjected to a pressure of 15 tons using a hydraulic press, in order to form pellets compatible with the wavelength-dispersive X-ray fluorescence (WDXRF) spectrometry system. The analyses were performed on a RIGAKU Supermini200 tabletop XRF instrument, which operates at 50kV and 4mA with 200W power.

Petrography and Mineralogy

The Kentavros pluton consists of different rock types, from basic to acid, differing to a certain extent in the mafic mineral contents and texture. Based on the TAS classification diagram of Cox *et al*. (1979) (Fig. 2), their texture and modal composition they are classified as: cumulates with pyroxene (Cum Px), cumulates with hornblende (Cum Hb) gabbros (Gb), diorites with hornblende (Hb-Dr) and diorites containing pyroxene and hornblende (Px, Hb-Dr), Qz monzodiorites (Qz-MzDr), tonalites (Ton) and pegmatite veins (Pgm).

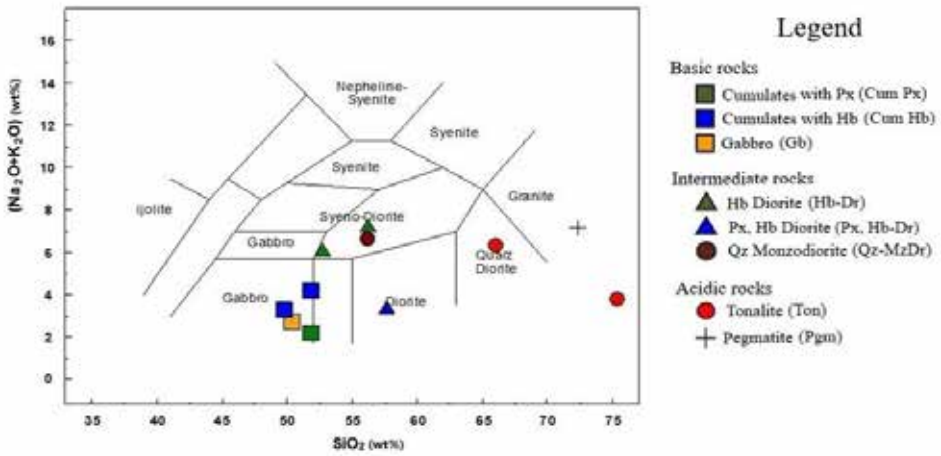

Figure 2: Chemical classification of the Kentavros pluton rock types (TAS after Cox *et al*., 1979).

All the rock types are medium grained apart from the Cum Hb rocks, which contain significantly large hornblende crystals (Fig. 3a). The cumulate rocks consist of hornblende, pyroxene, plagioclase (Fig. 3b), biotite (Fig. 3c) and contain minor amounts of orthoclase and quartz. The accessory minerals are titanite in remarkably large crystals (Fig. 3d), chlorite and apatite. The gabbros consist of plagioclase, hornblende and pyroxene. The diorites and quartz monzodiorites consist of plagioclase, orthoclase, hornblende, biotite, pyroxene and occasionally quartz. The accessory minerals are titanite, allanite, apatite, zircon and opaques. The tonalites consist of quartz, orthoclase, plagioclase, biotite, hornblende and occasionally pyroxene. The accessory minerals are chlorite, allanite and zircon. The pegmatite veins consist of quartz, microcline and plagioclase. The accessory minerals are epidote, clinozoisite and allanite.

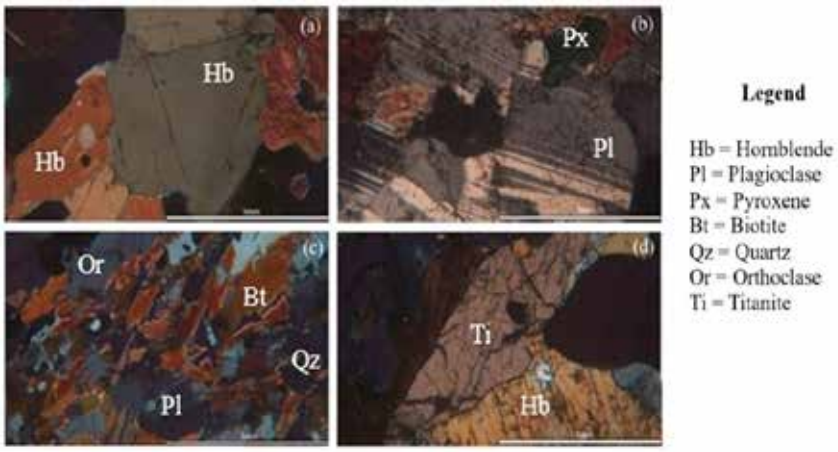

Figure 3: Representative minerals of the Kentavros pluton in N+. (a) Hb crystals, (b) Pl with Px, (c) Bt with Qz, Or and Pl, (d) Ti with Hb.

Geochemistry

The SiO_2 content of the basic rock samples (Cum and Gb) ranges from 49.08 to 51.35%. In the intermediate samples (Dr, Qz-MzDr) it ranges from 50.95 to 57.11%. In the acid samples (Ton, Pgm) it ranges from 65.60 to 71.92% (Table 1). TiO_2, FeO_{tot} (total Fe expressed as Fe^{2+}), MnO, MgO, CaO and P_2O_5 decrease with increasing SiO_2 (Fig. 4 and Table 1), while Al_2O_3, K_2O and Na_2O increase (Fig. 4 and Table 1). Regarding the trace elements, Sr, Ba, Cr, Ni, Zr, Y, Nb, V and Co decrease with increasing SiO_2 (Fig. 5 and Table 1), while Rb and Sc (Fig. 5 and Table 1) increase. According to the SiO_2 - K_2O diagram (Peccerillo & Taylor, 1976) the composition of the pluton varies mostly from calk-alkaline to high-K calc-alkaline (Fig. 4). Also, all the samples are metaluminous and characterized as I-type (Fig. 5).

Table 1: Whole-rock major (wt%) and trace (ppm) element analyses of representative samples from the Kentavros pluton.

Sample name	KE-12	KE-13	KE-03	KE-05	KE-08	KE-07	KE-10	KE-14	KE-11	KE-04	KE-06

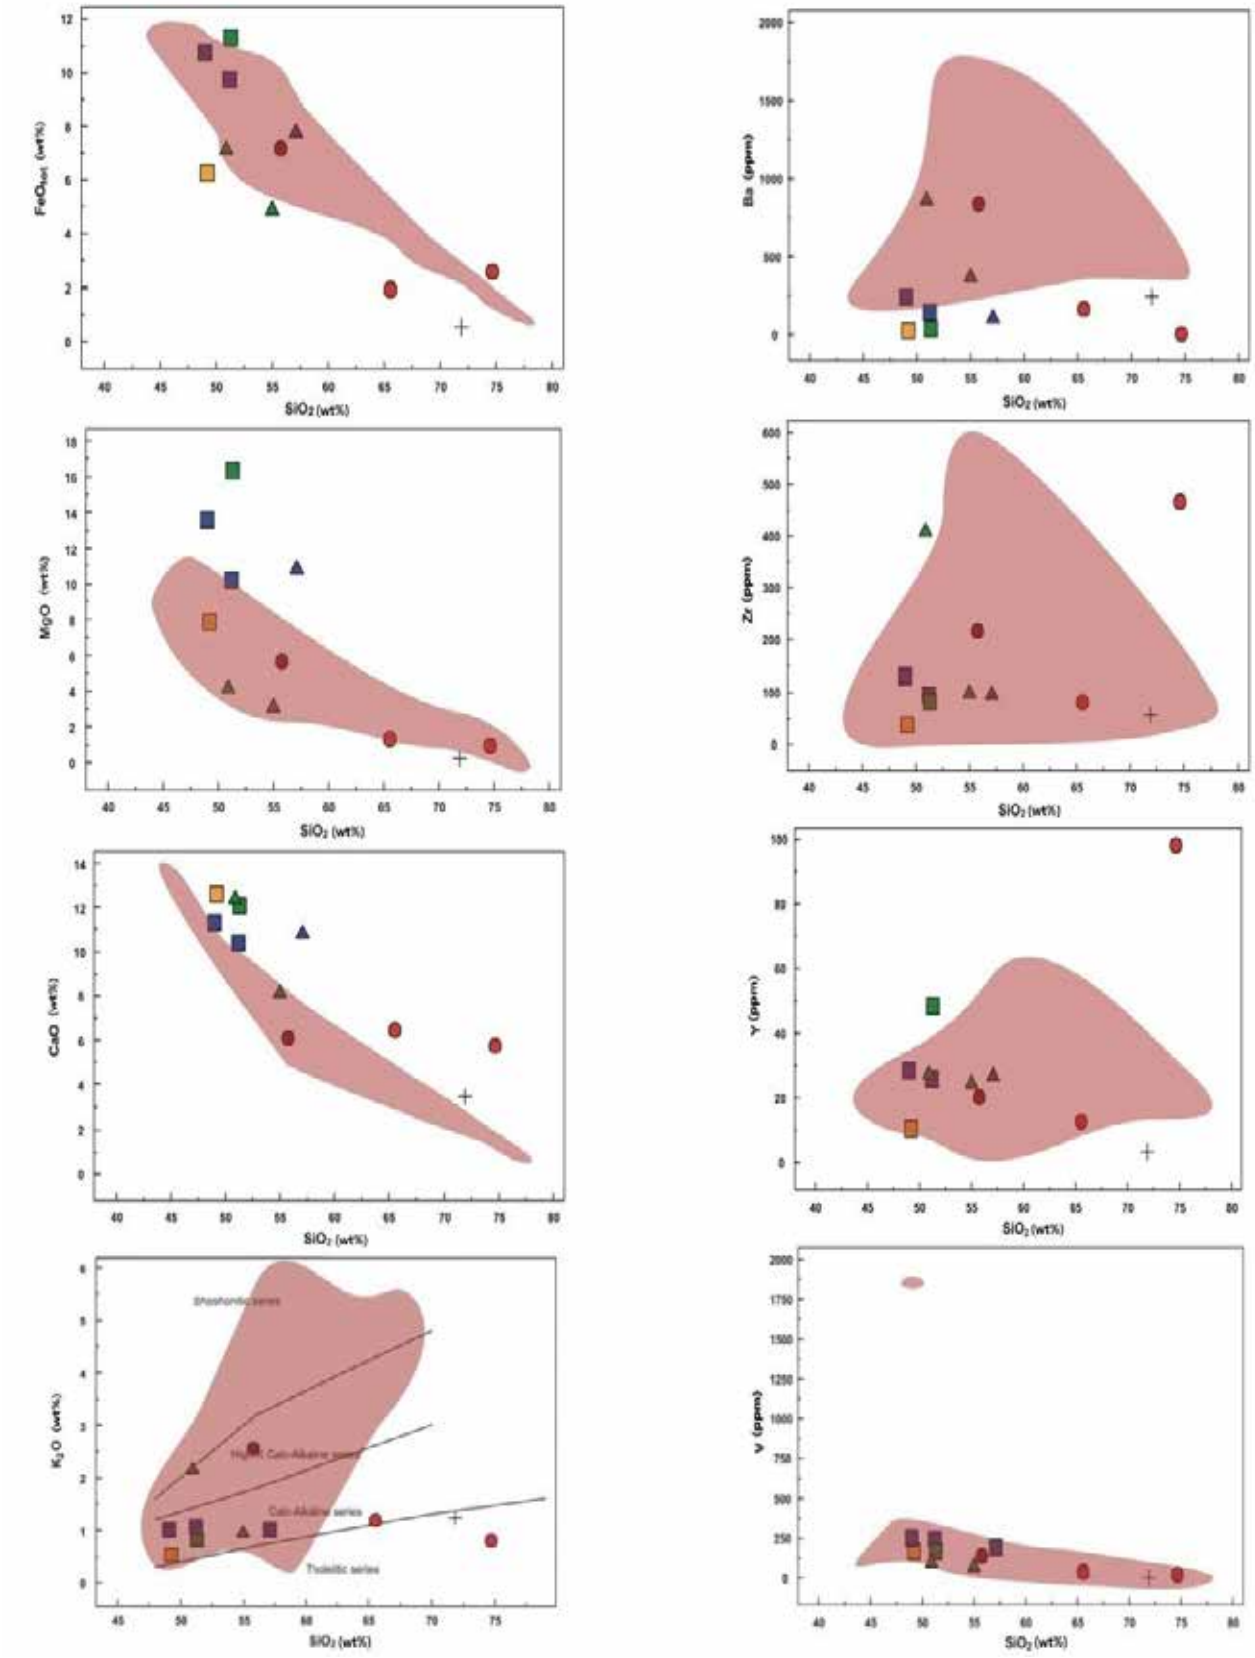

Figure 4 Cont.

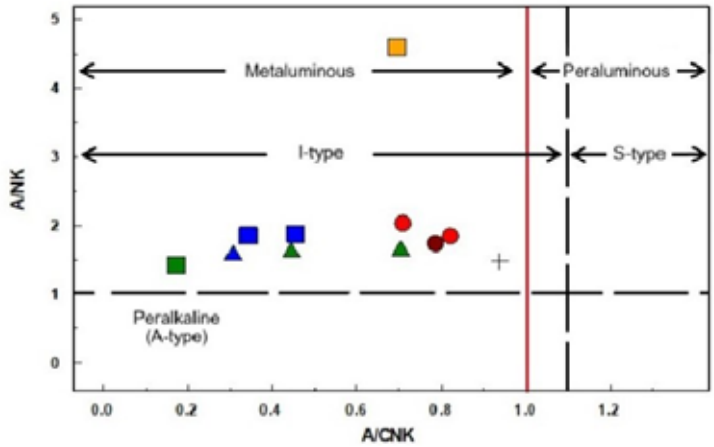

Figure 5: A/CNK - A/NK diagram. Legend as in Fig. 2.

Petrogenesis

According to the tectonic classification diagrams of Pearce *et al*. (1984) (Figs. 6 a and b) the analyzed samples plot mostly in the volcanic arc granitoids (VAG) field. This means that the magmatism of Kentavros is related to a subduction mechanism, which is typical for the Rhodope magmatic rocks of Eocene to Miocene age (Pipera *et al*., 2013).

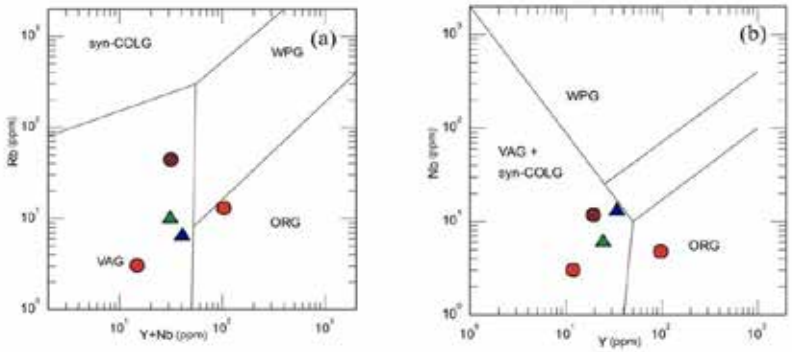

Figure 6: Tectonic classification diagrams (Pearce *et al*., 1984). Legend as in Fig. 2.

Kentavros gabbro represents a mantle-peridotite original melt (Fig. 7, brown area) and diorites are probably the results of evolution of the gabbroic magma although they might represent a high-Mg andesitic magma (Fig. 7, grey area). The tonalitic samples plot in the “Metagreywacke Sources” field (Fig. 7, pink area), indicating association with such sources. It is to note that, alternatively, the intermediate rocks can be probably a result of the metagreywacke’s melt interaction with peridotite melt during a mixing procedure.

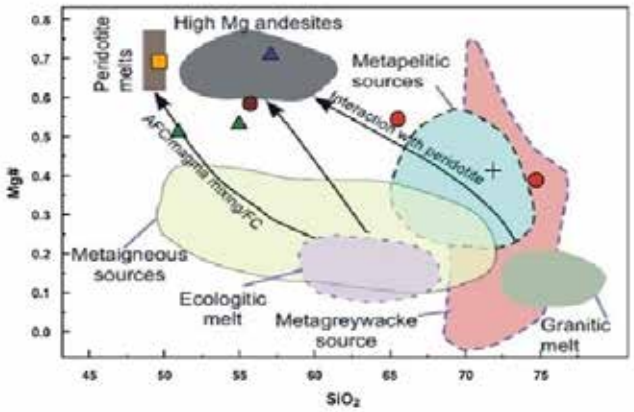

Figure 7: Mg# - SiO_2 diagram showing the melts’ origin (Sami *et al*., 2023 and references therein). Legend as in Fig. 2.

Comparison with Xanthi pluton

The fact that the Kentavros and Xanthi plutons are located close to each other (8.8 km apart) combined with their similar ages (Liati, 1986; Christofides *et al*., 2012), lead to the decision of comparing the two plutons, although the geochemical data are limited. Regarding the petrographic types they both contain Qz-MzDr, Dr and Gb, but they differ in the acid rock types. Xanthi pluton contains granodiorites (Gdr) and monzogranites (MzGr), while the Kentavros pluton contains Ton. It must be noted though that Gdr in Xanthi represents ~75% of the pluton. On the contrary, the amount of Ton in Kentavros pluton is limited. Major elements having similar behavior in both plutons are TiO_2, Al_2O_3, FeO_{tot}, MnO, MgO and P_2O_5 (Fig. 4). K_2O has lower values in Kentavros than Xanthi and Na_2O either lower and or higher values than Xanthi. Trace elements showing similar behavior in both plutons are Sr, Cr, Ni, Zr, Y, Co and V (Fig. 4). Rb and Ba have lower values in Kentavros than Xanthi, while Sc has higher values. Moreover, both plutons have calc-alkaline to high-K calc-alkaline affinity, even though Xanthi intermediate (monzonitic) rocks have higher K content (Fig. 4). Both plutons are associated to the same geotectonic environment (VAG) and to the Xanthi detachment system. It should be noted though, that Kentavros pluton is a syn-detachment intrusion while Xanthi pluton is characterized as late or post detachment intrusion (Krohe & Mposkos, 2002).

EXTENDED ABSTRACT 047

The Impact of Urban Sprawl on Areas of Natural and Cultural Heritage and Geoheritage. Evidence of Lemnos Island, Greece

Chatzi Efstratia[1] , Derdemezi Evangelia - Theodora[1] , Tsilimigkas Georgios [1]
(1) University of the Aegean, Department of Geography, Mytilene, Greece
Email: efi.chatzi@geo.aegean.gr, ederde@geo.aegean.gr , gtsil@aegean.gr

Research Highlights

Quantitative rendering of the impact of urban sprawl on Natura 2000 areas, Wild Life Refuges, Small Islands Wetlands, Archeological areas and Monuments and the Petrified Forest in Lemnos island. Interpretation of results based on spatial planning system in Greece.

Introduction

Cultural and natural heritage and geoheritage sites are vital for preserving the identity and history of regions, but they are increasingly threatened by urban sprawl, particularly in areas with high development pressures (AbdelMaksoud 2020, Lagarias and Stratigea 2023). Islands are highly vulnerable to such pressures due to their small size and growing tourism (Baldacchino 2004, Spilanis 2012). The urban sprawl on islands is often expanded into critical heritage zones, which are already under pressure from both natural and human factors (Salvati 2013, Tsilimigkas et al.2022). Islands are characterized by spatial fragmentation, which on the one hand makes them fragile socio-spatial systems and on the other hand enhances endemism, creating ecosystems of particular value. This is recognized at the European level, and thus a large part of the island areas is included in the Natura 2000 network (EEC 1992, EC2009). The importance of the natural environment and the need for management and protection is also recognized at the national level with legislation under which, among other things, National Parks (OGG 1986, OGG 2020), Small Island Wetlands (MD 2010, OGG 2011) and Wild Life Refuges (OGG 1998, OGG 2011) are delineated. The cultural heritage of the islands is characterized by an extensive network of traditional settlements and archaeological areas and monuments. The need for cultural heritage protection and management is recognized at European and national level (Council of Europe 1995, OGG 2002, OGG 2021). An important part of the identity of the islands, and a valuable tourist resource is their geoheritage, which consists of physico-geographical elements of geological interest and at the same time, over the years, these areas acquire a cultural significance that makes them landscapes of special value (Sotiriou and Nunes 2024). At the international level, the importance of geoheritage has been recognized mainly through the UNESCO'S Global Geoparks Networks. At the national level, legislation concerning geoparks and geosites is fragmented and falls both within institutional arrangements for the protection of environment and habitats (OGG 2011, OGG 2020) and for the protection of the cultural environment and landscape (OGG 2010).

The study area for this paper is Lemnos Island of the Region of the North Aegean. Covering an area of 478,97 km² and the permanent population is 16409 people. Lemnos has notable natural and cultural heritage, including 3 areas integrated into the Natura 2000 network, 9 wildlife refuges areas, 3 sections of the Petrified Forest, 59 wetlands, 18 traditional settlements and 20 designated archaeological sites. One of the island's most unique features is the Petrified Forest of Lemnos, which contains subtropical vegetation remains dating back at least 20 million years (Dasarxeio, 2020). Designated as a "Preserved Natural Monument" (Decision No. 75247/4865/10-12-2013 by the Secretary General of the Decentralized Administration of the Aegean), this site is protected across three delineated areas and several individual fossil-bearing locations.

Objectives

The aim of this research is the quantitative rendering of urban sprawl in areas of natural and cultural value on the island of Lemnos and its interpretation within the framework of spatial planning. Specifically, the research questions are: (1) What percentage of built-up area is located within and outside settlements' boundaries? (2) What percentage of built-up area outside settlements' boundaries is located within (a) Natura 2000, (b) archaeological areas and (c) petrified forest? The results are interpreted based on spatial planning and applicable legislation.

Methods

To answer the research questions, acquiring the appropriate geospatial data was essential:

- Impervious Built-up (IBU) 2018, provided by the European Environment Agency (EEA) through Copernicus, was used to represent built-up areas. This raster layer contains binary information, with buildings classified as 1 and non-buildings as

0 (EEA 2018). The spatial resolution of IBU is 10m.

- For distinguishing built-up areas inside and outside settlements, the boundaries of official settlements were sourced from the open platform e-poleodomia (MEE 2025). In Lemnos there are 40 settlements of which 18 designated traditional settlements, three traditional settlements were found to lack official boundaries. To avoid considering these built-up areas as exurban, we digitized their boundaries aaccording to the compact residential fabric with reference map the Google Earth. Additionally, the settlement boundaries for Myrina, the capital of the island, were missing. These boundaries were digitized using the General Urban Plan (GUP), with topographical charts georeferenced using the Greek Geodetic Reference System 1987 (GGRS87) at a scale of 1:5.000. This ensures accurate and consistent mapping across all settlements.
- The Natura 2000 areas were retrieved from the EEA (EEA 2022). The Wildlife Refuges were sourced from the Forest Service and forest maps, while the Wetlands were obtained from the Greek Ministry of Environment and Energy. The delineation of archaeological areas came from the Archaeological Cadaster.
- The delineation of the Petrified Forest of Lemnos was based on the map included in the decision declaring it a “Preserved Natural Monument” (Official Decision 2013). To ensure spatial precision, we digitized the forest boundaries from the forest map provided by the Forest Service, georeferencing the map using GGRS87 at a scale of 1:5.000.

The methodology employed was based on raster analysis. Vector-format data were rasterized to align with the raster layers. The identification of exurban built-up areas was achieved by overlaying the layers of IBU and official settlement delineations. This analysis produced quantitative data, which was further examined to assess spatial relationships with the Natura 2000 areas, wildlife refuges areas, wetlands archaeological areas and the Petrified Forest of Lemnos. The resulting insights were interpreted within the framework of spatial planning to evaluate the impact of urban sprawl on these protected areas.

Results

In Lemnos, the total built-up area occupies 4.74 km², which corresponds to 0.99% of the island’s total area. Of this built-up area, 3.41 km² (or 0.71%) lies within the boundaries of settlements, while the remaining 1.33 km² (or 0.28%) is located outside settlement boundaries. Comparatively, the percentage of construction on Lemnos is significantly smaller than on other islands, such as Santorini, where construction occupies 4.04% of the total island area, with 2.08% in extra-urban areas (Tsilimigkas and Derdemezi 2020).

The distribution of built-up areas outside official and traditional settlements in Lemnos highlights their significant impact on zones of natural and cultural significance, as shown in Table 1.Urban sprawl has impacted 8 of the wildlife areas, 6 of the wetlands, 2 of the Natura 2000 sites and 11 of the archaeological sites. Archaeological areas, which cover an impressive 89.44% of the island, are among the most affected by this type of development, hosting a substantial portion of the built-up area outside settlements. This overlap underscores the need for careful management, as interventions within archaeological site boundaries must comply with strict regulations to prevent unplanned and unregulated development.

Table 1. Impact of Built-Up Areas Outside Settlements on Natural and Cultural Zones in Lemnos

Island of Lemnos	Percentage %
Petrified Forest Area B1	2,42
Petrified Forest Area B2	7,67
Wildlife Refuges Areas	32,57
Wetlands	0,61
Natura 2000	14,4
Archaeological	89,44

Other areas of natural significance also show varying degrees of impact from built-up areas outside settlements: Petrified Forest: Area B1 is affected by 2.42%, while Area B2 is affected by 7.67%. Wildlife Refuges Areas: These zones experience significant impact, with 32.57% affected by built-up areas outside settlements. Wetlands: Though wetlands occupy only 0.61% of the island, their exposure to built-up areas outside settlements highlights the need for protection from encroaching development. Natura 2000 Sites: These protected areas are also impacted with 14.4% affected by built-up areas outside settlements, further emphasizing the urgency of integrated spatial planning.

To better visualize the spatial distribution of built-up areas in relation to the zones of natural and cultural significance, Figure 1 provides an overview of Lemnos, while Figure 2 zooms in on two key areas of the island. The labels B1, B2, and B3 in Figure 2 correspond to areas of the Petrified Forest, which are among the zones impacted by built-up areas outside settlements.

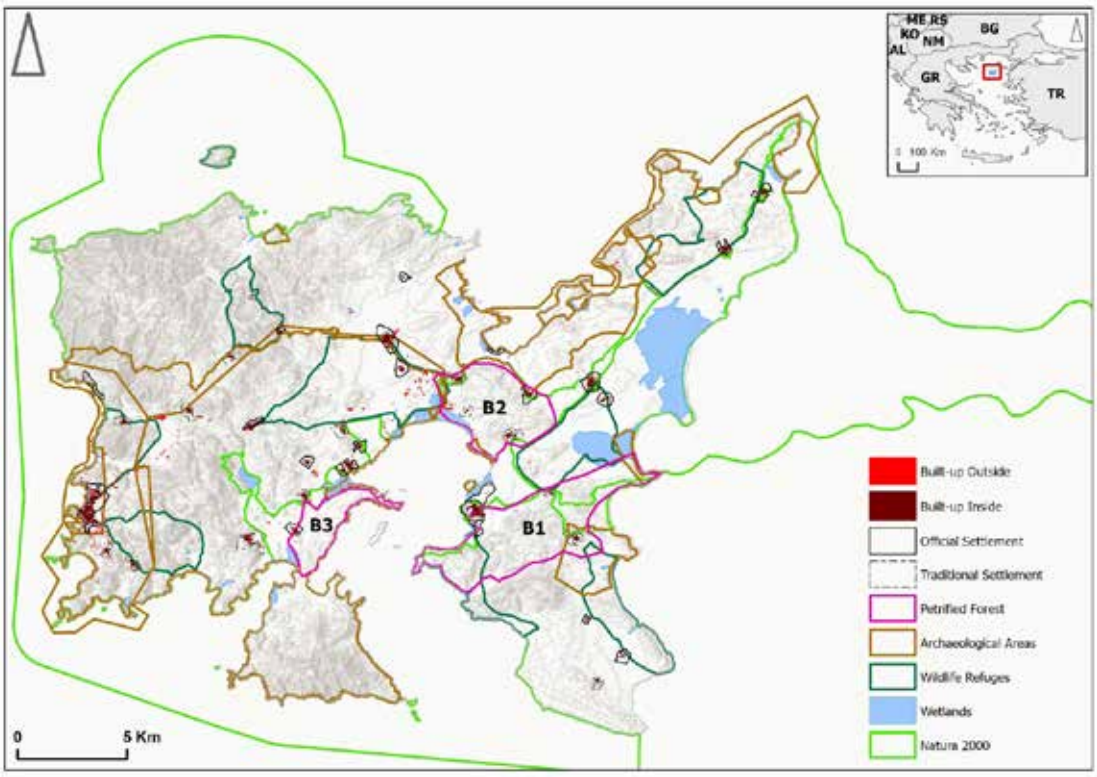

Figure 1: Overview of the Island of Lemnos, showing the spatial distribution of built-up areas, settlements, and protected zones.

Figure 1 provides a comprehensive view of the spatial distribution of built-up areas across Lemnos. The map highlights both built-up areas within settlements (dark red) and outside settlements (bright red). It also delineates key zones of natural and cultural significance, such as archaeological areas, wildlife refuges, wetlands, and Natura 2000 sites. This island-wide perspective allows for a clear visualization of how built-up areas intersect with these protected zones, underscoring the need for spatial planning to mitigate unregulated construction in sensitive areas. The map serves as a foundation for understanding the broader spatial dynamics of built-up development on Lemnos.

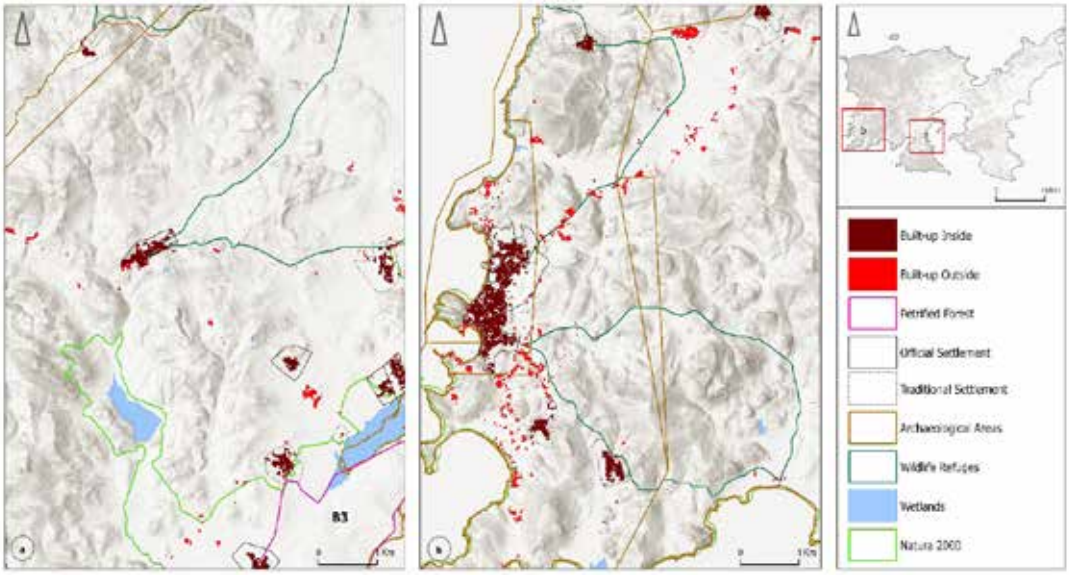

Figure 2: Zoomed-in views of two key areas in Lemnos, highlighting the overlap between built-up areas and protected zones. B1, B2, and B3 represent regions of the Petrified Forest.

Figure 2 zooms in on two critical regions of Lemnos, offering a closer examination of the overlap between built-up areas and zones of natural and cultural importance. The highlighted areas, B1, B2, and B3, represent sections of the Petrified Forest, a unique geological heritage site. The map illustrates the proximity of built-up areas to these sensitive zones, emphasizing the potential risks posed by unregulated construction. The focused view also shows how built-up areas extend beyond settlement boundaries into wildlife refuges, wetlands, and archaeological zones, providing a detailed context for the discussion on sustainable development and spatial planning.

In conclusion, these findings underscore the opportunity to implement a comprehensive and integrated spatial planning framework at the local level, aimed at regulating construction outside settlement boundaries. Such a framework is essential to align development with Lemnos' natural and cultural heritage and geoheritage, prevent the fragmentation of protected zones and balance growth with the preservation of archaeological sites and other critical areas.

Conclusions

This research underscores the critical need for an integrated and cohesive framework for the natural and cultural heritage and geoheritage While legal references and regulations exist, their fragmented nature, coupled with inconsistencies in spatial and temporal application, creates implementation challenges, fosters conflicts and leaves room for unregulated development in sensitive and significant areas (Tzeferis 2018; Tsilimigkas and Derdemezi 2020). A positive step was the inclusion of a section on landscape in the Regional Frameworks on Spatial Planning and Sustainable Development' (RFSPSD) according to European Landscape Convention principles. Although improvements are needed and especially for the island of Lemnos, geoheritage could be included more consistently in landscape zones. The directions of RFSPSD could form the basis to support downstream planning level regulations. The management and promotion of natural and cultural heritage, along with geoheritage, present significant opportunities for strengthening Lemnos' economy. Alternative forms of tourism, such as geotourism, can draw inspiration from neighboring Lesvos, where the Petrified Forest is part of the European Geoparks Network (Zouros 2004). Revised directions in the Special Spatial Framework for Tourism should focus on fostering such sustainable tourism development, emphasizing alternative and eco-friendly tourism models. At the same time, the RFSPSD should be revised to align with the upstream directions and plan a sustainable way of management and development. Finally,a significant challenge remains at the local spatial planning level, which is currently fragmented and incomplete, allowing unregulated built-up area expansion in exurban areas. The upcoming local plans are intented to restrain urban sprawl. . As highlighted in this study, such measures are imperative to prevent the pressures that urban expansion places on natural and cultural heritage and geoheritage.

EXTENDED ABSTRACT 048

Slope failures of friable sandstone in coastal areas. A Case study from Western Greece.

Chatziangelis E.[1*], Boumpoulis V.[1], Depountis N.[1]
*(1) Department of Geology, University of Patras, 26504 Patras, Greece, *up1089644@upatras.gr*

Research Highlights: **Investigation of the failure mechanism of steep sandstone slopes in coastal areas**

Introduction

Coastal slope failures are major geological phenomena that often lead to environmental degradation, land loss and destruction of property and infrastructure. These failures occur predominantly in regions with weak geological formations, steep slopes and dynamic coastal processes. The Kalamaki coastal zone in Western Achaia, Greece, is a representative example, featuring a stratigraphy of friable sandstone formations overlaying clayey marls, which are inherently prone to weathering, erosion, and slope instability. The susceptibility of these geological formations to failure is exacerbated by structural discontinuities in the sandstone layers, allowing water infiltration and subsequent slope destabilization (Zhang *et al.,* 2020).

Since 2014, progressive slope instability in Kalamaki has been observed through satellite imagery (Figure 1), aerial surveys, and field investigations. The main causes of this instability include natural processes such as wave action and erosion, combined with anthropogenic activities such as irrigation and excavation for road and building construction. In addition, water infiltration along vertical cracks in the sandstone, combined with the penetration of vegetation roots, widens these cracks over time, causing translational slides, rockfalls, and earth flows. These processes deposit significant sediment loads along the coastline, altering beach dynamics (Delgado *et al.,* 2018; Poulos *et al.,* 2019).

Figure 1. Satellite image of Kalamaki in Western Achaia, Greece (Google Earth 05/2015) with the white line representing the failure area as determined in 9/5/2022.

Localized high-wave events and marine undercutting further destabilize the base of the coastal slopes, creating overhangs and weakening the upper geological layers. This underscores the necessity for targeted mitigation measures addressing both geological and marine influences. While prior studies suggest relative stability in some parts of the Kalamaki coastline, high-energy events have repeatedly triggered localized failures, highlighting the importance of assessing these vulnerabilities. For a better understanding of the failures on the coastal slopes of Kalamaki, this paper uses the results of the Coastal Vulnerability Index (CVI) estimation for specific areas (Boumpoulis, 2024; Boumpoulis *et al.,* 2025) in combination with the classical slope stability analysis. Using Hoek et al. (1981) two-dimensional slope stability analysis for weak rocks and general CVI considerations (Gornitz, 1991; Depountis *et al.,* 2023), , this study identifies slope destabilization hotspots in a coastal area, identifying the failure mechanism and providing critical information on areas requiring immediate protection.

Methodology and geological regime

The methodological framework for investigating the sandstone slope failures in the Kalamaki coastal area focuses on the identification of the geological characteristics and the mechanisms of driving slope instability. Fieldwork was conducted to document the state of the slope and identify signs of instability. Observations were made regarding the slope and coast morphology, the distribution of discontinuities in the sandstone mass and the vegetation cover. The field surveys conducted, using UAV and GPS equipment, helped in the production of high resolution orthoimages and mapping of the affected area (Figure 2).

Figure 2. Aerial photograph of the sandstone slope failure occurred in Kalamaki, Western Achaia (UAV campaign, 9/5/2022).

The geological framework of the affected area consists of Plio-Pleistocene sediments, mainly friable sandstones overlying clayey marls (Figure 3) – από το διδακτορικό του Βασίλη και τη δημοσίευση του 2025. Both formations are very susceptible to weathering and have the characteristics of soft rocks; hence, low Uniaxial Compressive Strength (UCS). Moreover, the sandstones exhibit high porosity and permeability, making them susceptible to water infiltration, and are intersected by vertical and sub-vertical cracks, which act as pathways for root penetration and water ingress; thus, further weakening the slope's integrity along the coastline.

Figure 3. Geological map of the study area.

The geological and field surveys carried out allowed the precise delineation of the landslide boundary and its characteristics (Figure 4).

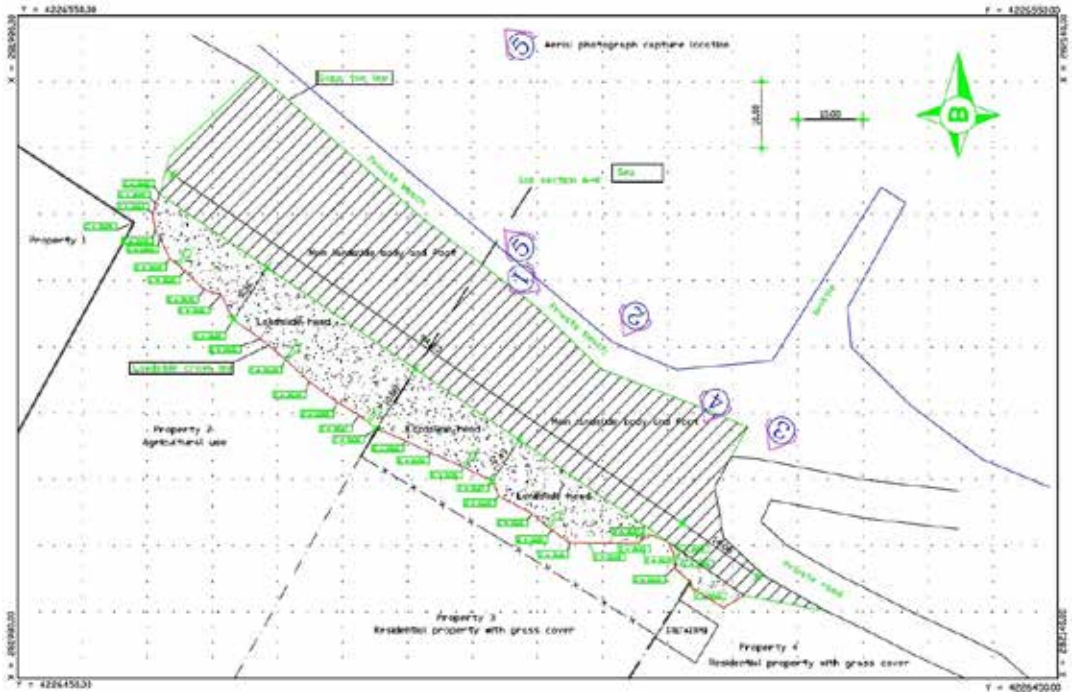

Figure 4. Plan view of the study area with the landslide delineation.

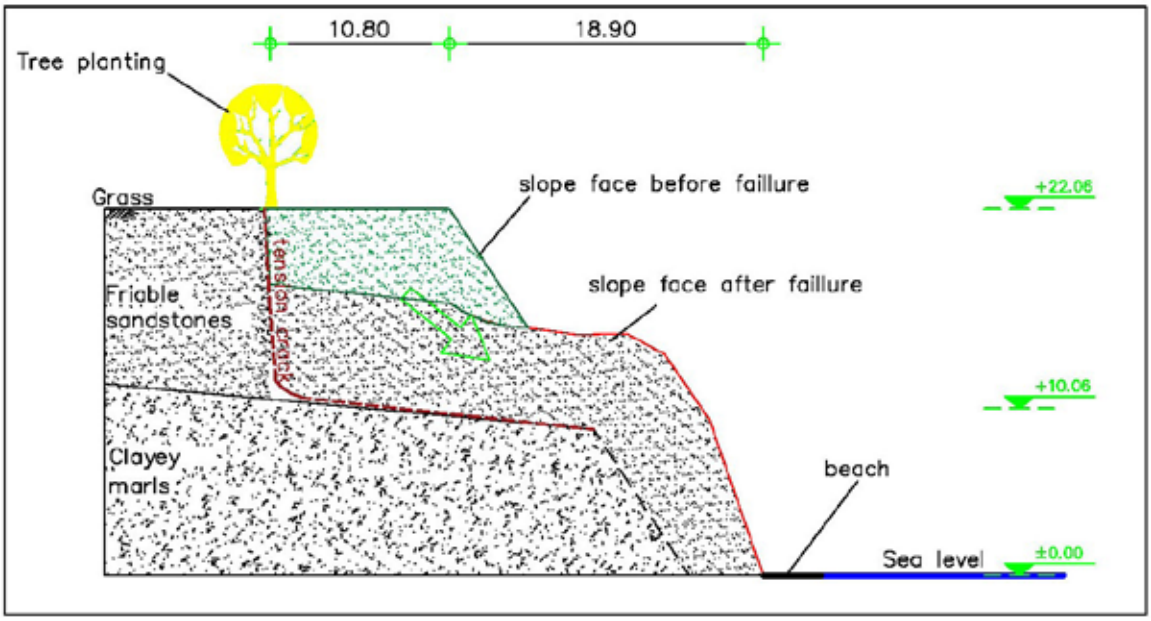
Measurements conducted during field surveys indicated that the landslide's total affected area was approximately 2,750 m², with the crown at an elevation of 18.5–22.5 meters above sea level. The landslide crown extended 120 meters in length, with a scarp of 3 meters and a head of 10.8 meters in width.

Analysis and Results

The failure mechanism was investigated based on the observed field data and geological regime, so a detailed two-dimensional geological cross-section was designed for further analysis (Figure 5).



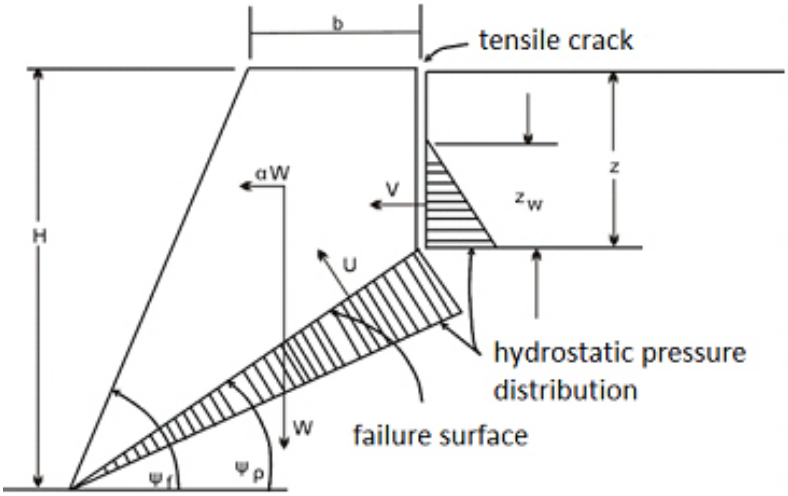


Figure 5. Geological cross-section presenting the landslide characteristics and the failure mechanism

The primary failure mode identified was translational sliding, where sandstone blocks detach along pre-existing discontinuities or tension cracks and slide over the underlying clay marls, even with low stratigraphic gradient between sandstones and clays. These discontinuities acted as tensile cracks, further widened by root penetration and water infiltration and facilitated block detachment and movement downslope. Earlier failure processes were also observed, such as sparse rock falls and earth flow, in places where marine undercutting had reduced the basic support of the slope.
Further destabilization of the slope occurred due to anthropogenic interventions, such as irrigation of vegetation and trees near the slope crest. These activities have contributed to the accumulation of water within the sandstone mass and its discontinuities, exacerbating the instability of the slope.
The failure analysis was based on the principle of a translational slide with tensile crack, as proposed by Hoek et al. (1981), as the most representative for the study area (Figure 6).

F	Factor of safety
H	Height of the sliding slope
W	Weight of the sliding block
U	Uplifting hydrostatic force
V	Hydrostatic tensile crack force
z	Depth of tensile crack
b	Width of the sliding block
z_w	Water level in tensile crack
ψ_p	Inclination angle of failure surface
ψ_f	Inclination angle of sliding slope
α	Seismic ground acceleration
γ	Unit weight of sliding block

Figure 6. Failure analysis of a rock mass in the form of translational slide with tensile crack (Hoek *et al.,* 1981)

The equations used for the calculation of the Factor of safety for this type of slide are (Hoek *et al.,* 1981):

$$F = \frac{cA + [W\ (\cos\psi_p - \alpha \sin\psi_p) - U - V\sin\psi_p]\ \tan\varphi}{W(\sin\psi_p + \alpha\cos\psi_p) + V\cos\psi_p}$$

$$Z = H(1 - \sqrt{\cot\psi_f \tan\psi_p})$$

$$A = (H - Z)cosec(\psi_p)$$

$$W = {}^1/_2\ \gamma\ H^2[(1 - (Z/H)^2)\cot\psi_p - \cot\psi_f]$$

$$U = {}^1/_2\ \gamma_w\ Z_w A$$

$$V = {}^1/_2\ \gamma_w\ Z_w^2$$

The data imported in the above equations are:
H = 12 m, z = 9,5 m, $\psi_\rho = 10^0$, $\psi_f = 80^0$, α = 0.12, γ = 23 kN/m^3, φ = 20^0, c = 10 kPa.
The geometrical data of slope derived by in-situ measurements and the geotechnical data (c and φ) of the sandstone material along the sliding surface considered to be similar to the residual state of a clayey sand with a minimum cohesion. The final calculation of the safety factor of the sandstone slope for three different scenarios is illustrated in Table 1, which shows that the main sliding force is hydrostatic uplift and lateral pressure. When the water level rises

within the discontinuities near the ground surface (0.5 m below the surface), failure occurs. This matches the actual conditions found in the research area and the moisture content of the samples that 1m from the ground surface was in a state of saturation.

Table 1. Factor of safety of the coastal sandstone slopes in the Kalamaki area

Scenario A (dry conditions)		Scenario B (hydrostatic fluctuation)		Scenario C (earthquake)	
Z_w	F	Z_w	F	Z_w	F
0	2.32	3	1.99	0	1.36
		5	1.64		
		7	1.3		
		9	**1**		
		10	0.88		

To exclude the hypothesis that this type of landslide was triggered by coastal erosion, the vulnerability status of the area was also analyzed, along with the calculation of the historical shoreline erosion changes in the coastline. The data was retrieved from two studies carried out in the Gulf of Patras by Boumpoulis (2024) and Boumpoulis *et al.* (2025).

In particular, the results of the Coastal Vulnerability Index (CVI) estimated by the previous studies indicate that the coastal zone of Kalamaki is characterized by very low vulnerability, represented by a green line in Figure 7 (Boumpoulis, 2024; Boumpoulis *et al.*, 2025). The green line in Figure 7 represents a stable coast, with an erosion rate ranging from -0.10 to -0.20 m/year, which suggests a low probability that the landslide event of 2022 was caused by coastal erosion. However, the sandy material of the beach has been created by past landslides, either due to undercutting of part of the slope by wave erosion or similar translational failures.

Figure 7. Coastal Vulnerability Index (CVI) along the Kalamaki coastline as adopted from a previous study conducted by Boumpoulis (2024). The image is a worldview 2018 aerial image and the red line indicates the landslide crown identified in 09/05/2022.

Conclusion/Discussion

This research bridges the perspectives of geology and coastal engineering by investigating the interaction between terrestrial and coastal processes in coastal slope failures. The research focused on finding the failure mechanism of a friable sandstone slope in the coastal area of Kalamaki and revealed that a combination of geological, hydraulic and anthropogenic factors contributed to the slope instability. The friable nature of the sandstone formations, combined with the increased hydrostatic pressure in the discontinuities of the sandstone mass, contributed to the instability of the slope. The vertical discontinuities within the sandstone mass serve as critical pathway for water infiltration, and hydrostatic pressure increases, while marine undercutting weakens the base of the slope; hence creating a complex geological environment for several types of instabilities that have occurred in the past, such as sparse rock falls and earth flows.

A key conclusion of this study is the role of anthropogenic activities in exacerbating slope instability. Practices such as irrigation of vegetation and trees near the top of the slope without any drainage, lead to water accumulation, further destabilizing the slope. These activities, combined with natural processes, highlight the progressive nature of slope failure in the area.

The results of this study underline the importance of an integrated approach to slope stabilization in coastal areas. Mitigation measures should prioritize the reduction of water infiltration in similar geological regimes by implementing appropriate drainage measures and preventing anthropogenic activities such as irrigation and excavation for road and building construction on the crest of coastal sandstone slopes.

Introduction

The conservation and restoration of cultural heritage structures requires a complete and detailed analysis of the geological and geotechnical hazards that affect them. Thus, it is possible to clarify the failure mechanisms that act upon them or might be activated due to technical interventions and to carry out detailed planning of measures to mitigate their effect at a time scale longer than conventional construction works. In the present paper, geological and geotechnical data from site investigation are presented and evaluated relating to the failure mechanisms affecting the foundation of the Holy Monastery of Chilandari mainly the western wing of the Monastery. The Monastery was founded on artificial backfill material followed by weathered soil formations - most probably residual soils of weathered granodiorite – that lay on top of granodiorite and marble rocks. Specifically, the paper presents the results of the geotechnical investigation carried out via sample drilling in situ and laboratory tests and the formulation of the geotechnical model of the foundation area of Monastery. Based on the model, the nature and mechanical behavior of the foundation soil is investigated against mass movements, deformations and settlement. Finally, the main failure mechanism of the subsoil foundation of the Monastery is established and mitigating measures are proposed.

Methodology

For the purposes of this investigation, a methodology of in situ along with laboratory investigation was followed to examine the physical and mechanical properties of the foundation subsoil of the buildings, aiming to assess its origin and mechanical behavior and identify the failure mechanism responsible for the deformations observed in the western wall of the Monastery. The main steps of this methodology are as follows:

1. Determination of the nature and origin of subsoil formations.
2. Evaluation of in-situ test results and design of a conventional Soil Mechanics testing program.
3. Comparison of in-situ test results with the results of laboratory tests. Tests conducted included the determination of physical properties, soil classification tests, and calculations of mechanical properties.

Based on the above, the following steps were taken:

1. Evaluation of shear strength so as to clarify the mechanical behavior of the foundation subsoil and produce design parameters.
2. Bearing capacity and settlement analysis using specialized software, including the calculation of the safety factor against shear failure and the estimation of expected settlements.
3. Interpretation of computational analyses and assessment of the main geotechnical hazards on site.

Geotechnical Model - Calculations

Based on the results of the geotechnical investigation the geotechnical model is derived via the respective steps and calculations:

- Description of the geological-geotechnical formations.
- Compilation of geotechnical sections of the foundation subsoil based on strength and compressibility parameters, the effect of groundwater levels (maximum annual and 50-year period), foundation levels of the main and neighboring constructions, etc.
- Indication of the main/critical conditions to be observed.

- Calculation of bearing capacity (short-term and long-term). Control of settlement due to consolidation and or hydroconsolidation, estimation of differential settlement etc.
- Full dimensioning of all required retaining and soil improvement works with references to the calculation assumptions and the way of analysis.
- Detailed description of the proposal for the type, level and dimensions of the foundation and a description of the sequence of construction works.
- Investigation and description of suitable alternative construction solutions for the foundation and improvement of

the subsoil, among which the best technically and economically optimal solution will be described.

Discussion

The subsoil formations are residual soils of weathered granodiorite, and the failures recorded to the structures of the western part of the compound of the Monastery are due to differential settlements.

- The differential settlements are due to the subsoils' volumetric change behavior under constant loading as well as changes in the moisture content.
- The changes in moisture content are caused by the seasonal fluctuations of the water table that were measured during the dry and wet periods of the year.
- The stratigraphy is dipping to the west which creates a thicker soil cover of the bedrock to that direction, thus producing differential settlement and failures.
- The drying of the foundation soils causes significant settlements because of swelling under wetting and shrinkage under drying. Overall, it is estimated that wetting affects the surficial deposits (S1, S2 and possibly R1) and drying affects the deeper deposits (layers S3 and C1), resulting in a total amount of settlements throughout a wetting-drying circle over a period of one year.
- No data that indicates possible creep - sliding phenomena or any short of horizontal deformations were observed.

Based on the above, it is suggested that remedial measures against the buildings' failures should adopt an approach to limit vertical deformations. Since it is very difficult to fully control the groundwater regime and the seasonal fluctuations, it is suggested that every structure's foundation separately should be connected to the solid bedrock, so that any further volume changes of the overlain soil layer could not affect them. It must be noted that at a certain point of investigation (location of borehole G3) the compressible layer has a small thickness and therefore the total final settlements in time will not be of great magnitude.

Mitigation Measures

Based on the above and to ensure the safety of the significant and historical structures of the Monastery against further settlements it is proposed that mitigation measures should be implemented along with a monitoring program that can assist possible future interventions. Due to the significance of the structure the suggested measures should have minimal disturbance or effect on the character of the construction and that of the broader area of the Monastery. The solution of micro-piles has several advantages relating to the above considerations:

- They are underground and thus hidden interventions that can be constructed on the perimeter and/or sides of the constructions and anchored to the existing foundations where possible, for further support.
- They can be linked with a capping beam to increase bearing capacity and prevent further differential settlements.

The monitoring should include crack gauges for potential deformations and piezometers for groundwater table measurements. These should be intercorrelated so as to verify the failure mechanism by correlating the rate of deformation with the groundwater levels and its seasonal variations.

EXTENDED ABSTRACT 050

Geotopes of Thessaly (central Greece) and their educational approach

Chatzipetros A.[1], Samantzi V.[2]

(1) Department of Structural, Historical and Applied Geology, School of Geology, Aristotle University of Thessaloniki, 54124, Greece, ac@geo.auth.gr (2) Department of Geography, University of Aegean, Mytilene, Greece

Introduction / Background

Geotopes play an important role in deducing the geological history and evolution of an area and can contribute to the understanding of geological processes that take place daily. Geotopes can be used for educational purposes, since they can function as natural laboratories in which citizens can come into contact with Geology and understand how the Earth works, thus contributing to the protection of natural monuments. At the same time, economic benefits can also potentially stem from the promotion of a geotope.

Thessaly is an area located in central Greece and is abundant with important geotopes. Tectonic structures, such as faults and folds, rocks, gorges, quarries, caves, monasteries, traditional settlements and more, are some of the impressive locations of Thessaly. Every year there are thousands of visitors in the broader region of Thessaly, who come to admire the treasures of nature and, at the same time, have the potential to come into contact with Geology and its principles.

For this project, six geosites of Thessaly were selected, which are related to different areas of Geology. Each selected geotope is related to a geological phenomenon, which can be presented and analyzed to secondary school students in the context of the course of “Geology – Geography”.

Objectives

This paper aims to help teachers who intend to organize educational trips to the region of Thessaly and for this reason these characteristic landforms have been selected, which have the potential to impress students and attract their interest.

At the same time, the Worksheets and Evaluation Sheets, which correspond to each geotope, include activities and tasks that can be done independently of the educational trip, but can be part of the teaching of the course of “Geology – Geography” of the first and second grade of High School, in order to understand geological concepts, such as weathering and erosion, deposition, faults and earthquakes, volcanos, fossilization, etc. that are phenomena that take place daily in areas of the planet and affect people’s lives.

It is important to mention that by completing the tasks during teaching of the selected geotopes and activities, students will have practiced writing and speaking, team collaboration, and will have developed their self-confidence.

Methods

Geotopes

Geotopes can be used as a source for collecting information about the geological history and paleoenvironment of an area, aiding science, research and education. At the same time, they are of archaeological, historical and folklore importance, while in many cases they host local ecosystems and contribute to the development of tourism in the area. Greece presents great geodiversity with complex geological structures due to geomorphological processes that have taken place and have shaped the image of the country on the surface and the interior of the Earth, thus creating a large number of geotopes throughout the country.

Geosites can contribute to the education of students through activities that lead to an understanding of Geology. Student visits to geological structures can make geotopes a means of understanding geological processes that have taken place in the past (Theodosiou et al., 2006). Educational (geo)tourism can support geoeducation, as geosites are open to the public and are “living museums”. The combination of a geotope with local history and mythology, with archaeology, religion, folk tradition and geological history, can attract the interest of young and old visitors.

Education

Today, courses of environmental interest are taught in Primary and Secondary Education, which bring students into contact with nature and the problems it faces and will face in the future, with the ultimate goal of raising students’ awareness about the protection of natural and geological heritage (Fermeli, 2023).

For the better consolidation of geological concepts, the teacher, in addition to the theoretical approach of the subject, is required to use other assignments or outdoor exercises, in order for the new knowledge to become the property of

the students. Although Greece has a rich geological and geomorphological heritage, few schools form environmental groups to implement environmental programs during the school year that will help students get in touch with the natural environment and love it. Educational activities in the context of Geoeducation, Environmental Education and Education on Natural Disasters is essential for students. Phenomena, such as earthquakes and volcanoes, can affect people's daily lives and even cause human losses.
The proper teaching of a lesson requires proper planning by the teacher, taking into account the general objectives of the course based on the Curriculum. When teaching a lesson, the teacher uses the Lesson Plan and the Worksheets and Evaluation Sheets, which complete the textbooks, for a better understanding and consolidation of the lesson. Initially, the teacher must start with the preexisting knowledge, then continue with the presentation of the lesson, follow the Worksheets for the application of the new knowledge, continue with the evaluation of the lesson through the Evaluation Sheets and finally, after summing up, connect the lesson with the next (Tzovla, 2021).

Geotopes of Thessaly

Thessaly is located in central Greece. It presents a simple geomorphological picture, with the mountainous parts bordering the lowlands in the central areas. Strong earthquakes have occurred in the region from time to time, causing problems, such as the great earthquakes of 1892, 1901, 1941 and the most recent ones of 2021, while the recent floods of 2023 have still left fresh memories, having created serious problems.
Thessaly is an area that combines geological, historical, archaeological and cultural elements. It has many characteristic geological sites, which attract the interest of visitors and scientists. Some geotopes of Thessaly are world famous.
For this paper, six (6) representative geosites of the geological history of Thessaly were selected, in order to develop the interest of students of the first two grades of High School in Geology in general and its individual fields, such as Structural Geology, Physical Geography, Seismology, Volcanology and Palaeobotany. Eventually, students develop into responsible and aware citizens. Initially, general data are given for each geotope, then the necessary geological knowledge is determined, required for the understanding of each geotope by the students, followed by an indicative Lesson Plan for the organization of the teaching of the geological phenomenon and, finally, the Worksheets and Evaluation with activities and homework for the best possible consolidation of the topic.

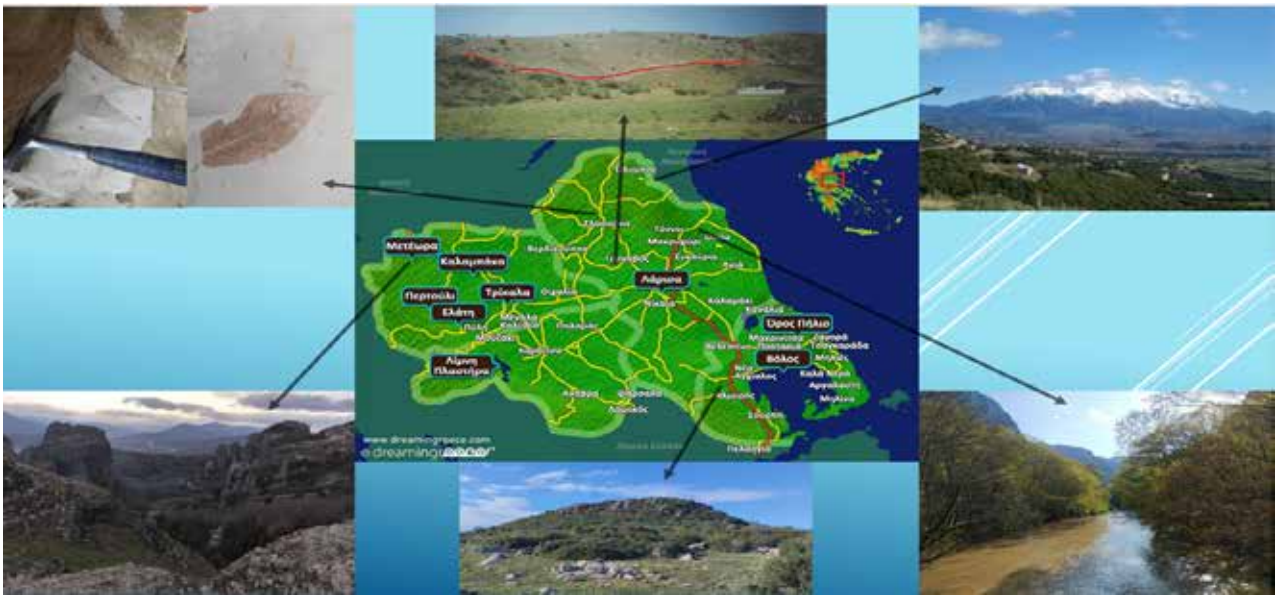

Fig. 1: The six selected geotopes of Thessaly.

The six (6) geotopes are the following (fig. 1, clockwise from top right):

- The **tectonic window of Mount Olympus**, a characteristic geological and tectonic form of Greece,
- The **valley of Tempi**, a characteristic geomorphological form of unique beauty, associated with the mythology of the whole wider area of Olympus and the river Pinios, which flows through it,
- The **volcano of Mikrothives**, as volcanism affected the region of Thessaly in the geological past,
- **Meteora**, a unique global natural monument, with the characteristic huge boulders of conglomerates, which are

a source of awe and admiration,
- The **Neogene basin of Elassona** with numerous flora fossils and
- The **Tyrnavos fault**, which is associated with the seismicity of the wider area, having being the source of a significant number of seismic events in the past.

As part of the work, field work was carried out on Olympus and Ossa mountains, from where one can admire the valley of Tempi, Meteora for the observation of the imposing volumes in western Thessaly, in the area of Tyrnavos – Damasi – Vlachogianni after the earthquakes of March 2021, in the area of Elassona (Sarantaporo, Lykoudi), in order to locate the plant fossils of the Neogene Basin of Elassona, as well as in the interesting, unexploited - but with growth prospects - area of the volcano of Mikrothives.

OLYMPUS

Mount Olympus is an important symbol and monument of Greece, as it is the highest mountain in Greece, known worldwide from Greek mythology, since on its top lived the Twelve "Olympian" Gods, according to the religion of the ancient Greeks. In 1938 it was declared as the first National Park in Greece, for the protection of the area, while later the Ministry of Culture declared Mount Olympus as an archaeological and historical site due to the number of its monuments. It is a compact, relatively small in size, multi-peaked and rocky mountain with an almost circular shape. It hosts about 1,700 plant species, i.e. about 25% of the Greek flora, as well as a multitude of vertebrates.

The "Olympus tectonic window" is of great geological value to scientists and was formed due to the intense pressures and temperatures, but also the intense tectonism, that the region of Greece undergoes. The area is mainly covered by limestone and dolomites of the autochthonous Olympus Unit, but also marble, shale, gneiss and amphibolite of the Pelagonian Zone, intruded by later magnetic products (granitic bodies).

Students of Greek schools come into contact with mythology and the Olympian gods already from the third grade of Primary School. Mount Olympus has a number of characteristic sites that show its geotectonic evolution. However, the concept of "tectonic window" and geological time in Geology is a difficult concept, even for students of Geological Departments. High School students, within the framework of the course of "Geology – Geography", taught in the first and second grades, can come into contact with simpler concepts of Structural Geology, such as faults and folds, which can be found in nature and make a reference to the tectonic window.

For the educational approach of the Geotope of Mount Olympus, the necessary knowledge is provided, which students should know and is mainly related to faults. Geological concepts related to tectonics, endogenous and exogenous factors that shape the relief of the Earth, lithospheric plates, earthquakes and seismicity, are interesting subjects for the students. The teacher can follow the respective lesson plan, which will be called *"Faulting in Greece"*, will be addressed to students of the first grade and will use Worksheets and Evaluation Sheets on faults.

TEMPI VALLEY

The well-known valley of Tempi is in the eastern part of Thessaly plain and located between the mountains of Olympus to the north and Ossa or Kissavos to the south. Along the valley, which has a NE-SW direction, Pinios River flows, which drains the waters of Thessaly into the Aegean Sea with intense meanderings through the plain and flows into the Aegean Sea forming its Delta near Stomio, creating a rich ecosystem. The valley of Tempi consists of mainly limestone, dolomites and marbles, while caves have been created in places, some of which have impressive decoration with stalactites.

The valley of Tempi is inextricably linked to Mount Olympus and mythology. Today the geotope of the Tempi Valley continues to attract visitors, but fewer than in the past, since it is easily accessible to everyone. The picturesque church of Agia Paraskevi, a landmark of the area, continues to attract visitors, who can come into contact with history, mythology, culture, religion and nature. The combination of the above with certain concepts of Geology can attract the interest of students during a visit to the area.

The educational approach of the Tempi Valley Geotope requires knowledge related to concepts of Physical Geography and Geomorphology. The Lesson Plan is related to concepts such as erosion, transport, deposition, weathering, drainage systems, estuary and river delta, but also floods, which in recent years have caused great disasters and human losses in the area. The relevant Lesson Plan with the corresponding Worksheets and Evaluation Sheets can be called *"How water affects the terrain of the Earth"* and addresses students of the second grade of High School.

THE MIKROTHIVES VOLCANO

In the prefecture of Magnesia near Nea Anchialos and Mikrothives is the hill "Kastro", visible and easily accessible from the Volos – Athens National Road, covered by volcanic rocks of the Pleistocene from the volcanic action of the now inactive Mikrothives volcano. The area is of great geological and historical interest, as the lavas of the volcano

cover a large area, while excavations have brought to light parts of an ancient theater, where the sites are made of volcanic rocks, as well as parts of ancient walls of the "Fthiotides Thebes" of the Hellenistic period (Clapsopoulos, 1991, Vavaliou, 2014, Samantzi, 2024).
It is a small low volcano of typical Maar form, where the volcanic cone is absent (Bournovas, 1999). To the SE there is a dome up to 50 meters thick, which is the main crater, from where lava is believed to have flowed and is called "Magoula". Fragments of volcanic rocks are scattered throughout the area of the "Castle" (basalt, andesite) (Clapsopoulos, 1991). The ancient basalt quarries of Phthiotides Thebes operated in the past in the area, probably during the Hellenistic and Roman times, as there are several sites where it seems that healthy rock has been processed and removed. The original rock was solid and hard and could be processed by workers and, in addition, very close was the Pagasetic Gulf and the ancient port of Pyrasos for the transportation of boulders (Vavaliou, 2014). During field work in the area, large basaltic blocks were observed with obvious marks from the tools used by the workers to carve and cut them off the natural rock, which have been altered mainly by wind erosion. The hill "Kastro" perfectly combines Geology with History and Culture, since the ancient inhabitants of the area utilized the "materials" offered by nature for the economic development of the area and come from the volcano.
The educational approach of the Geotope of the volcano of Mikrothebes requires students to possess knowledge of Volcanology, related to the interior of the Earth, lithospheric plates, volcanoes, as well as the volcanism of Greece. The Lesson Plan can be entitled: *"Volcanic activity in Europe and Greece"* and addressed to students of the second grade of High School with the corresponding Worksheets and Evaluation.

METEORA

Meteora is one of the most important geotopes in Greece, being a UNESCO World Heritage Site. It is a geological monument of exceptional value in terms of aesthetics and science, which is the object of study, promotion and protection. More than 50 vertical, steep and cut off dark rocks are located north of the city of Kalambaka and west of the village of Kastraki in the prefecture of Trikala, at the exact point where Pinios enters the plain of Thessaly. At the top of the rocks are the famous Monasteries of Meteora, which attract thousands of visitors every year. Nimas (1987) likens the area of Meteora to a unique in the world *"stone forest",* which during the post-Byzantine era was transformed into *"Lithopolis",* as hundreds of monks settled in the area.
The conglomerates of Meteora (Miocene) are marine sediments of great thickness, in which many marine fossils have been found. Rounded pebbles are of varying consistency, size and origin. The matrix is a fine-grained clay material rich in carbonates. Holes of various sizes are observed in places, created due to the corrosive action of water and wind and in some cases have formed caves (Rassios et al., 2020).
The flora and fauna in the area of Meteora are important. In addition, the Museum of Geological Formations of Meteora operates in Kastraki since 2018, which contributes to Environmental Education. Since 2024, the Meteora-Pyli Geopark has joined the UNESCO Global Geoparks network, where visitors can take part in various activities that will bring them into contact with the natural environment of the area.
For the educational approach of the Geotope of Meteora, concepts of Sedimentology, Physical Geography and Geomorphology are required. Concepts such as Sedimentary Rocks and Sedimentation, exogenous factors that affect the Earth's relief, such as weathering and erosion, lithification and diagenesis, can help students understand how to create forms, like Meteora. The relevant Lesson Plan can be called *"How weathering and erosion affect the relief of the Earth"* and addressed to students of the first grade of High School, while the Worksheets and Evaluation are about weathering and erosion.

NEOGENE BASIN OF ELASSONA

The basin of Elassona hosts a particularly rare and rich fossilized flora assemblage. This is a rare subtropical flora, having forest plants and swamp plants. The Neogene basin of Elassona is the southern part of a NW-SE trending elongated graben consisting also of the Florina, Ptolemaida – Amyntaio and Kozani – Servia ones. Neogene deposits in the region include Miocene, Pliocene and Quaternary sediments. Fossils of leaves, fruits, pollen and seeds have been found in the area and it is one of the most remarkable sites in Europe. However, the area has not yet been exploited (Samantzi, 2024).
'Sequoia', 'Cryptomeria', 'Cathaya', 'Egeria' fossils have been found (Velitzelos and Gregor, 1990; Velitzelos et al., 2014; Bouchal et al., 2020). In the basin of Elassona, plant fossils are enclosed in diatomites of white to yellowish – whitish color and occur in various places, such as Lykoudi, Drymos and Sarantaporos. Diatomite resembles chalk and forms an extremely fine-grained, soft and usually light-colored and friable sedimentary rock, which consists of fossilized diatomaceous remains (Aivaliotis, 2011, Stefanou, 2016). In the basin of Elassona, clay diatomites were deposited in a lagoon environment and their plant fossils correspond to a humid and warm climate in a clean water

lake environment, displaying a brownish yellow to brown color on the surface, while in depth they have a gray color (Stamatakis and Koukouzas, 2001).
For the educational approach of the Geotope of the Neogene Basin of Elassona, students must possess certain knowledge related to Palaeobotany, such as plant fossils, ways of fossilization, petrified forests in Greece. The Lesson Plan can be called *"Plant fossils in Greece"* and addressed to students of the first grade of High School, while the Worksheets and Evaluation Sheets will be related to fossilization and plant fossils.

TYRNAVOS FAULT

The region of Northern Thessaly is of particular interest to scientists, as it consists of several active normal fault zones. In 2021 two large earthquakes of magnitude 6.3 and 5.9 respectively took place in the region between the cities of Tyrnavos and Elassona and were felt in most of mainland Greece, causing significant damage in the epicentral area. Tyrnavos fault, although not directly related to the earthquakes of 2021, is an active normal ENE striking fault, activated during the Middle Pleistocene (Caputo et al., 1993, Kotsis, 1995, Caputo et al., 2004). The trace of the fault is clearly visible and has been mapped for more than 12 km (Koukouvelas et al., 2021), while it is characterized by seismicity of low to moderate magnitude. The maximum expected earthquake is of the order of 6.5R, while it is thought that the fault caused an earthquake of magnitude 6.0 in 1731 (Belesis, 2012).
The School of Geology, Aristotle University of Thessaloniki, the University of Ferrara and the Municipality of Tyrnavos collaborated for the construction of the Palaeoseismological Museum of Tyrnavos, a model research and educational center of Geology and Seismology at the 7th km of Tyrnavos – Damasi road within the valley of the Titarisios River in the middle of the Tyrnavos fault. Paleoseismic trenches in the site show successive reactivations of the fault, aswhile research instruments (seismograph and GNSS) have also been installed (Belesis, 2012). It is the only open museum park in Europe for the geology of earthquakes. Unfortunately, it is still not open to visitors, while today it shows signs of abandonment.
Tyrnavos fault is an important geotope for the region of Thessaly, but also for the whole country due to its seismic potential. The preparation of citizens of all ages is necessary so that their reaction before, during and after the earthquake is optimum and human losses are avoided. Secondary school students can visit the geotope of the Tyrnavos fault, as it is easily accessible, and be informed about the earthquakes of the past.
For the educational approach of the Tyrnavos Fault Geotope, students are required to know about seismology, earthquakes and their characteristics, seismic waves, seismographs, as well as about the surface manifestations of an earthquake (ground ruptures, rockfalls, landslides, subsidence, soil liquefaction). The lesson plan may be entitled: *"The earthquake in everyday life"* and addressed to students of the first grade of High School, while the Worksheets and Evaluation refer to earthquakes.

Results and Conclusions

Several, if not all, geosites can be classified as educational and, in the context of field trips, used by teachers to transfer geological concepts to students. The subject of "Geology – Geography", taught in the first and the second grades of the Greek High Schools, is linked to the natural environment, natural disasters and landforms and can instill a sense of responsibility in students towards the geoenvironment. Students can understand the value of geotopes, get in touch with the place where they live and how they were created.
In addition, the teaching of the subject of "Geology – Geography" needs to change to attract the interest of students. The school must be in accordance with the needs of the time and the students to become efficient and able to prepare them for the new challenges of the future. At the same time, teachers should teach their students topics that interest them and will activate them for the protection of natural and geological heritage, instead of providing them with sterile knowledge. For the above reasons, proper preparation and organization of the lesson by the teacher is required (Iliopoulou, 2006).
In conclusion, it should be mentioned that of the geotopes chosen, Mount Olympus and Meteora are places world famous with thousands of visitors every year. The other four geotopes (Valley of Tempi, Tyrnavos fault, Neogene basin of Elassona, Volcano of Mikrothives) are places that need support, empowerment and promotion in order to attract visitors of all ages while developing Geotourism and economic benefits.

Acknowledgements

This paper is part of the second author's MSc Thesis at the University of the Aegean, completed under the Inter – Institutional "Natural Hazards and Disaster Mitigation" Master Course programme. The authors would like to thank Professor Emeritus Spyros Pavlides, Dr. Charalambos Fassoulas and Professor Nickolas Zouros for their contribution towards the completion of the Postgraduate Program and the MSc Thesis.

Research Highlights

Assessment of beach flood risk using open source geospatial data and models.

Introduction

Coastal floods from extreme marine events have had increasing impacts on the coastal natural and human ecosystems, causing coastline changes, biodiversity losses, human mortality, increased health risks and poverty and induced coastal infrastructure/asset damages (IPCC, 2023). Under climate change, the frequency of extreme events is projected to increase and expose annually a large part of the global coastline to the current 1 in 100 years Extreme Sea Level by 2100 (Vousdoukas *et al*., 2018). 'Sandy' shorelines (i.e., the low-lying coasts built on sediments—beaches), which comprise a large segment of the global coastline (Luijendijk *et al*., 2021) will be particularly vulnerable. In addition to their own importance as ecosystems, beaches form natural buffers that protect backshore ecosystems, infrastructure, and assets from coastal flooding (Toimil *et al*., 2023); they also have high hedonic/recreational value, contributing very significantly to the tourism sector due to the current dominance of the 'Sun, Sea, and Sand—3S' model (UNWTO, 2024). Beaches in touristic islands face increased vulnerability to coastal flooding, due to their generally limited width, scarce sediment supply and the high potential exposure to coastal flooding of their backshore infrastructure and services (Brett, 2021). However, the flood assessment of beaches, presents certain challenges due to the need for accurate geospatial information, as well as the accuracy/costs of the used models (Almar *et al*., 2021).

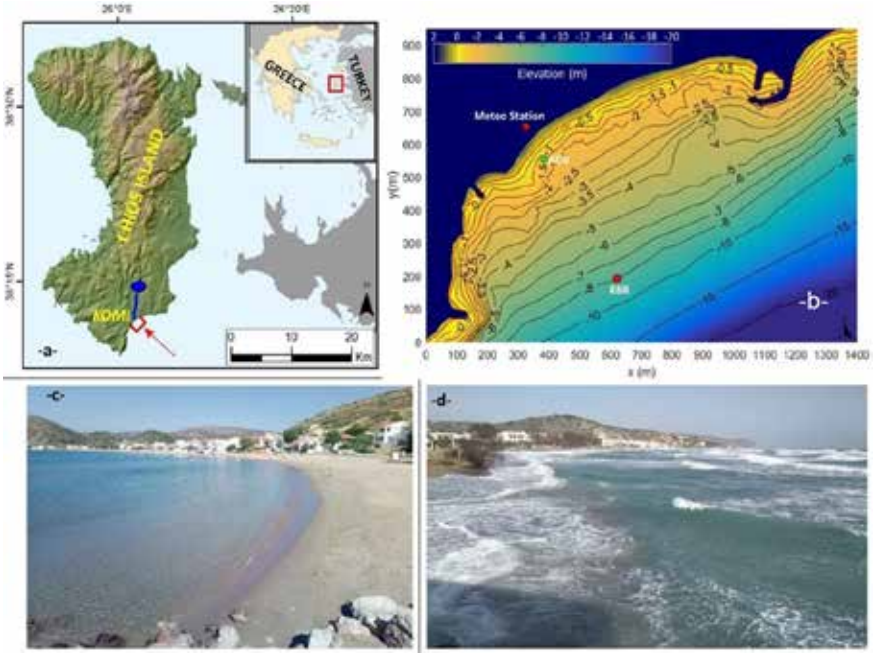

Figure 1. (a) Chios island and Komi beach, showing Katraris river and dam (blue line and circle). (b) Beach nearshore topography/bathymetry. Photos of Komi beach, (c) from the ENE under calm conditions and (d) from WSW during a storm.

Therefore, the objective of this short contribution has been to assess the flood risk of an island beach (Komi, Chios; Fig. 1), using readily available geo-spatial information and an open - source numerical model. Komi is a 1.2 km long barrier beach with a maximum dry width of 38 m. Its backshore hosts a coastal road and many residential and touristic assets, sometimes at a distance of <10 m from the coastline. The beach is characterized by low slopes with elevations that in many areas do not exceed 1.5 m (slopes of approximately 3%). In addition, the backshore elevations are in many areas <1 m. A stream is present at the western segment of the beach, whereas at its eastern end there is a small fishing port. The stream is the outlet of the Katraris river, the land sediment supply of which has been diminished due to the construction of the Kalamoti-Katraris Dam (Andreadis *et al*., 2021).

Methods

In addition to the simple static inundation 'bathtub' model, a simplified two-dimensional finite difference hydrodynamic model LISFLOOD-FP (Bates and de Roo, 2000) was also used. This simulates flood dynamics in a pre-designed grid using a Digital Elevation Model (DEM). Specifically, LISFLOOD-FP applies fluid continuity to calculate the depth at each grid cell while the water flow is channeled along the ground using a simple storage algorithm based on the difference in hydraulic head between adjacent cells (Bates *et al*, 2005). In each cell, the calculated height of the water surface above the topographic elevation as well as the Manning soil friction coefficient are used to calculate the flow rate. The water flow is described by the momentum conservation and mass continuity equations:

$$h_{(i,j)}^{(t+\Delta t)} = h_{(i,j)}^{t} + \frac{\Delta t * Q_{(xi,j-1)}^{t} - Q_{(xi,j-1)}^{t} - Q_{(yi,j-1)}^{t} - Q_{(yi,j)}^{t}}{\Delta x^2} \quad [1]$$

$$Q^{t} = \frac{q_t - \frac{g h_{flow}^{t} * \Delta t * \Delta (h^{t} + z)}{\Delta x}}{1 + g h_{flow}^{t} * \Delta t n^2 * |q^{(t-\Delta t)}| \left(h_{flow}^{t}\right)^{(10/3)}} \Delta x \quad [2]$$

where, (Q^t) is the flow at time (t) between cells, calculated using a centered difference scheme resolved in the (x) or (y) direction; (h_{ij}) is the water depth at the center of cell (i, j); (h_{flow}) is the depth between cells where flow is possible; (z) is the topographic height in the cell; (n) is the ground friction coefficient; (g) is the acceleration of gravity; (q) is the flow from the previous time step; and (Δt, Δx) is the width of the cell.

The flood flows are discretized into a grid of square cells, thus allowing the model to represent two-dimensional flows on the ground surface. LISFLOOD-FP results (ascii files) can be easily imported into a GIS environment for further analysis. The model had been originally designed to simulate river floods, but, in recent years, has been also successfully used to simulate coastal floods (e.g., Monioudi *et al*., 2018; Le Gal *et al*., 2023).

The DEM of Komi beach used the 'Digital Terrain Model of the LSO25 project' (LSO - Large Scale Orthophotos) of the Hellenic Cadastre, which was constructed using high-resolution aerial photographs (2014-2016). The Cadastre DEM has a resolution of 2 m, which allows capture of both the slopes of the coastal topography and adjacent coastal works with much greater accuracy than the EU-DEM (resolution of 25 m, spacedata.copernicus.eu/documents/20123/121239/GEO1988-CopernicusDEM-RP-001Validation_Report_I3.0.pdf). Application of the model at a local level allows the use of this specific spatial resolution with a very reasonable computational cost. The DEM were processed in QGIS software. The Manning friction coefficient was calculated on the basis of the land uses recorded in the Coastal Zone Land Use/Land Cover (LU/LC) geospatial file of the European Copernicus service (https://land.copernicus.eu/en/products/coastal-zones). Manual corrections were applied, which mainly concerned the more accurate design of the beach boundaries (and coastal works and port facilities). As an additional check, the corrections were also taken into account in the DEM of the area to ensure that there were no significant discrepancies between the land uses and the topography, e.g. the polygon corresponding to the sea was checked to overlap pixels with zero elevation. Then, a value for the Manning coefficient was entered for each land use, using the calculations of Papaioannou *et al*. (2018).

The model was driven by the projected Extreme Sea Levels (ESLs) for Chios under the RCP8.5 climatic scenario for 2050 and 2100 extracted from the EU-JRC (Joint Research Centre) database https://webcritech.jrc.ec.europa.eu/SeaLevelsDb detailed in Vousdoukas *et al*. (2018). ESLs were projected using the numerical hydrodynamic model Delft3D-Flow driven by the wind and atmospheric pressure fields corresponding to the climate conditions

of the RCP4.5 and RCP8.5 scenarios calculated by an ensemble of 8 climate models; model performance was assessed for the period 1980 – 2014 (baseline) driven by wind/atmospheric pressure fields extracted from the ERA – Interim database. The ESLs form the sum of the future long-term relative mean sea level rise (RSLR), the astronomical tide (n_t) and the episodic sea level rise (n_{ce}) due to meteorological tides (storm surge) and the storm wave set-up; the latter, which can be quite significant during an energetic event, is set using a generic approximation of 0.2 Hs, i.e., of the offshore significant wave height projected for the same scenarios.

Results

The ESLSs with return period of 100 years (ESL_{100}) projected for the area were 1.12 m and 1.77 m for 2050 and 2100, respectively. The bathtub model results showed inundation of 70,850 and 128,300 m^2 for 2050 and 2100, respectively, with maximum flood extent more than 220 m and 260 m.

The projections show that a large part of the area will be flooded (Fig. 2), with maximum flood extents of 118 m and 190 m for 2050 and 2100 respectively, The beach itself is projected to be completely inundated, presenting a flood risk to all assets at its immediate backshore. Already from 2050 the flood appears to significantly penetrate inshore at the western beach, affecting assets along and to the west of the stream. By 2100, the flood is projected to reach >100 m to the east and west of the stream affecting considerable infrastructure/assets, while the small fishing port will be completely flooded. Overall, it is clear that due to the low relief and many backshore infrastructures/assets there is a high food risk that can cause serious damages/losses, especially if combined floods (i.e., from land and the sea) are considered, which is a likely occurrence during extreme storms.

Figure 2. Flood extent at Komi beach in 2050 (left) and 2100 (right) under theRCP8.5 scenario. The different colors correspond to the estimated beach width that will be flooded.

Discussion and Conclusions

The results show considerable inundation for Komi beach which is projected to be worse by the 'bathtub' approach. However, the static method is considered to overpredict the flood extent, mainly because it ignores bed friction effects on the flood flow as well as its flood inundation predictions for cells are not hydraulically connected with the rest of the flooded area. Similar discrepancies between the two approaches have been found also in other island beaches (Chatzistratis *et al*., 2024). In general, flood simulations with numerical models appear more appropriate for local scales while on regional assessment the bathtub approach may be used as fine grids for numerical modelling increase substantially the computation cost (Seenath *et al*., 2016). Moreover, LISFLOOD-FP provides outputs of flood characteristics at user defined timesteps, providing significant information for flood risk preparedness.

It should be noted that the coastal flood risk in Komi is likely to be exacerbated by the beach erosion/retreat due to the relative sea level rise (RSLR). Andreadis *et al*. (2021) have estimated that Komi beach retreat due to the RSLR will be 3-9 m and 6-9 m by 2050 and 2100, respectively, even under the moderate RCP4.5 climatic scenario. It is noted that these beach erosion/retreat projections are even more conservative, as they

do not take into account the (cumulative) effects of storm events (which, both observations and modeling suggest, could be significant at Komi beach), or the effects of the diminished land-sourced sediment supply due to the construction of the Kalamoti-Katraris Dam. Therefore, in order to assess the flood risk more accurately, coupled beach erosion/flood models will be required. Although such models present large challenges, particularly due to uncertainties at the land/sea boundary condition, future efforts should be focused on it as a response to the major flood disaster risks under climate change.

(3) Independent Geotechnical Engineering Consultant, Greece

Introduction / Background

Rockfall and landslide hazards pose significant challenges for mountainous road networks in Central Greece, particularly in the region of Evritania, which is recognized as one of the most susceptible areas to landslides in Greece (Marinos et al., 2015). In cooperation with the Region of Central Greece, the NTUA Engineering Geology & Geohazards Research Group initiated a targeted research program focusing on several key sites in the region. These areas were selected due to their geological complexity, different mechanisms of failure, challenging terrain, and history of documented landslides. Detailed investigations have been conducted to assess slope stability and analyze the mechanisms contributing to slope instability.

Building on these investigations, this study highlights advancements achieved through the research program over the past three years, focusing on the application of innovative technologies and the development of methodologies for geotechnical analysis and hazard monitoring. By leveraging advanced 3D reality capture technologies, the research integrated high-resolution aerial and terrestrial data to produce precise digital replicas of the investigated areas. These replicas enabled the extraction of critical engineering geological information and supported the development of advanced digital tools for terrain analysis and hazard assessment.

Furthermore, the digital replicas formed the foundation of a comprehensive monitoring program designed and implemented by the research team. When combined with ground-based instrument monitoring (e.g., inclinometers), this program provided a continuous stream of data, enabling regular updates to datasets and significantly improving the accuracy and reliability of detailed 2D geotechnical simulations. These analyses, along with 3D numerical simulations, offered valuable insights into slope behavior, advancing landslide hazard assessment and informing the development of site-specific mitigation measures.

Finally, the study evaluates key limitations encountered during data acquisition, processing, and analysis. These insights are examined in the context of each site, demonstrating how challenges were addressed or remain to be resolved to further enhance hazard assessment and optimize mitigation strategies.

Methodology

The methodological framework for this study builds on the integration of advanced digital tools with systematic monitoring programs, aiming to continuously refine geotechnical analyses and optimize solutions to address landslide and rockfall hazards in mountainous terrains. The workflow, illustrated in **Figure 1** begins with detailed engineering geological investigations, including field and laboratory assessments. These investigations enabled the classification of engineering geological units (EGUs) and the development of preliminary hazard maps, geotechnical models and stability analyses that delineated zones of instability and proposed conceptual mitigation designs.

To enhance the accuracy of the preliminary analyses, high-resolution topographic and geospatial data were acquired through UAV-based photogrammetry (Westoby et al., 2012) and terrestrial laser scanning (TLS). UAV surveys using DJI Phantom 4 Pro RTK and Mavic 3 Enterprise drones generated point clouds, digital surface models (DSMs), and orthomosaics with sub-centimeter accuracy, while TLS LiDAR scanning with the Leica ScanStation P40 provided millimeter-level precision for capturing detailed discontinuity characteristics, such as orientation, spacing, and persistence. These datasets facilitated advanced discontinuity mapping using techniques like Principal Component Analysis (PCA) and DBSCAN clustering (Riquelme et al., 2015; Farmakis et al., 2020), as well as the creation of Slope Relief Models (Chatzitheodosiou et al., 2024) to identify overhangs and undercuts. Semantic segmentation tools further refined the analysis by distinguishing vegetation, bedrock, and infrastructure, optimizing the detection of unstable zones and supporting rockfall trajectory analyses (Chatzitheodosiou et al., 2023).

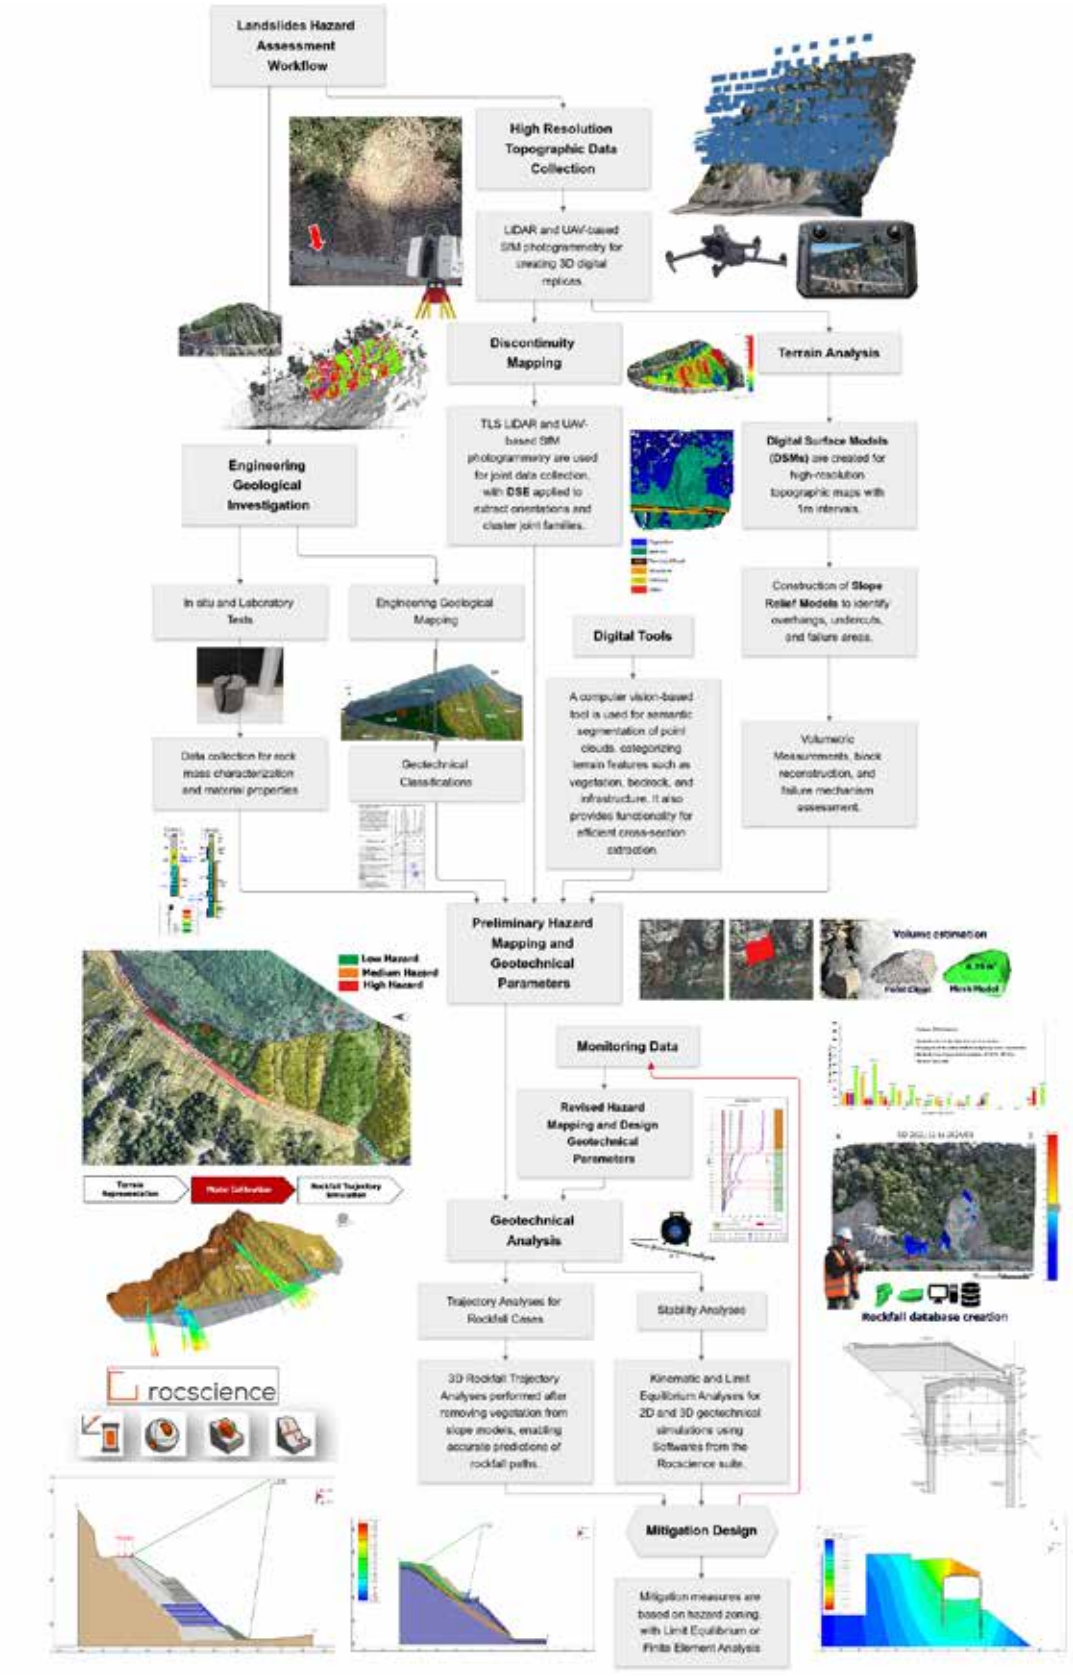

Figure 1. Integrated workflow for Landslide Hazard Assessment.

Monitoring, as illustrated in **Figure 2,** formed a crucial part of the methodology, implemented through a hybrid approach combining UAV surveys (Chatzitheodosiou, 2023) and ground-based instruments. Sequential UAV campaigns produced multi-temporal datasets that were analyzed using the Multiscale Model-to-Model Cloud Comparison (M3C2) algorithm (Lague et al., 2013) to detect and quantify surface deformations and rockfall volumes. Spatial changes were clustered using the Density-Based Spatial Clustering of Applications with Noise (DBSCAN) algorithm (Ester et al., 1996), enabling the identification of discrete events. To enhance volume reconstructions of rockfall events, 3D mesh models were generated using the Iterative Alpha Shape algorithms (Edelsbrunner and Mücke, 1994). Additionally, the VoxFall non-parametric volumetric change detection method (Farmakis et al., 2024) provided an unbiased approach for volumetric rockfall measurements directly between mesh models, cataloging key metrics such as size and location with high accuracy.
Ground-based instruments, such as inclinometers, offered complementary data on subsurface movements, particularly in rotational landslides, where a comparative analysis revealed the attenuation of subsurface displacements near the surface due to material properties and failure plane stratification. The integration of these datasets refined kinematic models and enhanced hazard assessments. Over a three-year period, this dynamic monitoring workflow informed iterative updates to hazard maps and geotechnical models, incorporating stability analyses with kinematic, limit equilibrium, and numerical methods from the Rocscience suite. These analyses, combined with real-time data on rockfall trajectories, guided the design of effective, targeted mitigation measures tailored to the evolving conditions of the study areas.

Results and Conclusions

High-resolution datasets generated through UAV-based photogrammetry and TLS LiDAR enabled the precise identification of critical geohazards, including overhanging rock masses, undercuts, and structurally controlled failure zones in the mountainous terrains of Central Greece. These results underscore the value of combining advanced digital tools with traditional geotechnical methods, providing a robust foundation for hazard mapping, geotechnical modeling, and the classification of engineering geological units (EGUs) with millimeter-level precision. The multitemporal monitoring program provided valuable insights into the dynamic behavior of slopes. The M3C2 change detection algorithm successfully quantified surface deformations and detected rockfall volumes over time. The use of VoxFall for volumetric change detection ensured accurate modeling of these events, minimizing user bias and enhancing the overall reliability of the analysis. The database enabled the team to characterize the frequency, magnitude, and spatial distribution of rockfall events, offering a detailed understanding of hazard zones. For rotational landslides, the comparison between inclinometric data and UAV-based change detection revealed how movement attenuates as it approaches the surface. This attenuation pattern was linked to the geotechnical properties of the subsurface materials and provided critical data for refining stability models and estimating the depth of the failure plane.
Geotechnical analyses, informed by these datasets, identified the predominant failure mechanisms in the study areas. For instance, in structurally controlled limestone slopes, wedge sliding and toppling failures emerged as the dominant modes of instability. Physically based trajectory modeling, calibrated with real-time data, accurately predicted the impact zones of these rockfalls, thereby supporting the design of targeted mitigation measures. Similarly, rotational landslides in weak flysch formations were classified using a modified Geological Strength Index (GSI) tailored for heterogeneous rock masses like flysch (Marinos, 2019) and analyzed in detail, with stability simulations indicating the zones most susceptible to failure and highlighting the effectiveness of potential stabilization interventions. To address the specific challenges at each site, various mitigation measures were proposed to enhance slope stability and safeguard infrastructure. These measures included the installation of rockfall nets and anchored rock bolts to stabilize critical rock masses. Where space constraints limited conventional approaches, reinforced embankments or lane covers were recommended. In areas requiring additional structural support, deep reinforced piles were proposed to provide both lateral and vertical stability by anchoring into stable substrata. Hazard zoning, informed by refined analyses, facilitated proactive planning, while real-time monitoring ensured timely evaluations of the effectiveness of each intervention and allowed for iterative improvements.
Finally, the study addressed several challenges encountered during data collection and processing, such as suboptimal lighting conditions, vegetation interference, and noise in point cloud data. These obstacles were mitigated through adaptive methodologies, including optimized flight paths, advanced clustering algorithms, and rigorous manual validation procedures. Overall, the integration of digital tools with traditional engineering geological and geotechnical approaches has produced significant advances in landslide and rockfall hazard assessment, emphasizing the importance of continuous monitoring, dynamic hazard mapping, and data-driven design proposals for managing geohazards in complex mountainous regions.

Acknowledgements
The authors sincerely thank the Region of Central Greece and the Regional Unit of Evritania for their invaluable support in this research. Their collaboration with the National Technical University of Athens highlights the important role local governments play in advancing scientific efforts to improve infrastructure safety and address geohazards. We are especially grateful for their assistance in facilitating access to key sites, providing logistical support, and contributing to the successful completion of this research.

EXTENDED ABSTRACT 053

Mapping and Categorization of damage on the built and natural environment caused by the 2023 Daniel and Elias storms in MountPelion, Greece

Eleftheria Christodoulopoulou[1], Olga-Joan Ktenidou[2], Grigorios Tsinidis[3]
1 University of the Aegean, Mytilene, Greece, christodoulopoulouleftheria@gmail.com
2 Institute of Geodynamics, National Observatory of Athens, Athens, Greece
3 University of Thessaly, Volos, Greece

Introduction and motivation

Storms Daniel and Elias occurred in September 2023 with only a 20-day gap between them and left a severe impact on the affected areas, since their aftermath is still clearly visible to date, 16 months later. The meteorological station in Zagora at Mount Pelion recorded the highest daily rainfall value in the country (around 760 mm) during Daniel storm, breaking the previous record of Paliki, Kefalonia (645 mm) recorded during the mediterranean cyclone Ianos in 2020 (Ντάφης κ.ά., 2023; Βουγιούκας κ.ά., 2023). Figure 1 shows the total amount of rainfall (in mm) for September over a period of ten years, as recorded by three different meteorological stations in the vicinity, namely Volos, Zagora and Makrinitsa (see Figure 4 for station locations). Studies exist already analysing the effects of these storms on various aspects of the community and ecosystem; e.g., Dimoudi *et al*. (2024) performed analyses to examine the effect on water quality, He *et al*. (2024) used SAR technologies to map effects on crops and livestock, while Mavroulis *et al*. (2024) highlighted all the risk factors that favor the occurrence of infectious diseases. Here, we consider effects on the built environment and infrastructures through in-situ visits.

In this study we focus on the types of damage that these storms caused in the Pelion region. Through photographic documentation the damage was categorized into six key categories referring to: loss of life, damage to the road network, damage to bridges and other structural elements, soil erosion, debris accumulation, and property loss. These findings provide valuable insights into the diverse and severe impacts of storms and their effects on communities and the environment. We aim to showcase the extent of this destruction caused to the villages and communities of Pelion and provide a comparison between Pelion's three municipalities and the types of damage each one suffered. We also point to the degree to which reparation actions have progressed at the time of writing this abstract, which is 16 months after the incident.

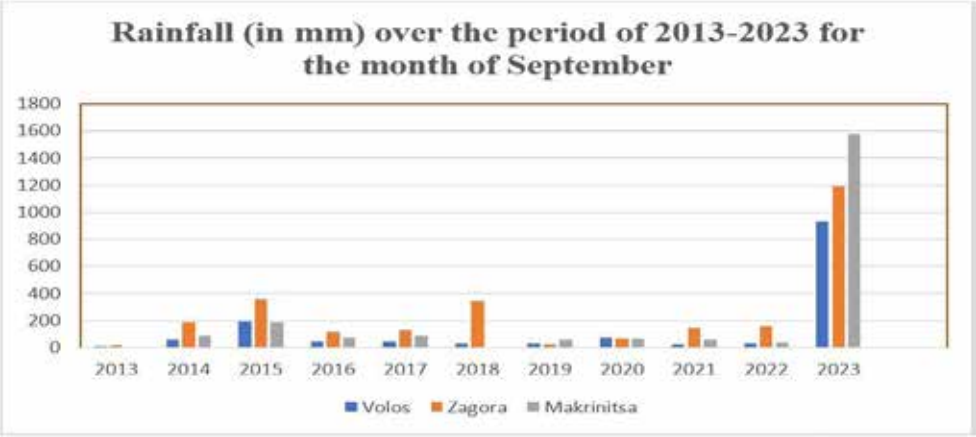

Figure 1. Rainfall of the study area over a ten-year period for the month of September (data from: https://meteo.gr/climatic.cfm)

Method and data collection

In total, seven routes were arranged based on news reports of extensive damage in the region. Data was collected on site through geotagged photographs. A total of 554 photographs were taken, of which 137 were included in the study's detailed analysis. ArcGIS Pro software was used in order to create a map that visualizes the relation between the seven survey routes and the location of damages recorded during field visits. Then, damages were sorted and categorised depending on their content alone, i.e., disregarding their coordinates. Lastly, another map was created to feature the relation between the spatial distribution of damage depending on their type and municipality.

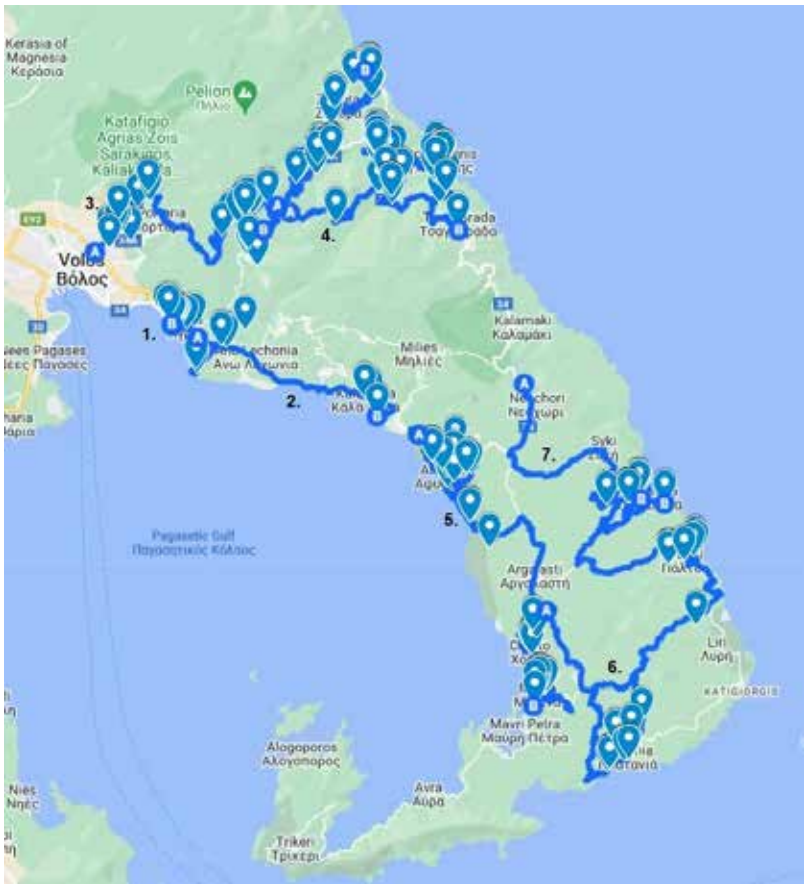

Figure 2. The seven routes that were followed in relation to all damages recorded

Results

Every photograph had georeference through its coordinates, as is standard practice for all post-disaster reconnaissance activities in order for photographs taken in the field to be acceptable for use in the desk analysis. This rendered it possible to visualise all damages and map locations where they were concentrated (Figure 2). After studying the available data, these were categorized into six groups according to the type of damage they were depicting. The groups were formed as shown below:

- Loss of Life: Four fatalities were recorded in the Pelion region alone during Storm Daniel.
- Road Networks: Significant damage was observed, especially near streams and water bodies. Roads were washed away or severely eroded due to the discharge and the high speed of water flow.
- Bridges and Infrastructure: Bridges collapsed or were rendered unsafe, as their structural foundations were compromised. Key access routes were severed. The damage was mainly attributed to scouring phenomena at the approaching embankments of the bridges.
- Property Loss: Houses, vehicles and businesses suffered extensive damage, particularly in areas close to riverbeds.
- Soil Erosion: Landslides and mudflows led to large volumes of soil being moved, exacerbating the damage.
- Debris Deposition: Tree trunks, stones, and other debris clogged waterways, damaged vehicles, and destroyed public spaces.

Figure 3 shows some of the damages recorded, namely: road network destruction in Kala Nera, structural damage of a bridge in Horto, debris deposition on a playground in Agios Onoufrios, extensive damages to a house in Platanias and lastly a large volume of soil that was moved due to a landslide in between Chania and Drakia village. Finally, it was deemed necessary for this study, to create a map where all groups of damages were shown in relation to municipalities (Figure 4), since each one differs from the other regarding environmental conditions (vegetation, gradient).

Figure 3. Different types of damages recorded on site during field visits

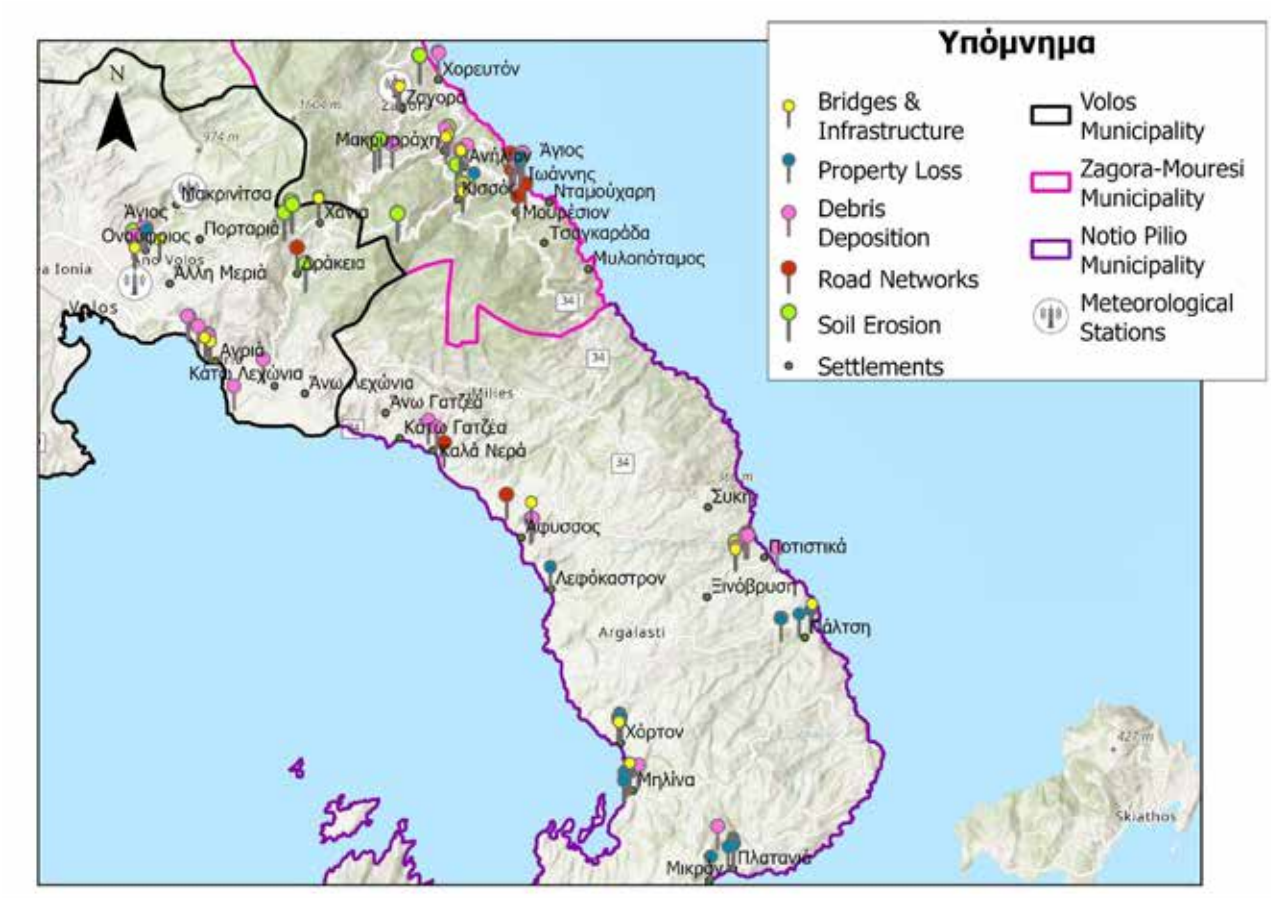

Figure 4. Distribution of types of damages in relation to each municipality of the study area

Conclusions

Proximity of infrastructure and settlements to water bodies played a crucial role in the severity and extensiveness of the damages recorded. Four people lost their lives in Pelion region alone, due to the violent water flow of the torrents. Huge amounts of soil were removed, especially from locations with great inclination (mostly in municipality of Zagora – Mouresi, followed by Volos municipality), and were carried away violently by the water, finally redepositing within riverbeds, private houses, public spaces and the sea. Bridges were washed away or severely damaged, roads were eroded and some settlements were cut off for a few days because of it. These findings highlight the need for improved urban planning and infrastructure resilience in flood-prone areas, but also updated, well-known to all residents evacuation plans. Recovery efforts, one year after these events, indicate slow progress in rebuilding and rehabilitation. In most cases temporary rehabilitation measures have been applied. This study underscores the importance of better disaster management practices, followed by everyone involved, in order to mitigate future risks.

EXTENDED ABSTRACT 054

ERBE SYMPOSIUM 2027– LAVRION GREECE: Honouring the Values of Geo-Mining Heritage

Demetrios C. Constantinides, RNDr.
Exploration Geologist, Nicosia, Cyprus, email: dimkon46@gmail.com

Introduction

The word Symposium is very understandable to the Greeks, since their ancestors had started organising these events already in the 7th century BC. At such gatherings, the more experienced members of the community were expected to impart practical guidance to younger generations. This mentorship helped maintain the steadiness of certain cultural traditions. A symposium usually took place in a men's dining room of a nobleman. The room was called "andron" and was specially designed for such meetings, with couches placed around the perimeter for guests to lie down, while they while they were eating and drinking (Fig. 1).

Fig. 1: Relief depicting a scene from a symposium in ancient Greece[1]

The ERBE Symposium

An ERBE Symposium has a strong element in common with the ancient Greek symposia: it aims to bring out the cultural heritage of those "who crawl like worms in the earth, denying the sun and the air", as the Cypriot poet Costas Montis describes the miners in one of his poems.

ERBE is a German word that means heritage. The International "ERBE" Symposium, exploring the cultural heritage of geology, mining and metallurgy, has a tradition that goes back more than three decades, since the first one was organised in Freiberg of Germany in 1993. Since then, the Symposium has been organised 15 more times to return to Freiberg in 2023. So far, it has been held in the following cities and countries:

Freiberg/Saxony – Germany (1993)
Leoben – Austria (1995)
St. Petersburg – Russia (1997)
Banská Štiavnica – Slovakia (1999)
Golden/Colorado – USA (2000)
Idrija – Slovenia (2002)
Leiden – The Netherlands (2003)
Schwaz – Austria (2005)
Quebec-City – Canada (2007)
Freiberg/Saxony – Germany (2009)
Real del Monte – Mexiko (2011)
Bozen/Bolzano – Italy (2013)
Banská Štiavnica – Slovakia (2015)
Ravne na Koroskem – Slovenia (2018)
Eggenburg – Austria (2021)
Freiberg/Saxony – Germany (2023)

The next city to host the Symposium will be again Ravne na Koroskem on 22nd – 27th September 2025. Here are some scenes from previous symposia (Fig. 2-6). The source of figures 2 to 6 is https://photos.erbe-symposium.org/index.php?/categories.

Fig. 2: Participants of the last ERBE Symposium in Freiberg during a city sightseeing tour.

Fig. 3: The building of the Old Castle in Banská Štiavnica, the venue of the 13th ERBE Symposium.

Fig. 4-5: Children's performance and miner's choir at the 13th ERBE Symposium.

Fig.6: An old mining locomotive that was exhibited at the ERBE Symposium in Quebec (2007).

For those interested in enjoying thousands of images from all the sixteen symposia, a visit to the website of the ERBE Association is recommended[2].

The Main Goals of an ERBE Symposium

The main objective of an ERBE Symposium is to exhibit the cultural heritage in Geosciences, Mining and Metallurgy. However, each symposium tried to highlight more specific cultural characteristics relating to the local mining tradition. For example, the last Symposium held in Freiberg, focused on libraries, archives and museums associated with historic mining industry. The Principles of the Cultural Heritage of Geosciences, Mining, Metallurgy and Archaeology have been established some time ago[3].

The aim of both international and national commissions of the Symposia is to make available the entire human cultural heritage relating to the earth's crust, including geo-memorials. The committees are made up of personalities who promote and develop the values and the heritage of mining culture.

We could go on presenting the objectives of the Symposia held to date. However, this is not the subject of this paper. What really needs to be highlighted here is the decision of a small group of people to take over the 2027 Symposium that we would like to organise in Lavrion.

Our Initiative

The author of this paper has joined the 13th ERBE Symposium in Banská Štiavnica, where he lived for about 10 years. It is a town of 16,000 inhabitants whose economy is heavily dependent on the tourism generated by its mining heritage.

The idea of applying for one of the next ERBE Symposia, which could be organised by the Lavreotiki Geopark and

the Committee of Geological-Geomorphological Heritage of the Greek Geological Society, was strengthened in our minds after the inclusion of the Lavrion area in the UNESCO Geoparks Group. Nevertheless, the maintenance of a Geopark on this List and its potential inscription on the UNESCO World Heritage Register, will require a great deal of effort. That is why we believe that, apart from the fact that we will be able to present the history, incredible monuments and natural beauty of Lavrion so broadly, the organisation of such a symposium would help us to gain international supporters for the inclusion of the area in the UNESCO World Heritage List.

Why Lavrion?

The beginning of mining and metallurgy in Lavreotiki is placed in the 5th millennium BC. In particular, the inhabitants of Velatouri hill are thought to have been there since the Middle Neolithic, around 4500 BC. At the foot of the hill was the oldest theatre in ancient Greece, that of Thorikos (Fig. 7).

Fig. 7: Thorikon theatre and an ore washing plant.

Next to the amphitheatre is the entrance to the adit where the Ag-Pb ores were mined (Fig. 8). Photo @Richard Kaňa

Fig. 8: The entrance of a mining adit. Photo @Richard Kaňa

The most important technological achievement of this period was mining and metallurgical processing. The archaeological remains of these activities can be found and visited in Souriza (Fig. 9).

Fig. 9: Ruins of the water management system at Souriza. Photo @Richard Kaňa

Not to be missed

Apart from being famous for the exploitation of silver and funding the famous projects of the "Golden Age of Pericles", as well as the fleet of the Naval Battle of Salamis, this mining area contains more minerals than any other region of the Earth, making it also a unique site of mineral heritage.

According to the Mindat Organisation 805 mineral species and varietal names are listed in the abandoned mines of Lavreotiki district[4], whilst it is the type-locality for 23 of them.

Fig. 10: Minerals from Hercules Katsaros collection. Photo @H. Katsaros

Circulars, Sessions and Tours

As soon as our proposal to hold the ERBE Symposium in Greece is officially accepted, the Organising and Scientific Committee of the Symposium will be set up so that the sessions of the Symposium can be decided and the first Circular Letter can be sent out. Of course, the Symposium will include excursions to geological and mining monuments of Lavrion and the surrounding archaeological sites (Sounion and the Temple of Poseidon, the ancient marble quarry at Agrileza and others).

Obviously, the programme will include a full-day trip to Athens including a visit to Acropolis and its modern museum, as well as a lunch in Plaka. Perhaps some delegates who have the time could be offered more distant excursions, e.g., to Serifos and/or Milos.

The Venue

The proposed venue is an important part of the cultural heritage of Lavrion. The buildings are located within the Lavrion Technological and Cultural Park, which was established in 1992 on the site of the former French Mining Company of Lavrion, on the initiative of the National Technical University of Athens. The premises are of high aesthetic and architectural value (Figs. 11), although most of them were built between 1875 and 1940. They include the processing facilities, as well as administrative and other buildings. The site was the location of the company's operations until 1988.

Fig. 11: Historical buildings of the French Mining Company of Lavrion. Photos: @H. Katsaros

The proposed emblem for ERBE Lavrion Symposium

The concept of the ERBE Symposia banner was established at the Freiberg Conference in 1993. With three exceptions, the rest of the countries respected the original emblem by adding only the city and date of the event. It is for this reason that we are proposing the following emblem for the ERBE Symposium to be held in Lavrion in September 2027 (Fig. 12). The exact dates will be added to the logo once they have been finalised in consultation with the International Committee.

Fig. 12: The proposed emblem for the 2027 ERBE Symposium in Lavrion.

What are we looking forward to?

What are we looking forward to?

As the promoters of this initiative, we expect the following:

- The acceptance by the international geological and mining ERBE community of our proposal to hold the 2027 Symposium in Lavrion.
- Effective cooperation between the organising bodies of the Symposium to ensure its success. And above all, to properly promote the cultural heritage of the geological and mining Lavreotiki.
- The General Directorate of Mineral Resources of the Greek Ministry of Environment and Energy to support the efforts of the organisers in an un-bureaucratic way.
- The Greek Geological Society, the Union of Greek Geologists, the Technical Chamber of Greece, the Association of Mining Enterprises, the Eastern Attica Region, the National Technical University of Athens and other relevant bodies to support this initiative.

If all goes well, we believe that Lavrion and its Geopark will not only establish its reputation as one of the world's most Historical Mining Centres and become better known around the world, but also raise the bar for a place on the UNESCO World Heritage List.

17th INTERNATIONAL CONGRESS of the Geological Society of Greece

BULLETIN OF THE GEOLOGICAL SOCIETY OF GREECE, SP. PUBL.

EXTENDED ABSTRACT 055

The Geoheritage of the "Atlantic Geopark" Project (Central Portugal) at a Glance

Custódio, S.C.[1], Henriques, M.H.[2], Sá, A.A.[3]

(1) Geosciences Center, Department of Earth Sciences, University of Coimbra, Rua Sílvio Lima s/n, 3030-070 Coimbra, Portugal; scmcustodio@student.uc.pt

(2) Geosciences Center, Department of Earth Sciences, University of Coimbra, Rua Sílvio Lima s/n, 3030-070 Coimbra, Portugal

(3) Department of Geology and Pole of the Geosciences Center, University of Trás-os-Montes e Alto Douro, Quinta de Prados, 5000-801 Vila Real, Portugal

Introduction

The history of the Proto-Atlantic and the opening up of the Atlantic are particularly well expressed on the Western Iberian Margin (WIM) and are of interest to many geosciences' experts and curiosity to many citizens. The expressiveness of the last 600 million years of the WIM's geological history is particularly eloquent in a territory that covers an east-west strip of the Beira Litoral (Central Portugal), comprising the municipalities of Figueira da Foz, Mira, Cantanhede, Mealhada, Montemor-o-Velho and Penacova (Fig. 1).

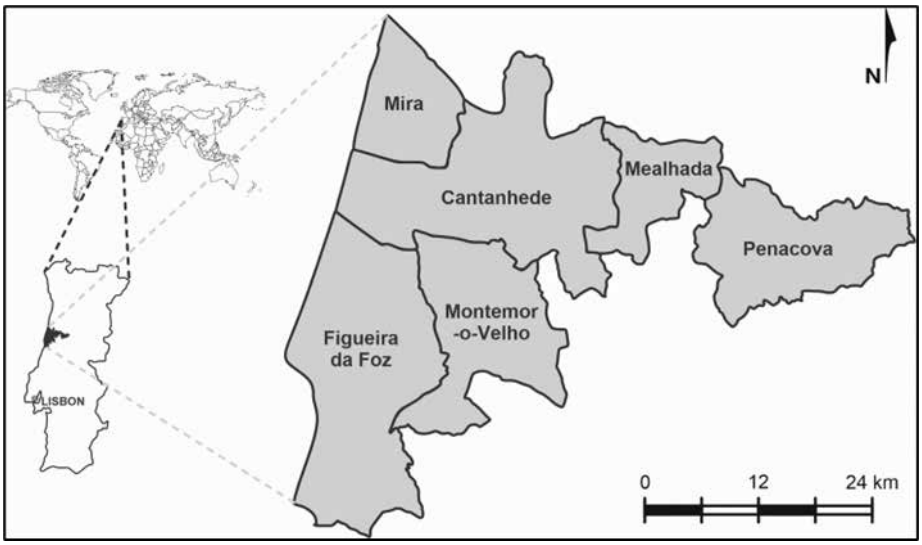

Figure 1: Location map of the "Atlantic Geopark" territory.

The "Atlantic Geopark" Project consists of inventorying and evaluating the geological heritage of those six municipalities, with a view to its conservation, valuation and monitoring for a future application to the Global Geoparks Network (GGN). The results obtained will provide technical support for the application dossier, that has to also include a sustainable management plan for the territory aiming at fostering socio-economic development, conserving the geological heritage and inspirating its replication in similar transatlantic territories.

Conceptual framework

This research assumes that the Earth's natural heritage includes two components - abiotic and biotic - which must be preserved namely through local, regional and national actions/organizations, as well as supranational ones, of which the current UNESCO programs are an example (e.g., Man and the Biosphere Program (since 1971); Convention for the Protection of the World Cultural and Natural Heritage (since 1972) and the International Geosciences and Geoparks Program (since 2015)).

The abiotic component of nature is reflected in its geodiversity, which can be defined as the variety of geological characteristics/features that can be identified in a given territory and taking into account their frequency and distribution, as well as their expressiveness as a reflection of the geological evolution of that territory. When they have scientific, educational and tourist value, such geological sites and elements take on heritage value and are part of the Earth's geological heritage (Carcavilla *et al.*, 2007; Brilha, 2016).

Geoconservation is a geological science that, based on the geodiversity of any territory and/or geological element

(e.g., fossils, rocks and minerals), seeks to safeguard the Earth's geological heritage through specific methods and techniques of inventorying, evaluating, conserving, valuation and monitoring (Henriques *et al*., 2011). From this need emerged the concept of geopark, whose historical foundations date back to the Digne Convention (1991), where an international declaration to protect the geological heritage as a legacy for future generations was approved (IDRME, 1995).

UNESCO defines a geopark as a single, unified area, where sites and landscapes of international geological importance are managed in a holistic concept of protection, education and sustainable development (UNESCO, 2024). UNESCO's link with geoparks officially began in 2004. However, numerous previous initiatives, such as the creation of the European Geoparks Network in 2000, contributed to UNESCO's commitment to the dynamics of geoparks. In 2015, UNESCO enshrined the UNESCO Global Geopark concept within the framework of the new International Geosciences and Geoparks Programme (Henriques & Brilha, 2017).

In 2024, Portugal has six UNESCO Global Geoparks - Azores, Arouca, Estrela, Naturtejo, Terras de Cavaleiros and Oeste (CNU, 2024) – and two Aspirants - Litoral de Viana do Castelo and Algarvensis. The "Atlantic Geopark", which is still in the design phase, emerged from the willingness of six municipalities located in Central Portugal (Cantanhede, Mealhada, Mira, Montemor-o-Velho, Figueira da Foz and Penacova) to apply for their territory to become a UNESCO Global Geopark. To this end, it is necessary to inventory, assess, conserve, valuate and monitor the geological heritage of its territory with a view to incorporating it into the application file for the GGN. This is the main goal of this project which have already produced some relevant results.

First results

The geodiversity of this area, which comprises a strip that crosses Portugal in an approximately east-west direction, allows us to recognize the main episodes in the geological history of the WIM over the last 600 million years (Fig. 2). This is supported by a set of sites of geological interest that illustrate the main episodes related to the opening and closing of the Rheic Ocean, the fragmentation of Pangea, the opening of the North Atlantic Ocean and the Quaternary geodynamics of the North Atlantic Ocean (Custódio *et al.,* 2024; Table 1).

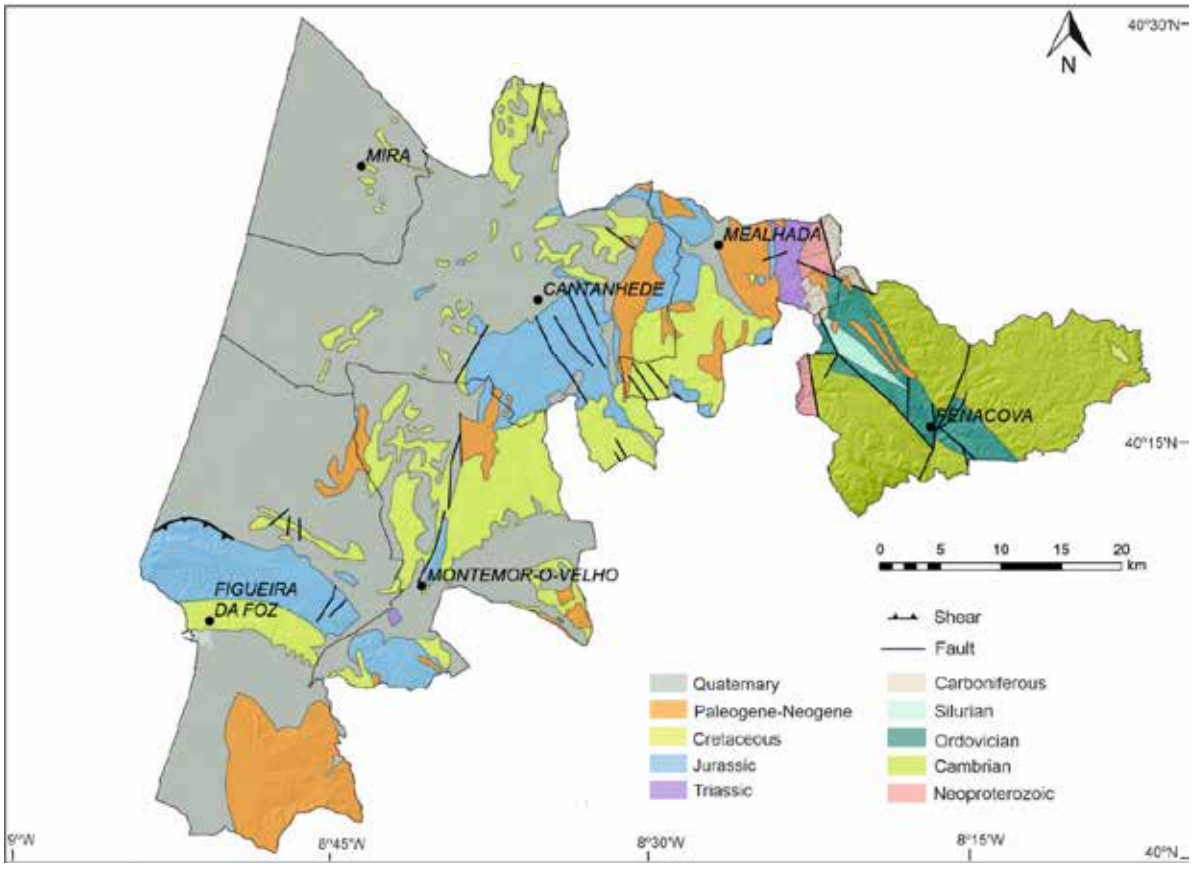

Figure 2: Geological map of the study area. It covers materials from the Neoproterozoic (600 Ma) to the Cenozoic (Vaz *et al*., 2023).

The first geological framework in the study area is the Beiras Supergroup (635 Ma), that represents the oldest record in the study area, outcropping in Penacova Municipality (Fig. 3A). This record is associated with the evolution of a volcanic arc (Cadamian Orogeny; 650-550 Ma) on the margin of the Gondwana continent. It was later inverted by the beginning of the Variscan Cycle (Cambrian—Ordovician; 495–485 Ma), and another deformation episode which is related to the closing of the Rheic Ocean and the Pangea assembly.
The geological record of the Buçaco Synclinal (Lower Ordovician - Silurian; 485-423 Ma) was deposited in a passive margin context of the Rhein Ocean, and it outcrops in Penacova and Mealhada Municipalities (Fig. 3B). In Mealhada Municipality it also crops out the east sector of the Buçaco Carboniferous Basin (Early Ghzelian - 303 Ma), whose units were deposited in a continental basin context located between the Variscan mountains (Fig. 3C).
The next geological framework is represented by the Silves Group (Upper Triassic; Mealhada Municipality a siliciclastic unit that can attest to the central position that Iberia occupied in Pangea just before the opening of the North Atlantic Ocean, marking the break-up of that supercontinent (Fig. 3D).
The Jurassic Carbonate platform of the Proto-Atlantic is well represented in Cantanhede and in Figueira da Foz Municipalities (Figs. 3E and 3F). The reference section of Cabo Mondego (Figueira da Foz) includes the GSSP for Bajocian (170 Ma) and the ASSP for the Bathonian (168 Ma), which represents geoheritage of global relevance. The same section provides a continuous record from the Middle Jurassic fossiliferous marly limestones interpreted as a sag episode of the first rift to the syn-rift episode of the Late Jurassic second rift.
The transition to a passive margin is represented by the next geological framework of the “Atlantic Geopark”, the Carbonate Platform of the Atlantic (Cenomanian—Turonian, 100–93 Ma), which is also well recorded in Figueira da Foz, and in Montemor-o-Velho Municipalities (Fig. 3H).
The Quaternary geodynamics of the Atlantic Margin is well represented throughout the territory, with extensive superficial deposits that cover most of the littoral, dated from the Pleistocene to the Holocene (Fig. 3I).

Table 1. The geological frameworks of the “Atlantic Geopark” and its representative geological site.

Geological framework	Episode	Geological site	Relevance	Municipality
Beiras Supergroup (Neoproterozoic)	Opening of the Rheic Ocean	Aguieira Dam (40°20’24.5”N 8°11’54.6”W)	Regional	Penacova
Buçaco Synclinal (Ordovician - Silurian)	Evolution of the Passive Margin	Livraria do Mondego (40°17’00.9”N 8°15’58.0”W)	Nacional	Penacova
Buçaco Carboniferous Basin (Carboniferous)	Closing of the Rheic Ocean	Santa Cristina Fountain (40°20’55.2”N 8°23’02.8”W)	Regional	Mealhada
Silves Group (Triassic)	Fragmentation of Pangea	Vacariça (40°20’53.6”N 8°23’23.0”W)	Local	Mealhada
Carbonate platform of the Proto-Atlantic (Jurassic)	Opening of the North Atlantic Ocean	Cabo Mondego (40°10’48.4”N 8°54’20.7”W); Ançã limestone (40°17’17.6”N 8°32’22.5”W)	Global	Figueira da Foz; Cantanhede
Carbonate Platform of the Atlantic (Cretaceous)	Marine transgression of the North Atlantic Ocean	Nossa Sra. dos Olivais Chapel (40°14’12.4”N 8°35’20.3”W)	Regional	Montemor-o-Velho
Quaternary Dunes	Quaternary geodynamics of the Atlantic Margin	Barrinha de Mira (Ria de Aveiro; 40°27’05.5”N 8°47’53.3”W)	Local	Mira

Figure 3: The representative geological site of each geological framework recorded at the "Atlantic Geopark". A) Aguieira Dam (Penacova); B) Livraria do Mondego (Penacova); C) Santa Cristina Fountain (Mealhada); D) Vacariça (Mealhada); E) Ançã (Cantanhede); F) Cabo Mondego (Figueira da Foz); G) Nossa Sra. dos Olivais Chapel (Montemor-o-Velho); H) Barrinha de Mira (Mira).

These preliminary results have been reported in several scientific forums, and as geoeducative and geoturistic products (Fig. 4). A promotional video was produced in 2021 by AD ELO, the organization in charge of implementing the future application to GGN (https://youtu.be/NFVJGIL4PX8?si=vPztmIP6BM6vRuMT). The most emblematic geological sites for each municipality were described in detail by Custódio *et al*. (2024). They feature the Oceans Route, a set of outcrops that make it possible to reconstruct the geological history of two oceans—Rheic and Atlantic. Other geo-itineraries (the water route, the stone route and the beach route) were created and are available online (AD ELO, 2024) and as a book in the region's tourist offices (Vaz *et al*., 2024). Other initiatives promoted by municipal authorities regarding the conservation and valuation of local geoheritage resources include the recent designation of the Ançã Limestone as Global Heritage Stone (David Lista *et al*., 2024) and the classification of Livraria do Mondego (in the Buçaco Syncline) as Local Natural Monument included in the National Network of Protected Areas of Portugal (Henriques *et al*., this volume).

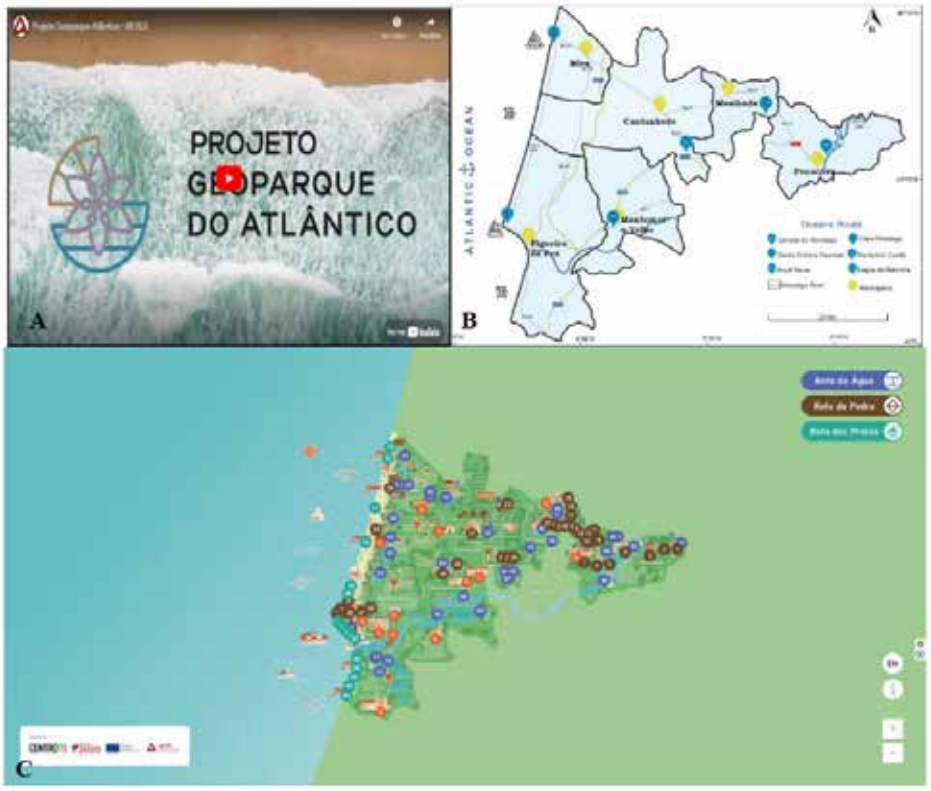

Figure 4: Different types of products resulted from the ongoing "Atlantic Geopark" Project. A: the promotional video (AD ELO, 2021); B: the geo-itinerary with selected geological sites (Custódio *et al*., 2024); C: the geo-itinerary of the heritage routes comprising the water route, the stone route and the beach route (Vaz *et al*., 2024).

Next steps

The results obtained so far allow us to conclude that the territory related to the "Atlantic Geopark" project has geological heritage of international importance, as required by the GGN guidelines (UNESCO, 2022). The geological sites that have been identified so far make it possible to create geotourism routes that tell the story of the various episodes of the geological history of the WIM. But a successful application seeking recognition as a UNESCO Global Geopark requires go through other steps, namely the design and implementation of a comprehensive management plan, covering governance, development, communication, protection, infrastructure, finance, and partnership issues (UNESCO, 2024). This task falls to AD ELO, which has been developing a number of initiatives aimed at publicizing the project through promotional products like a detailed map of the area that connects the area's geological sites and other local resources. Communities' involvement on geoconservation of the "Atlantic Geopark" territory is a challenging goal, and this implies the implementation of a territorial-based program that brings residents closer to the geopark concept.

3 University of Patras, Department of Geology, Laboratory of Paleontology and Stratigraphy 26504, Patras, Greece

In the NW part of the Ionian Basin (Ioannina region, Western Greece), Triassic evaporites and Jurassic to upper Eocene carbonates (interbedded with minor cherts and shales) are overlain by Eocene to Miocene siliciclastics. These deposits reflect the depositional environments that prevailed during the pre-orogenic, extensional stage and the following syn-orogenic, contractional stage, respectively. During the Middle Eocene, a transition from extension to compression and growing of the Pindos Orogen took place. This caused a change of sedimentation from slope carbonate to siliciclastic submarine fan deposits. Clastic deposits accumulated in a pre-foreland basin at the margin of the Apulian microcontinent from the Late Eocene to the early Miocene because of the uplift of Pindos Orogen and the activity of Pindos Thrust. This change is relatively rapid, so the total thickness of the transitional beds is up to 12.67 m in the Mazia village. In the lower 5 m, there are only thinly bedded mudstones, whereas in the upper 7.5 m within the thinly bedded mudstones there are sandstones and marly limestones. The mudstone is thin- to medium-bedded (0.01–0.02 m) and is either structureless or parallel-laminated. The sandstone beds display sharp bases and include sedimentary structures, such as parallel and ripple cross-laminations. Individual carbonate beds may be either structureless, parallel, or ripple-cross laminated calcarenites. Some of them show an upward transition from structureless (base of the beds), through parallel-lamination to ripple-cross-lamination (top of the bed). This facies association is interpreted as deep-water abyssal plain deposits, according to the dominant lithology and sedimentary structures. Within the marly limestone beds, the trace fossils *Chondrites intricatus, C. targionii, Planolites isp., Nereites isp.,* and *Avetoichnus* are recognized. In the underlying deposits, *Zoophycos* is present. The overlying clastic deposits in the area contain diverse trace fossils typical of the *Nereites* ichnofacies. The sedimentological and ichnological features point to the transition from the *Zoophycos* to the *Nereites* ichnofacies and slope to abyssal plain deposition.

Key words: slope facies, carbonates, Eocene, Greece.

EXTENDED ABSTRACT 057

Statistics on seismic moment tensors for the Aegean Sea and surrounding area: preliminary results

Dasoula M. G.[1*], Roumelioti Z.[1], Sokos E.[1], Kokkalas, S.[1]
*(1) Department of Geology, University of Patras, Patras, Greece, *up1074036@ac.upatras.gr*

Abstract
Moment tensors (MTs) are an essential tool for understanding earthquake source processes, improving seismic hazard assessment at various scales, and mitigating earthquake disaster risk. The Aegean Sea and its environs have the highest seismic activity in Europe and the Eastern Mediterranean, providing a wealth of earthquake data that can be used for moment tensor computations. In this work, we summarize moment tensor solutions published by the Global Centroid Moment Tensor Group (GCMT) and compare a subset of them with corresponding moment tensors from the Institute of Geodynamics of the National Observatory of Athens (NOA). We statistically examine the two datasets, primarily from the point of view of the style of faulting implied by the moment tensors in the study area and the associated Mw reporting. We also analyze the metrics of this comparison with respect to various factors, such as the location and magnitude of the associated earthquakes, their hypocentral depth, etc. Overall, we find a good agreement between the moment tensors of GCMT and NOA for 85% of the cases studied. Poor comparisons are mostly restricted to moderate magnitude events along the Hellenic Arc.

Moment tensors of the Global Centroid Moment Tensor Group
There are many institutions and universities around the world that study seismic data and publish MTs. The reliability of each is an issue that often concerns researchers. When conducting seismic research on a particular area, the GCMT project MTs are often used as a reference, as they are the most widely accepted by the seismological community.
For more than 40 years, the GCMT project has provided MTs for strong to moderate earthquakes around the globe using methods that involve inversion of long-period seismic waveforms based on normal mode summation and a 1D Earth model with path corrections (Dziewonski et al., 1981). In 2004, GCMT methods and processing underwent significant changes towards the incorporation of intermediate-period surface waves (Ekström et al., 2014). This led to improvements in shallow earthquake source parameters and a significant reduction in the smallest earthquake size for which GCMT publishes solutions.
In this first part of our work, we review all published GCMT solutions for the wider Aegean region (the exact study area is shown in Figure 1a), with statistics focusing on the implied style of faulting and moment magnitude, Mw, reporting. In total, we review 746 solutions, whose epicenters are shown in Figure 1a. The distribution of solutions unsurprisingly follows the distribution of seismicity in the area, with most MTs corresponding to earthquakes along the Hellenic arc, in the transition area of the Ionian islands, the Gulf of Corinth, and a zone subparallel to the western coast of Turkey. The well-known North Aegean trough zone collects a fair number of solutions, but is not as pronounced as in the seismicity maps. Figure 1b shows the distribution of solutions with Mw or Mw_GCMT to distinguish from another subset in the following. Nearly 80% of the dataset consists of solutions for earthquakes with Mw<5.5. Figure 1c shows how the Mw in GCMT MTs is distributed over time and clearly reflects the methodological change of GCMT in 2004, which resulted in a sudden appearance of much smaller earthquakes in the catalog.
The MTs were classified according to the implied fault style following the projection technique of Kaverina et al. (1996) and the classification scheme of Álvarez-Gómez (2014, 2019) implemented in the FMC software. The scheme is based on the plunges of the three eigenvectors of the moment tensors (P, B, T axes) and their relations and includes seven types of faulting: normal (N), normal with strike-slip component (N-SS), strike-slip with normal component (SS-N), strike-slip (SS), strike-slip with reverse component (SS-R), reverse with strike-slip component (R-SS) and reverse (R). The projection of the classification diagram is shown in the inset of Figure 2a. Figure 2a shows the projections of all 746 MTs, with the dimensions of the circle symbols analogous to the size of the earthquakes and their color reflecting the hypocentral depth. About 43% of the MTs are classified as N or N-SS, 23% as R or R-SS, and 34% as SS, SS-N, or SS-R. Overall, almost half of the GCMT MTs for the study area are normal or have some normal faulting component. However, Figure 2b, which shows the cumulative seismic moment release per faulting class, clearly indicates that reverse faulting is the predominant type. This is also reflected in the concentration of larger earthquakes (larger circles in the lower right part of the plot in Figure 2a). Considering that more than 82% of the total seismic moment released by the 746 earthquakes in our dataset comes from the 55 Mw_GCMT ³ 6.0 events, i.e., above the magnitude of completeness of the GCMT catalog for the Aegean area, at least since 1985 (González,

2024), the statistics in Figure 2b can be considered representative of the total seismic activity in the Aegean region for the examined time period.

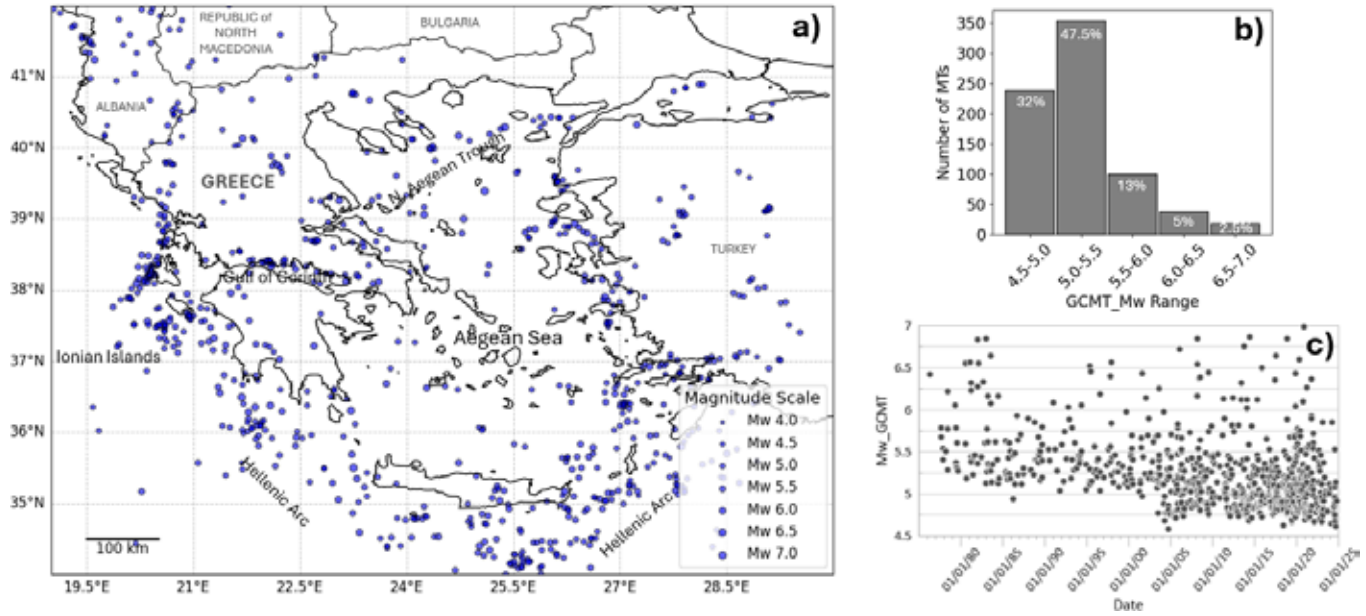

Figure 1. a) Map of the study region showing the epicenters of earthquakes with reported moment tensors in the GCMT catalog and the distributions of b) solutions in M_w bins and c) M_w with time.

Another interesting observation in Figure 2a is the concentration of most intermediate depth earthquake MTs near the center and more generally in the mixed faulting parts of the diagram. This may reflect the increased complexity of the stress field and source processes at greater depths within the subducting system of the Aegean region, the uncertainty of data processing in such depths that result in mixed mode fault-type, the complexity of data from fault branching with decollement surfaces or any combination of these.

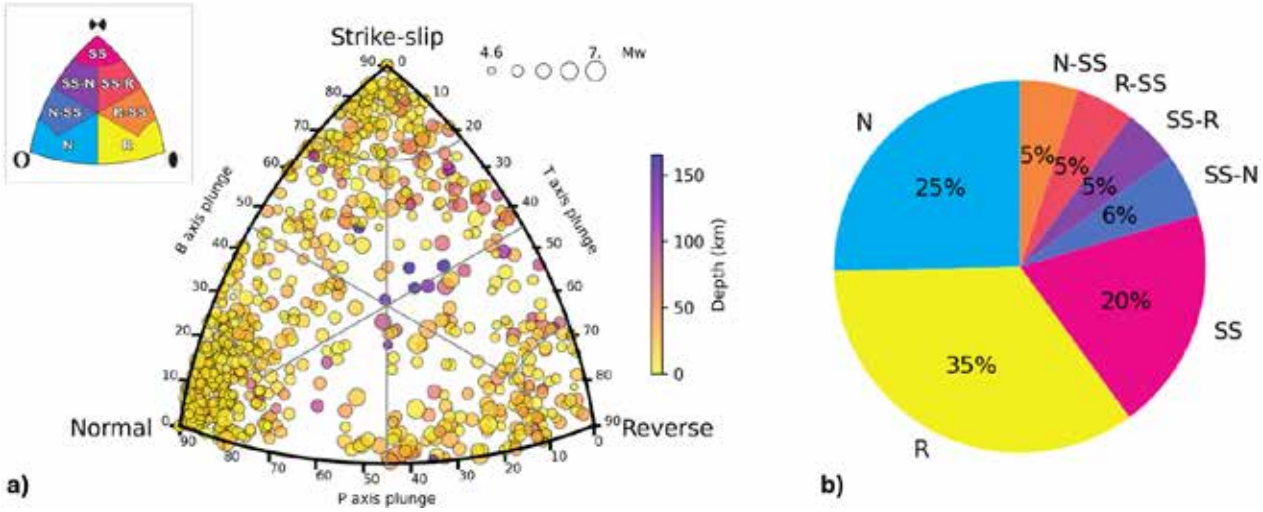

Figure 2. a) Faulting type classification diagram with seven types: N (normal), N-SS (normal with strike-slip component), SS-N (strike-slip with normal component), SS (strike-slip), SS-R (strike-slip with reverse component), R-SS (reverse with strike-slip component), R (reverse). Circle symbols are colored according to the hypocentral depth, and their dimensions are analogous to the magnitude of the earthquakes. The inset (after Álvarez-Gómez, 2014, 2019) shows the sectors of the diagram and corresponding classes b) pie chart with moment release by each class as a percentage of the total moment release from all earthquakes in the examined dataset.

Comparison of GCMT and National Observatory of Athens moment tensors: Faulting Style

The Institute of Geodynamics of the National Observatory of Athens (NOA) provides moment tensors for strong, moderate and even relatively weak earthquakes (down to ~Mw=3.5) as part of its routine services. The MTs published so far by NOA, either automatically derived or manually processed, are based on full waveform inversion of regional broadband waveforms and can be divided into two parts. The first part includes the solutions for the period 2001-2011, when NOA used the method of Hermann and Ammon (2002) (e.g., Konstantinou et al., 2010; Konstantinou, 2015). The second part includes the MTs since 2012, derived by the method of Sokos and Zahradnik (2008), more recently extended by Zahradnik and Sokos (2018) and implemented in the software packages ISOLA and GISOLA (Triantafyllis et al., 2021). This is currently the method routinely used at NOA, and relevant results from its implementation are available on the institute's website (https://bbnet.gein.noa.gr/HL/seismicity/mts).

In order to quantify how well these regional MTs compare to those of the GCMT, we collected the seismic events that occurred in the Aegean and the wider area from 2001 to 2023, for which solutions are available from both sources (i.e., GCMT and NOA). We identified 450 events and as a result we created a database of 450 pairs of MTs. The locations of these events are shown on the map in Figure 3a.

We first examined the pairs of MTs for their similarity in implied fault geometry. To quantify similarity, we adopted an angular measure of the relative orientations of the two MTs in each pair, specifically the smallest angle required to rotate the principal axes of one MT into the principal axes of its paired MT. This angle has been studied extensively by Kagan (e.g., 1991, 2007) and is therefore often referred to as the "Kagan angle". A detailed description of the Kagan angle can be found in the aforementioned publications by Kagan himself and, for example, in Tape and Tape (2012) and references therein.

To define the Kagan angles for our dataset, we used the homonymous MATLAB function (Kolar, 2025). The results are incorporated into the map in Figure 3a by coloring the epicenters based on three classes of Kagan angles: 0˚ - 30˚, indicating that the two focal mechanisms are very similar, 30˚ - 50˚ for acceptable resemblance that allows the focal mechanisms to be identified as similar, and >50˚, where the two focal mechanisms in a pair are very different. Figure 3b shows examples of MT pairs from our dataset for different levels of Kagan angle. The distribution of computed Kagan angles in Figure 3a suggests that there is good agreement between GCMT and NOA solutions, i.e. most epicenters (85%) are colored blue (63%) or yellow (22%), implying Kagan angles <50˚. Red colored epicenters represent only 15% of the cases examined and are almost exclusively located in the outer parts of the study area, where earthquake epicenters are poorly covered in azimuth by the Hellenic Unified Seismological Network, the backbone data source for NOA MT inversions. The largest concentrations of high Kagan angles occur along the southeastern part of the Hellenic Arc and the Ionian Islands.

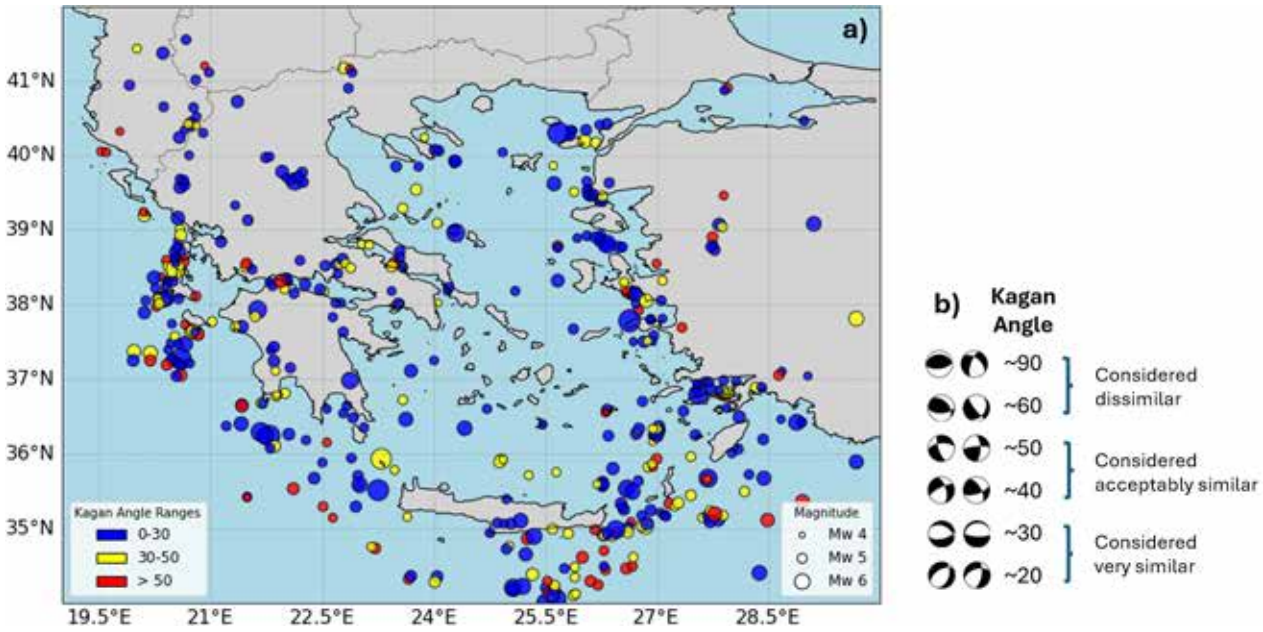

Figure 3. a) Map of the study region with epicenters of earthquakes for which both the GCMT and NOA have published MTs. Circle symbols are colored by Kagan angle ranges. b) Example pairs of MTs from the studied dataset for various levels of the Kagan angle.

Kagan angles were also examined as a function of earthquake magnitude (Mw), hypocenter depth, and time, as shown in Figure 4. Figure 4a shows the distribution of angles with the Mw_GCMT, where it is noticeable that high magnitude events (>6) have low Kagan angles. All angles >50˚ appear at lower magnitudes and especially at Mw<5.5. Combining this observation with the distribution in Figure 3a leads to the expected result that MTs of events with Mw<5.5 in the periphery of our study area are not always accurately resolved.
Figure 4b shows how the Kagan angles vary with the hypocentral depth of the events in our dataset. Most of the high Kagan angle values are concentrated at shallow depths, following the distribution of seismicity. However, several high angles appear to be distributed throughout the sampled depth interval, and the paucity of data at great depths does not allow us to draw any firm conclusions about a possible relationship between changes in the similarity of MT pairs and depth.
Finally, Figure 4c shows the Kagan angles with respect to the date of the events/MTs and gives the impression that the number of events associated with high angles has remained relatively stable over the years (2001-2023), despite the significant methodological changes by both GCMT and NOA. Moreover, since 2012, NOA has adopted GISOLA and has also allowed the release of automatic MT solutions, which has increased the number of events with MT pairs. The high Kagan angles have not followed this increase, indicating that the MT solutions provided by GCMT and NOA have become more similar in recent years.

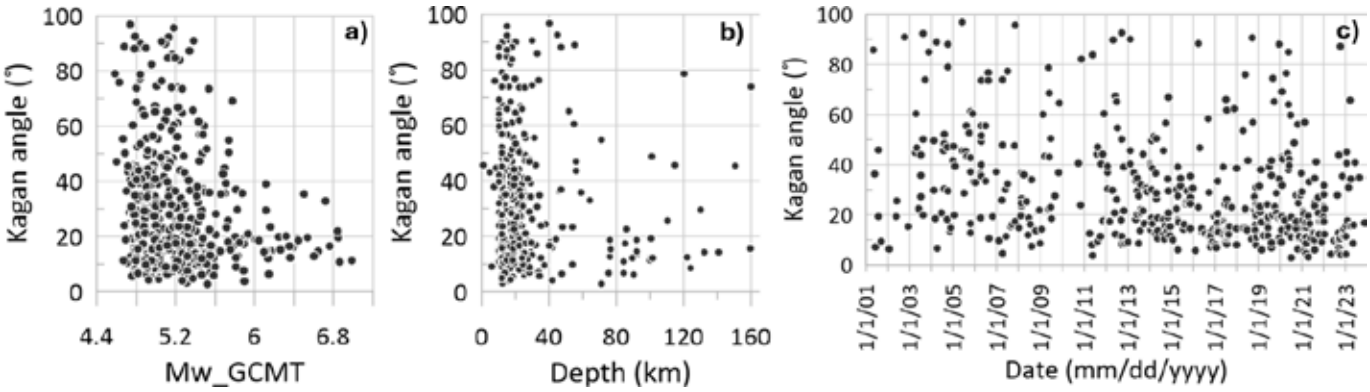

Figure 4. Distribution of computed Kagan angles with respect to a) Mw_GCMT, b) the hypocentral depth of the earthquakes in the examined dataset and c) the date of occurrence of the earthquakes considered to coincide with the date of MT solutions release.

Comparison of GCMT and National Observatory of Athens moment tensors: Mw

The moment tensor is derived by modeling the full waveform and amplitude of the seismic waves, providing the most accurate measure of earthquake energy to date. The radiated seismic energy, in turn, is directly related to the seismic moment and, through it, to the Mw. Thus, the routine computation of MTs has provided a rich dataset of Mw values that should be consistent around the globe. However, it has been shown that different Mw catalogs can show systematic discrepancies. This is, for example, the case of Mw reported by GCMT and Mw reported by NOA based on their respective MT solutions as highlighted by Konstantinou (2015). Konstantinou (2015) collected MTs from GCMT and NOA concerning the same earthquakes and the period May 2001 to October 2014, formed a dataset of 185 paired MTs and examined the differences in their respective Mw values. He concluded that NOA Mw values are smaller than GCMT Mw values by 0.15-0.25 magnitude units and attributed this rather systematic difference to the limited bandwidth in NOA inversions methods with respect to GCMT.
In this final part of our work, we use our paired GCMT-NOA MTs to perform a similar comparison to that performed by Konstantinou (2014). It should be noted that in addition to the differences that may arise from the different methods, data, and metadata of the two MT solution sources, there are also minor differences that may result from the post-processing of the moment tensor metrics. These arise, for example, from the use of a slightly different relation to calculate Mw from the seismic moment, M_0 (Kanamori, 1977; Hanks and Kanamori, 1979), the form of these relations (i.e., to be used with M_0 in N×m or in dyn×cm and rounding tactics of the relations constants), and from different rounding tactics of the reported Mw. To constrain the latter, we have recalculated the Mw of both GCMT and NOA directly from the reported values of M_0 using Kanamori's (1979) relation. The comparison of the derived sets of Mw values is shown in Figure 5a and the result of the standard regression is expressed by the blue thick line described by:

$$Mw_NOA=1.032(\pm0.014)Mw_GCMT-0.367(\pm0.074) \quad (1)$$

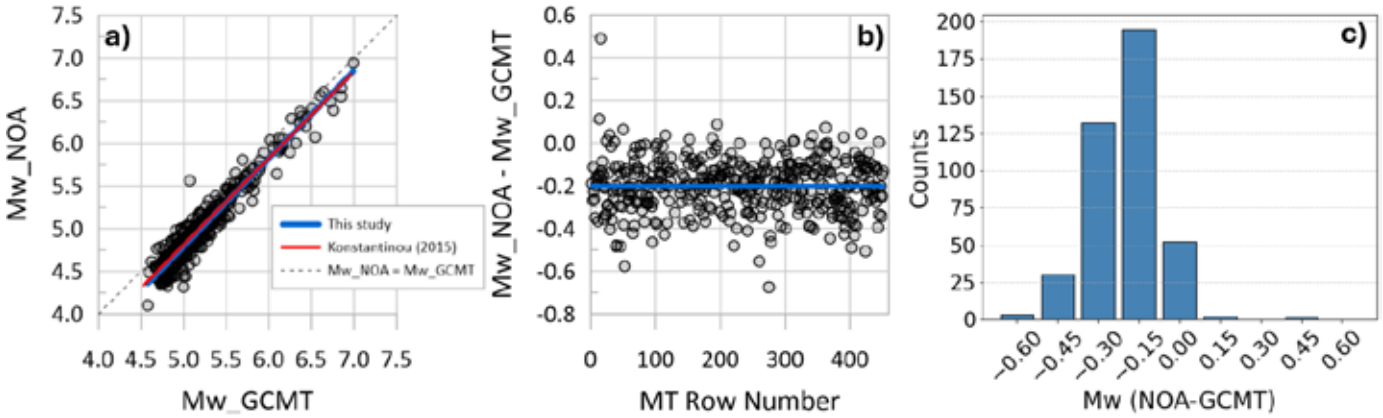

Figure 5. a) Moment magnitude of NOA (Mw_NOA) versus moment magnitude of GCMT (Mw_GCMT) from the corresponding moment tensors. The thick blue line indicates the standard regression result of this study, the red line the orthogonal regression results of Konstantinou (2015) and the dashed gray line the 1:1 relation. b) Differences of the two examined Mw sets with the blue line marking the average difference of 0.2 magnitude units. c) Distribution of Mw differences in 0.15 difference bins.

Equation (1) shows a coefficient of determination R^2=0.93, which is slightly improved (by 0.01) compared to that of the relationship of Konstantinou (2015), despite the fact that our dataset is more than twice as large. Our result is also compared graphically with that of Konstantinou (2015) in Figure 5a, where it is evident that the two lines are practically identical in the upper half and differ only slightly towards lower magnitudes. In fact, our result seems to deviate more from the 1:1 line (gray dashed line) as the magnitude decreases.
Figures 5b,c show the distribution of the differences between the two magnitudes in our dataset, and the blue line shows the practically constant mean of -0.20. Almost all differences are below zero, confirming that Mw_NOA is systematically lower than Mw_GCMT.

Conclusions/Discussion

We present preliminary results of an extensive statistical investigation and comparison of moment tensors (MTs) of earthquakes in the Aegean Sea and surrounding area, using data from the Global Centroid Moment Tensor (GCMT) project and the Institute of Geodynamics of the National Observatory of Athens (NOA). We investigate the MTs with respect to the implied faulting type during strong to moderate magnitude earthquakes in the area, the moment magnitudes (Mw), and the consistency between the two datasets.
Statistical analysis of the GCMT's 40-year archive of 746 MTs for the area showed that approximately 80% of this dataset consists of solutions for earthquakes with Mw<5.5. It also showed that although normal faulting is more frequent, reverse faulting accounts for the largest share of seismic moment release in the form of larger earthquakes. This is consistent with the mechanics involved, which are not facilitated by gravity as in normal faulting, with compressional forces often "locking" large areas and preventing movement for extended periods. This allows for the long build-up of stress that is eventually released in larger magnitude earthquakes.
We also examined the comparison of 450 pairs of MTs from GCMT and NOA for earthquakes from 2001 to 2023. To quantify the similarity/difference in the proposed fault geometry, we used the Kagan angle and concluded that the two compared sets of MTs show good agreement in 85% of the cases studied. Poor comparison of MTs provided by GCMT and NOA for the same events was found for only 15% of the pairs studied and was mostly associated with moderate magnitude events (Mw<5.5) along the Hellenic arc. Over time, despite methodological changes in both GCMT and NOA, the number of events with high Kagan angles has remained stable and the similarity between MT solutions may have increased over time, as suggested by the larger number of good comparisons in recent years.
A comparison of Mw values from GCMT and NOA MTs confirmed previous studies (e.g., Konstantinou, 2015) that NOA Mw values are systematically lower than GCMT Mw values by an average of 0.20 magnitude units. Regression analysis of Mw values showed that this difference is consistent across the magnitude range, with a slightly larger deviation from the 1:1 Mw_NOA - MwGCMT relationship as magnitude decreases.

Acknowledgements

We acknowledge the Global Centroid Moment Tensor project and the National Observatory of Athens for the invaluable moment tensor data provided for decades. The study was carried out in the framework of the research project "UNMASK", supported by the

Hellenic Foundation for Research and Innovation (H.F.R.I.) under the “2nd Call for H.F.R.I. Research Projects to support Faculty Members & Researchers” (Project Number: 2724).

EXTENDED ABSTRACT 058

Environmental Seismic Intensity Scale (ESI 2007)

Deligianni Stamatia
(1) University of Aegean, Mytilene, Greece, stamatia.deligianni@gmail.com

Introduction / Background

The Environmental Seismic Intensity Scale (ESI 2007), introduced by the International Union for Quaternary Research (INQUA), is an innovative tool for quantitatively assessing macroseismic intensities. The scale comprises 12 levels, based exclusively on the environmental impacts of earthquakes, such as surface ruptures, tectonic uplifts, landslides, liquefaction, and hydrological changes. Unlike traditional macroseismic intensity scales, which focus on damage to anthropogenic structures, ESI 2007 relies on physical observations, eliminating uncertainties associated with socioeconomic and cultural factors (Michetti et al., 2007).

The ESI 2007 scale offers several advantages over traditional macroseismic intensity scales. First, it relies on natural data, providing an independent assessment of earthquake intensity while reducing the influence of anthropogenic factors (Serva, 1994). Second, it enables the comparison of earthquakes from different time periods, geographical locations, and tectonic settings (Porfido et al., 2007). Third, the scale captures local variations in intensity, making it particularly useful in microzonation studies (Ota et al., 2010). Additionally, it is suitable for assessing seismic intensity in areas without anthropogenic infrastructure or population coverage (Tatevossian, 2007). Finally, the integration of paleoseismological data enhances the understanding of seismic hazards and contributes to the development of long-term risk management strategies (Serva et al., 2016).

Despite its advantages, the ESI 2007 scale has certain limitations. Its application requires specialized knowledge of geological phenomena and access to high-quality data. Moreover, it does not replace traditional macroseismic intensity scales but functions complementarily, enhancing the environmental perspective (Papathanasiou et al., 2011).

The ESI 2007 is a crucial tool for site selection in seismic hazard studies. Through the analysis of environmental parameters and the mapping of geological features, the scale identifies areas of increased seismic vulnerability. These include regions with a high probability of liquefaction, active faults, and geomorphological changes. Furthermore, the use of historical and paleoseismological data strengthens predictive capabilities and the effectiveness of risk management strategies. In remote or sparsely populated areas, ESI 2007 provides critical data that cannot be derived from traditional approaches.

In conclusion, ESI 2007 is an exceptional tool for the quantitative and objective assessment of seismic intensity. It expands our understanding of the environmental impacts of earthquakes and enhances the management of natural hazards on a global scale.

Methodology

This study employs a systematic approach involving data collection, the creation of a GIS database, and the generation of maps to analyze earthquakes in western Turkey. The analyzed events include the Gediz, Simav-Kütahya, Samos-Izmir, Marmaris, and Izmit earthquakes. Data were collected from geological observations, historical records, and seismological databases. These data were integrated into a GIS system, enabling the visualization of tectonic structures and affected areas.

The map generation process involved processing geospatial data to highlight active faults, liquefaction zones, and high seismic risk areas. The analysis utilized high-resolution data, enhancing the accuracy of the mapping.

Results

The study focused on the investigation of the environmental, geomorphological, and socioeconomic impacts of five major seismic events that affected the Eastern Mediterranean and Western Turkey. The regions analyzed were Marmaris (1957), Gediz (1970), Izmit (1999), Simav-Kütahya (2011), and Samos-Izmir (2020). The collected and analyzed data provide a comprehensive view of the severity of geodynamic phenomena and their effects on both the natural and anthropogenic environment, contributing to the understanding of the mechanisms governing these phenomena.

In Marmaris, the 1957 earthquake, with an ESI intensity of 8, caused extensive surface ruptures with vertical and horizontal ground displacements of up to 2 meters. Secondary phenomena
such as liquefaction, landslides, and local tsunamis caused severe damage to agricultural lands, infrastructure, and buildings.

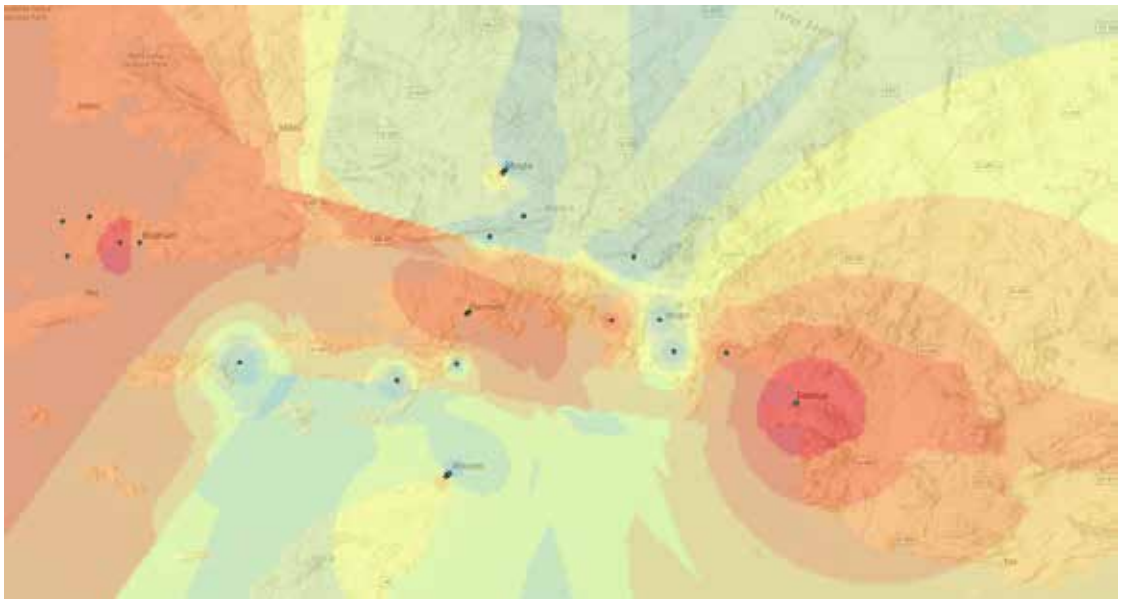

Figure 1. Map of Seismic Intensity Curves for the 1957 Marmaris Earthquake.

The Gediz earthquake of 1970, with an ESI intensity of 7, resulted in intense geomorphological phenomena such as subsidence and landslides. The impacts were catastrophic for the local economy and population, leading to building collapses and disruptions to critical infrastructure, necessitating extensive restoration efforts.

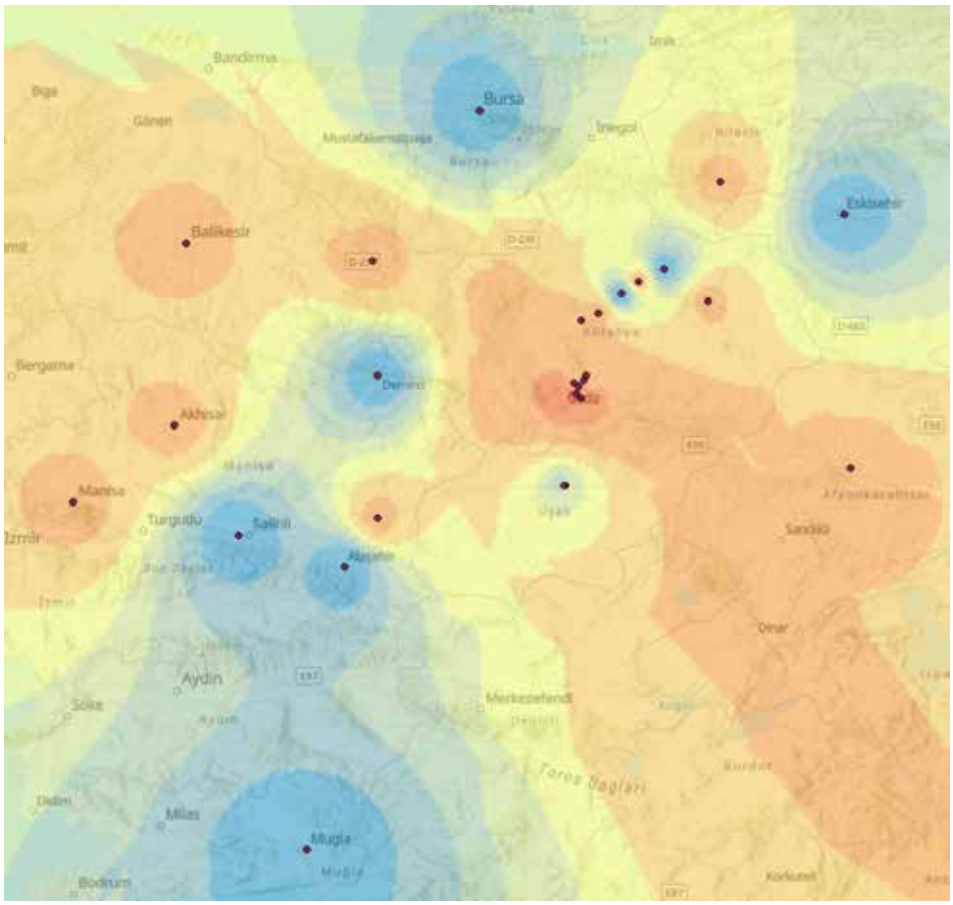

Figure 2. Map of Seismic Intensity Curves for the 1970 Gediz Earthquake

The 1999 Izmit earthquake, with an ESI intensity of 8, was one of the most destructive events, with extensive ruptures exceeding 150 kilometers in length and ground displacements surpassing 5 meters. The geomorphological and anthropogenic impacts were dramatic, as industrial zones and residential areas were destroyed, resulting in numerous fatalities and injuries.

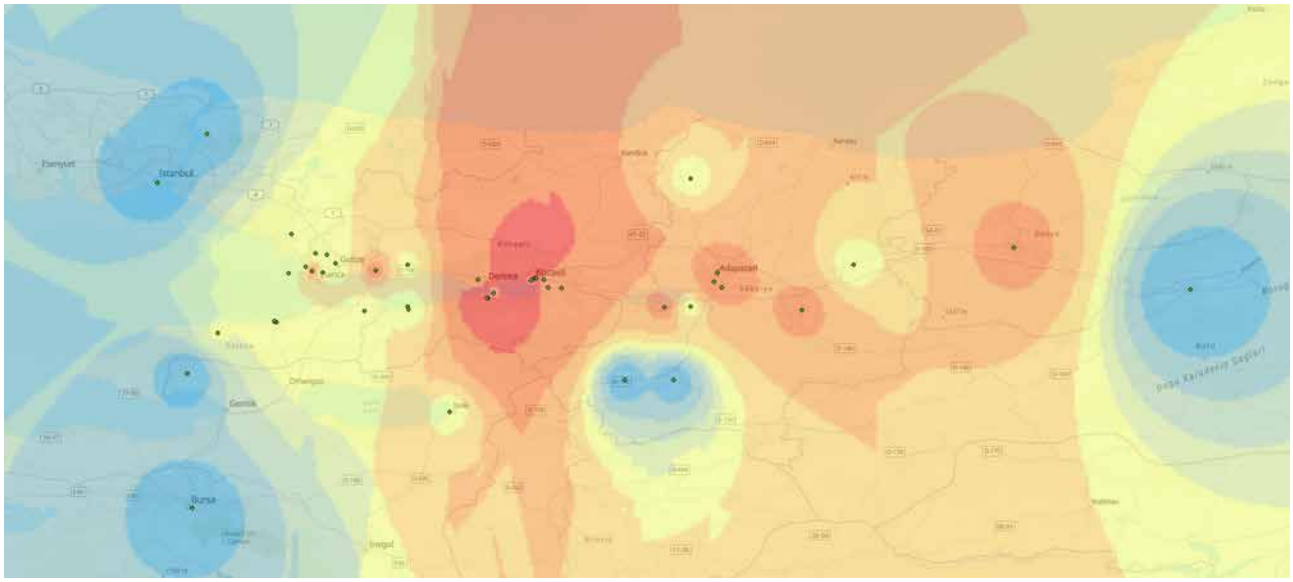

Figure 3. Map of Seismic Intensity Curves for the 1999 Izmit Earthquake.

The 2011 Simav-Kütahya earthquake, with a lower intensity (ESI 6), caused significant geomorphological changes, including widespread subsidence and new landslides. These alterations affected local ecosystems, infrastructure, and the daily lives of residents, requiring substantial restoration efforts.

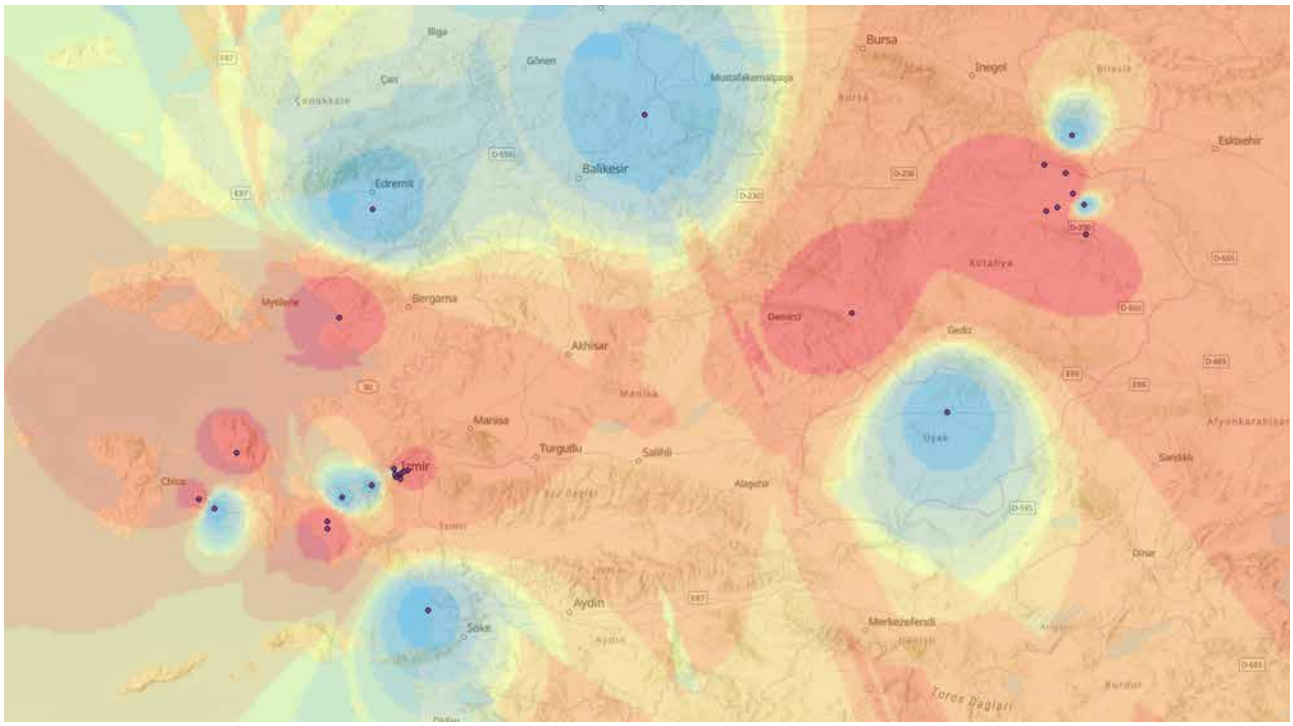

Figure 4. Map of Seismic Intensity Curves for the 2011 Simav - Kutahya Earthquake.

Finally, the 2020 Samos-Izmir earthquake, with an ESI intensity of 8, caused a combination of geodynamic phenomena. Extensive ruptures with displacements of up to 5 meters, as well as secondary impacts such as

liquefaction, landslides, and tsunamis, had devastating consequences for coastal zones and urban centers, with severe socioeconomic impacts.

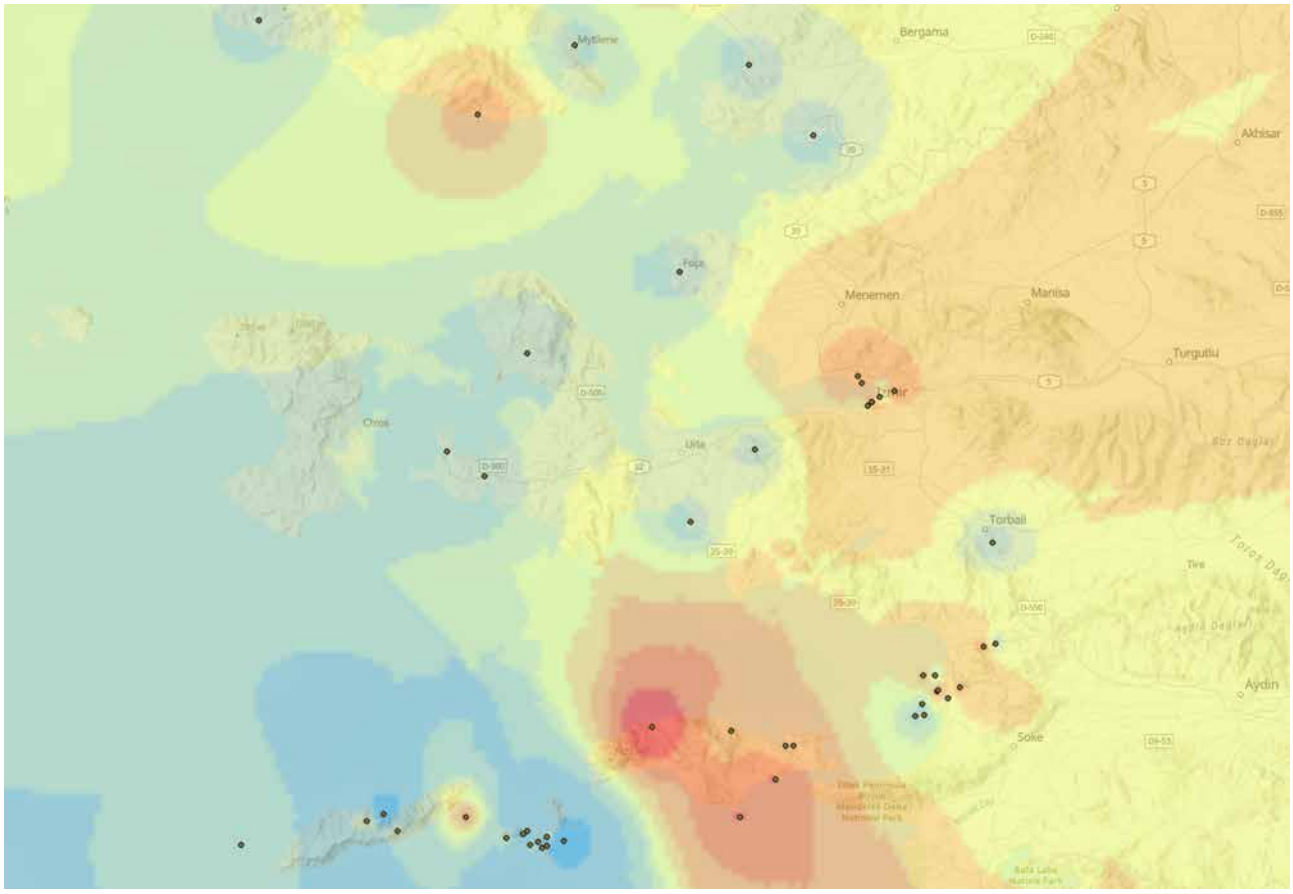

Figure 5. Map of Seismic Intensity Curves for the 2020 Samos - Izmir Earthquake.

Comparison with the Mercalli Scale

This study emphasizes the comparison of earthquakes in five significant regions of the Eastern Mediterranean using the Mercalli and ESI 2007 scales to assess their impacts. The earthquakes of Gediz (1970), Izmit (1999), Simav-Kütahya (2011), Marmaris (1957), and Samos-Izmir (2020) are evaluated based on their primary and secondary consequences on the anthropogenic and natural environments. The Mercalli scale focuses on damage to infrastructure, human casualties, and perceived impacts by human populations, while the ESI 2007 scale records geological and environmental changes, such as ruptures, ground liquefaction, landslides, and morphological alterations.

Specifically, the Izmit and Samos-Izmir earthquakes exhibited intense ruptures and extensive geomorphological changes, demonstrating the utility of the ESI 2007 scale for understanding impacts at a natural level. On the other hand, the Gediz and Simav-Kütahya earthquakes showed more pronounced social impacts, such as residential destruction, effectively captured by the Mercalli scale. The Marmaris earthquake, with its significant effects on both the anthropogenic and natural environment, underscores the need for a combined use of both scales for a more comprehensive understanding of impacts.

The comparison of these scales reveals that their integration provides valuable complementary data for better understanding and managing seismic risks and their impacts. The findings highlight the importance of a multidimensional approach to seismic analysis for improved preparedness and recovery.

Discussion

To visualize the above results, contour maps were created in GIS, capturing the deformation of the Earth's surface. The geometry of the contour lines was examined to determine whether the ellipsoidal shape formed by the contours aligns with the orientation and geometry of the fault responsible for each earthquake. The findings revealed that, in most cases, the shape of the contour lines matches the location and mechanism of the main fault, highlighting the

dynamics of the geodynamic phenomena.
For instance, in the case of the Gediz earthquake (1970), the contour maps depicted deformation aligned with the fault in the area, with the intensity of deformation being stronger near the fault and gradually diminishing with distance. In the case of the Samos-Izmir earthquake (2020), the contour maps captured the deformation caused by the offshore fault between Samos and Izmir in great detail. The ellipsoidal shape of the contours was consistent with the orientation of the fault, highlighting zones of intense deformation concentrated in the coastal areas and urban centers of the region. The contour lines revealed higher deformation values close to the fault, gradually decreasing towards the interior of Izmir and Samos. Moreover, significant secondary impacts such as landslides and liquefaction were recorded in areas of greater deformation. This analysis provided a clear depiction of the dynamics of the seismic event and its geomorphological impacts.
While the comparison between the Mercalli and ESI 2007 scales, presented in the Results section, highlights their complementary nature in evaluating seismic impacts, the Discussion focuses on the limitations and broader implications of these tools. The Mercalli scale, despite its widespread use in capturing human-centric impacts, is limited in its ability to detail geomorphological and environmental changes. Conversely, the ESI 2007 scale excels in documenting geological alterations but may face challenges in highly urbanized regions or in areas where secondary phenomena like tsunamis obscure field evidence.
One critical finding of this study is the role of ESI 2007 in enhancing the spatial and environmental understanding of seismic phenomena. By focusing on physical deformation, such as ruptures and landform changes, ESI 2007 provides insights that are often overlooked by traditional scales like Mercalli. However, its reliance on field observations introduces practical limitations in remote or inaccessible terrains. To address these challenges, future research could incorporate remote sensing technologies, such as LiDAR, InSAR, and satellite imagery, to supplement and expand ESI 2007 analyses.
The integration of both scales offers a multidimensional approach to seismic risk assessment. While the Mercalli scale effectively captures social and structural impacts, ESI 2007 adds a layer of detail about environmental consequences. This dual perspective is particularly valuable for regions like Samos and Izmir, where both anthropogenic and natural environments were significantly affected by the 2020 earthquake.
Furthermore, previous studies, such as Michetti et al. (2007), emphasize the utility of ESI 2007 in regions with significant environmental changes. Our findings build on this by demonstrating how integrating ESI 2007 with Mercalli can provide a more comprehensive framework for seismic preparedness and recovery strategies. This approach could be further refined by applying machine learning algorithms to analyze patterns of seismic impact across multiple datasets, enhancing predictive models for future events.
In conclusion, this study underscores the necessity of a multidimensional framework for analyzing seismic phenomena. The integration of the Mercalli and ESI 2007 scales not only broadens the understanding of seismic impacts but also contributes to more effective disaster risk reduction strategies, emphasizing the value of combining geological, environmental, and social perspectives.

Acknowledgments

I would like to express my heartfelt gratitude to Professors Alexandros Chatzipetros, Spyridon Pavlidis, and Georgios Drakatos for their invaluable guidance and unwavering support during the completion of this dissertation. Their expertise and insightful scientific observations significantly contributed to the shaping of this study and the enhancement of my scientific approach.
Their contribution was pivotal, and I extend my sincere appreciation for their continuous support throughout my academic journey.

Introduction

This paper presents new geochemical and mineral chemistry data of the Early Triassic granitic rocks of Miriofito intrusion, which comprises part of the Kerkini Granite Complex (KGC), in northern Greece (Poli *et al*., 2009). We revisit the issue of petrogenesis of Miriofito granite (MIR) which, according to available literature data, illustrates, together with the main Kerkini intrusion, variable behaviour combining A- and I-type characteristics (Christofides *et al*., 1999; 2007; Poli *et al*., 2009; Himmerkus *et al*., 2009). The main objective of the study is to examine the geochemical characteristics of MIR, as well as to contribute to the existing knowledge regarding the granite's tectonic setting.

Regional Geology

The Serbo-Macedonian massif (SMM) is a NW–SE-trending crystalline complex consisting of amphibolite- to granulite-facies gneisses and schists, and together with the Rhodope massif to the east, constitutes the crystalline core of the internal Hellenides. The SMM comprises two major basement units, the Vertiskos and Kerdilion (Kockel *et al*., 1978; Kilias *et al*., 1999; Himmerkus *et al*., 2007). The Vertiskos unit occupies the central part of the SMM and is mainly composed of felsic augen and mica gneisses which attained amphibolite-facies conditions. U-P zircon dating on the crystalline rocks of this unit revealed three major magmatic episodes: i) 458.8 ± 11 M and 460 Ma (Himmerkus *et al*., 2007; Papapavlou, 2021), ii) 300 ± 1 Ma from the central part of the Arnea Pluton (Abbo *et al*., 2020), and iii) 243.6 ± 1.5 Ma for the Arnea A-type granitoid and 247 Ma for Kerkini granite complex (Poli *et al*., 2009).
The Kerkini granite complex (KGC) comprises a large intrusion, the Muries granite (MUR), and two smaller bodies, the Miriofito granite (MIR) and the Kastanousa granodiorite (KAS) (Christofides *et al*., 1999).

Methods

Seven (7) granite samples were collected from two areas, five (5) from Miriofito and two (2) from Kerkini (Fig. 1). The mineralogical composition of the samples was determined using optical microscopy, Scanning Electron Microscopy accompanied by Energy Dispersive System (SEM/EDS) and X-ray Diffraction analysis (XRD). Geochemical analyses included X-ray Fluorescence Spectroscopy (XRF) and Inductively Coupled Plasma Mass Spectrometry (ICP-MS).

Results and Discussion

The typical MIR rock type is a biotite-bearing (±muscovite) granite which ranges to (±muscovite) leucogranite (Fig.1). It consists of a high content of quartz, K-feldspar, albite and Fe-biotite (annite). The characteristic micrographic texture of quartz in K-feldspar, the perthitic K-feldspar and the occurrence of anorthoclase in the studied rocks indicate that this granite represents the last stage of crystallisation, at shallow intrusion depth and high PH2O (subsolvus granite). Mineral relationships show that biotite is a late magmatic phase after feldspar crystallisation. The mineral chemistry of biotite reveals that the primary ferroan magmatic biotite has been re-equilibrated by a hydrothermal fluid. Muscovite is entirely phengitic in composition and represents a secondary phase forming at the expense of the primary magmatic minerals. In the profoundly altered parts (veins, cracks) minerals such as grossular, fluorite, epidote, monazite, Fe-Ti oxides and sulfides occur.
Geochemically it is a high-K to ultrapotassic granite, variably peraluminous i.e. low- to high-peraluminousity as indicated by the ASI (= mol. $Al_2O_3/CaO + Na_2O + K_2O$) values i.e. 1 to 1.25. The trace element systematics indicate the dominant role of K-feldspar and minor plagioclase fractionation in the differentiation of Miriofito

intrusion. Advanced fractional crystallisation is supported by large depletions of Sr-Ba-Eu, P and Ti associated with feldspars, apatite/monazite and Fe-Ti-oxides (rutile, ilmenite) respectively.
In the discrimination diagrams for I-S- and A-type granites the Miriofito and Kerkini granite both straddle the field of A-type (Whalen et al. 1987). Our new geochemical data illustrates a strong enrichment of K, Cs, Rb, Th and U relative to the average continental crust, for the Miriofito granite and even more so for Kerkini granite. This enrichment is considered a source characteristic for the high-K calc-alkaline (HKCA), either juvenile crust or K- enriched lithospheric mantle. Further use of tectonic discrimination diagrams for granites (Pearce *et al*., 1984) delineates a trans-discriminant affinity for the MIR samples, between volcanic arc and within-plate environments, while other discrimination diagrams show explicitly a volcanic arc setting, or active continental margin settings. In general, rocks belonging to the high-K calc-alkaline magmatism occurs in a post-collisional setting, commonly after 30 to 50 Ma after the cessation of subduction (Bonin et al. 1990; Liégeois *et al*., 1998).

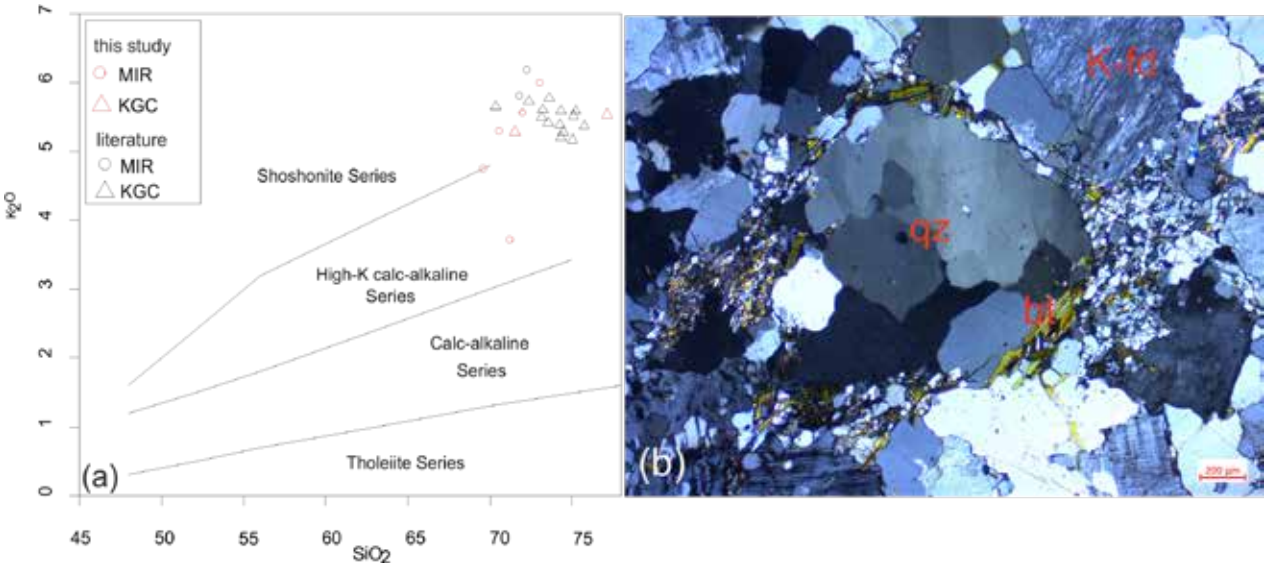

Figure 2(a) Miriofito and Kerkini samples (red symbols) plotted on the SiO_2 *vs.* K_2O classification diagram of Peccerillo and Taylor (1976). Literature data after Christofides *et al*. (1999). (b) Photomicrograph of Miriofito biotite granite (crossed pollars).

Conclusions

- Our new geochemical data agrees with published data for a common origin of Miriofito and Kerkini granite. The Miriofito granite has high SiO_2 (69.5–72.3 wt.%), K_2O (3.7–6.7 wt.%) and Na_2O (3–4 wt.%) and low MgO (0.02–0.4 wt.%) and is ferroan alkali-calcic in composition. It belongs to the high-K magma series and is a highly fractionated and peraluminous A-type granite.
- Petrographic evidence indicates that the granite rose to shallow crustal levels and underwent advanced fractional crystallisation of K-feldspar, minor plagioclase, apatite, and Ti-bearing phases (rutile, ilmenite, titanite).
- Tectonic discrimination diagrams indicate that the whole complex Kerkini-Miriofito-Kastanousa intrusion was likely formed in a post-collisional setting, linked to a transition in the geodynamic setting from an arc-related to a post-collisional extensional setting in the Vertiskos realm.
- The main point is that the generation of the HKCA magma needs the former existence of an important subduction phase to generate this type of source. The K-enrichment event is considered to reflect a subcontinental mantle enrichment /or K-rich mafic crust from the preceding subduction period.

Research Highlights

In this study we argue about the biogenicity of biomorphous structures related with As-mineralization from the Kolumbo diffuser chimneys based on their syngenicity and indigenousness, geological context, morphology and composition.

Introduction

Modern seafloor hydrothermal vents present a hostile environment for life which consists of high acidity, discharge of high-temperature magmatic gases and potentially toxic metal(loids) such as As, Sb, Pb, Tl. Arsenic is widely recognized as a major pollutant for marine ecosystems and a potentially toxic element harmful to most living organisms (Hu *et al*., 2020). It is established that hydrothermal vent fields are a vast microbial habitat, hosting a significant population of microorganisms (Runge *et al*., 2023, Kilias *et al*., 2013) Furthermore, this kind of environment is regarded as analogue for the emergence of primordial life while As-enriched oceans are considered a potential cradle for the origin of life (Russel *et al*., 2005, Hu *et al*., 2020). To endure direct exposure to such extreme environments, various microbial species have evolved resistance mechanisms involving detoxification, biotransformation and even generating energy by oxidizing arsenite. (Hu *et al*., 2020). It is well known that microorganisms in the hydrothermal vents can contribute significantly to the formation of mineral deposits rich in metal(loid)s (Southam and Saunders, 2005, Kilias *et al*., 2013). However, little is known about the microbial processes associated with the precipitation of arsenic sulfides. (Hu *et al*., 2020). Here we present morphological, mineralogical and geochemical evidence for the biogenicity of arsenic sulfides on the active hydrothermal diffusers at Kolumbo arc volcano.

Geological Background

The submarine volcano of Kolumbo located in the Anhydros Basin, Aegean Sea as part of the Christiana-Santorini-Kolumbo volcanic field that lies in the center of the Hellenic Volcanic Arc (HVA). Kolumbo crater has a basal diameter of 3 km with NE-SW orientation. (Hector *et al*., 2024). On top of the crater lies an active hydrothermal vent field with diffuser chimneys emitting shimmering water to ~265°C pure gaseous CO2 fluid forming, a polymetallic Au-rich Seafloor Massive Sulfides (SMS) deposit. The studied samples present four distinct mineralogical zones. The thick porous Inner Sulfide-Sulfate Core (ISSC) is composed of barite, pyrite, marcasite, sphalerite, galena, Pb-Sb sulfosalts, minor anglesite, and minor chalcopyrite. Surrounding the ISSC is the Outer Arsenic Layer (OAsL), which contains barite, pyrite, sphalerite, Pb-Sb sulfosalts, stibnite, As-Pb-Sb sulfosalts, and amorphous arsenic-rich sulfides resembling realgar and orpiment. Encasing the OAsL is a gelatinous orange to brown Surface of Fe-rich Microbial Crust (SFeMC), primarily composed of amorphous Fe-(hydrated)-oxyhydroxides. In this study we focus on the OAsL where the As-related biomorphous structures are observed on that layer (Kilias *et al*., 2013).

Materials and methods

Sampling

The samples studied were collected during two oceanographic expeditions collected from the northern part of the Kolumbo crater floor using the Remotely Operated Vehicles (ROV) Hercules and Max Rover.

Optical microscopy and Scanning electron microscopy

All samples were petrographically examined via transmitted and reflected light microscopy at the Department of Geology and Geoenvironment, National and Kapodistrian University of Athens (NKUA). The biomorphous structures were further observed under a Scanning Electron Microscope (SEM) in order to a) examine the morphologies and textural relationships under high magnification, b) obtain semi-quantitative X-ray elemental maps. For that purpose, a Nova NanoSEM Field Emission-SEM (FE-SEM) was utilized, equipped with, a BacksSattered Electron (BSE) detector, a Secondary Electron (SE) detector, and a Bruker X Flash EDS detector. Samples were carbon-coated with an average thickness of 15 nm, to achieve surface conductivity, and the instrument was operated at a 30-kV accelerating voltage, while electron beam stability was calibrated using a copper standard.

Raman spectroscopy

Raman spectroscopy analyses were performed using a Renishaw inVia Raman confocal microscope, equipped with two lasers, emitting at 532 (green) and 785 nm (red). The green and red lasers are coupled with gratings of 1800 and 1200 groves per mm^2, respectively. Spectra were obtained using the 785 nm laser with a power range between 0.5 and 0.05 mW, due to the varying stability and fluorescence of the analysis spots. Samples were exposed to the laser through a long-focal distance, 50X objective lens with 0.55 numerical aperture, and with the measured spectral range extended from 100 to 3200 cm^{-1}. The obtained spectra were then processed by the WiRE software for Windows. Background noise was reduced by the subtraction of a polynomial baseline, and cosmic ray removal corrections were performed for all spectra.

Results

Optical Microscopy

To provide a detailed description, the biomorphous structures are classified in three types based on morphology as well as differences in chemistry. Type 1 structures are identified as diatoms species. Type 2 are filamentous biomorphs. Type 3 are globular biomorphs. Diatom morphology is very evident in Fig. 1. After thorough observation and due to morphology and spectroscopic data (see below) we conclude that it belongs to Chaetoseros sp., one of the most diverse planktonic diatom species (De Luca *et al*., 2019). The main characteristic of the family is the existence of setae that appear to come out from the valve of the cells. Setae help diatoms create chains of cells that a expand for tens of micrometers. To prevent the chains from extending too far, terminal setae are produced from several cells. Each cell exhibits an outer layer known as frustule. It is crucial to mention that diatoms in this study demonstrate different levels of As-mineralization. Diatoms are mostly observed in open spaces and in close association with barite.

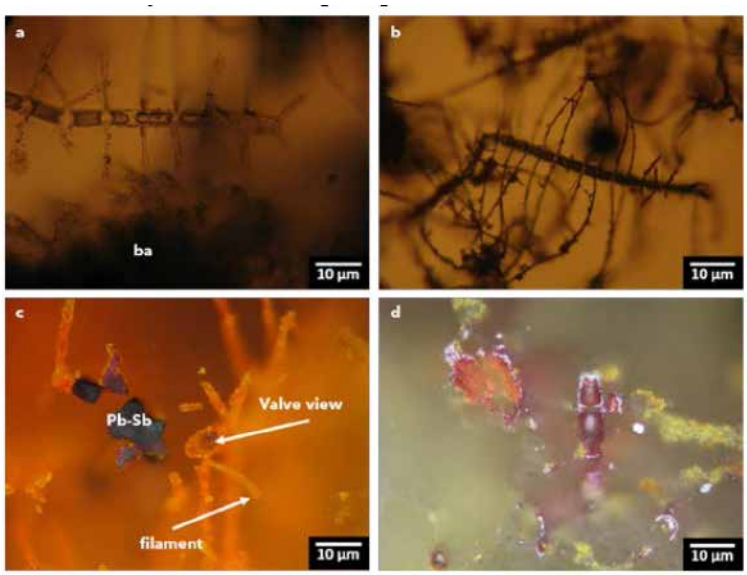

Figure 1. a) Two non-As-mineralized diatom chains with visible intercalary and terminal setae, also the frustule and aperure are very clear b) Partially mineralized diatom with longer setae c) Valve view of a diatom, partially mineralized frustule and setae, also a filamentous type 2 biomorph can be observed d) Fully mineralized diatom, only the cells remain

The type 2 biomorphous structures are filamentous and extend up to several tens of micrometers. Depending on their width, a stibnite core is visible which appears black or gray depending on parallel or crossed polaroids under reflected light, while arsenic is mostly in the form of orpiment. The filaments exhibit a plethora of different characteristics. (Fig. 2). Some of them appear more lineal and demonstrate terminal swelling while others exhibit twisting and branching or even septated structures (Qu *et al*., 2023). Sometimes those can co-exist. The thinner filaments tend to form net-like structures and exhibit pinching (Hu *et al*., 2020). Furthermore, in some cases filaments appear to grow on diatoms (Fig 2. c). It is important to note that even the thinner filaments exhibit a stibnite core, but it is not always visible due to scale. The filaments are usually found as intergrowths with stibnite and Pb-Sb sulphosalts on a barite substrate as they also develop in open space. Type 3 biomorphous orpiment like structures are quite different in morphology

(Fig. 3). They appear as globules either observed on diatoms (mostly on setae) or forming grape-like structures in open spaces. Their diameter is not bigger than 3 micrometers. They can be found in association with filaments as well. (Fig. 4). It is interesting that when a lineal substrate appears (like a diatom seta or a needle-like stibnite) these globular biomorphs can display a string of beads (Qu *et al*., 2023).

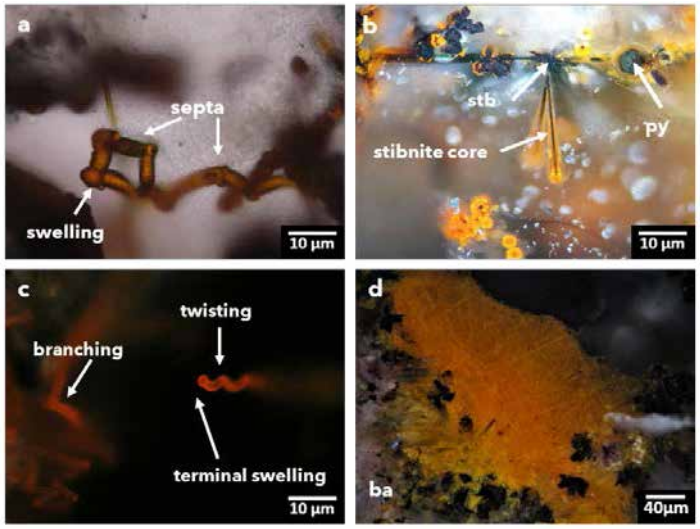

Figure 2. a) Thick filament with swelling and septated structures b) Linear filament with visible stibnite core c) Filaments that exhibit branching as well as twisting and terminal swelling on the same time d) Thinner filaments with net-like structures on a barite substrate.

Mineral Chemistry-SEM EDS

Further detailed geochemical analyses on biomorphous structures were performed by SEM-EDS to evaluate their chemical composition. The results showed the presence of As-sulfide in all the examined biomorphs. Regarding type 1 biomorphs, SEM-EDS confirmed the presence of silica which further proves they are diatoms. As it has been established, diatoms are known to form silica cell walls (Hildebrand, 2008). It is evident (Fig. 5) that silica is distributed on the frustule as well as on setae. When it comes to filamentous biomorphs, SEM-EDS confirms the stibnite core as well as the As-sulfide shell and absence of silica. As for the globular biomorphs, arsenic, antimony and sulfur seem to be equally dispersed.

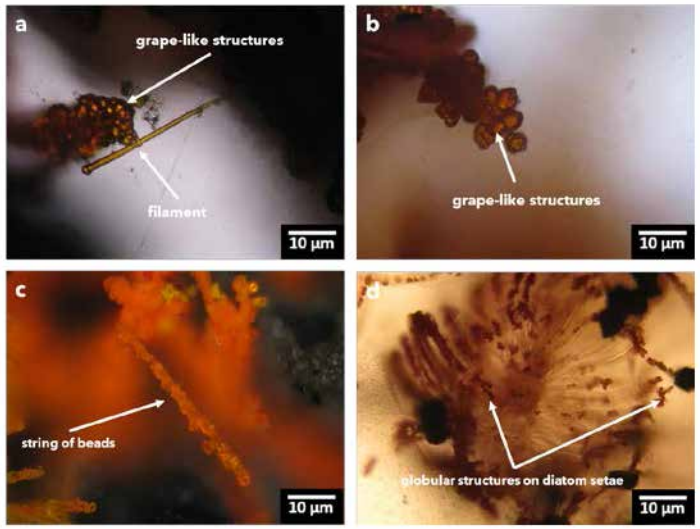

Figure 3. a) Globular structures in asociation with filaments b) Grape-like structures in open space c) Globular biomorphs forming a string of beads d) Globules on diatom setae

Spectral characterization of biomorphous structures

The contribution of Raman spectroscopy for this study was crucial. Point analyses revealed the presence of carbonaceous matter (CM) in all the biomorphs under investigation. Raman mapping was used to better understand the pattern of mineral phases on the studied biomorphs. Spectroscopic data showed the presence of amorphous hydrated silica and orpiment (As_2S_3) and realgar (As_4S_4) mineralization on biomorphous structures (Papoutsa *et al*., 2024). The occurrence of CM as a structural component was verified by the occurrence of first order (1000-1650cm^{-1}) and second-order (2500-3200 cm^{-1}) bands (Papoutsa *et al*., 2024). The notable features consist of a prominent G-band at 1583 cm^{-1}, distinct from the D2 band at approximately 1608 cm^{-1}, along with clearly defined D1 and D4 peaks at 1347 cm^{-1} and 1245 cm^{-1}, respectively. G/D2 band ratio was used to better interpret the distribution of CM. For the type 1 biomorphs, Raman peaks at ~490, 602, 812, 980 and 1000 cm^{-1} are indicative of Si-OH (hydrated silica) that compose the diatomaceous cell wall (Papoutsa *et al*.,2024). The hydrated silica seems to be concentrated mainly on the frustule. Regarding the filamentous biomoprhs, Raman spectroscopy confirmed the presence of stibnite core and orpiment-realgar shell. CM was also identified within the structure.

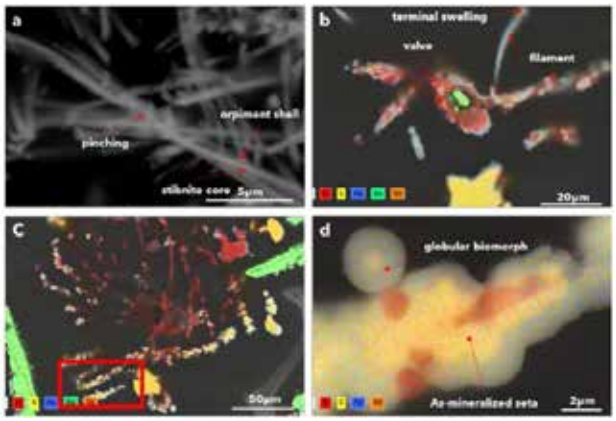

Figure 4:FE-SEM microphotographs and elemental maps of biomorphs. a) Open space filamentous cluster exhibiting pinching features. Note the differentiation in brightness, indicating the presence of a denser stibnite core. b) Microphotograph of As-filament and valve view of a diatom. Note the characteristic presence of Si on the diatom frustule and the absence of Si in the filament. c) Partially mineralized diatom. d) Zoomed area of C (red box) showing the replacement of Si by As and Sb sulfides. Globular biomorphs can be observed growing on the surface of mineralized diatoms. Also displaying a distinct Sb-rich core and an As-rich shell.

As for the globular structures, CM and orpiment were identified as well. However, it is important to note that their small diameter approaches the limit of spatial resolution of Raman mapping with the available objective lens. Regardless that, Raman maps of CM distribution in the type 3 structures, were successfully constructed.

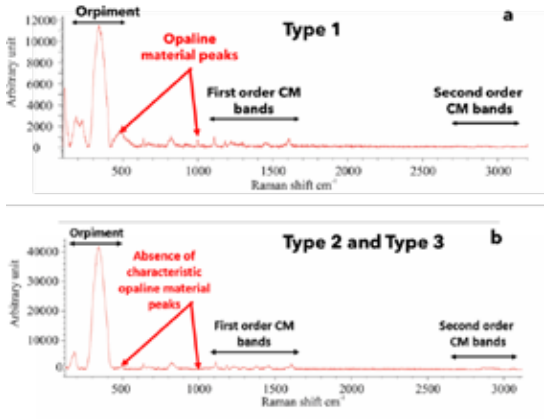

Figure 5. a) Point analysis of a diatom frustule with visible CM peaks, orpiment peaks and opaline material peaks b) Point analysis of filamentous and globular structures with CM and orpiment peaks, also absence of opaline material peaks as it is characteristic for diatoms.

Criteria for biogenicity

To examine the biogenic origin of the aforementioned biomorphs, 4 criteria were tested. (Ivarsson *et al*., 2015)

Geological context

Modern hydrothermal vent fields associated with Seafloor Massive Sulfides (SMS) deposition are widely regarded as significant microbial habitats (Hu *et al*., 2020). They sustain extraordinary biological communities, featuring rare and endemic species uniquely adapted to the conditions of hydrothermal vents (Georgieva *et al*., 2021). SMS being the closest modern analogue of ancient Volcanogenic Massive Sulfides (VMS) deposits, which are proven to be one the earliest known habitats for microbial life (Hu *et al*., 2020). Therefore, these types of environments are closely associated with the history of life and its origination (Hu *et al*., 2020, Georgieva *et al*., 2021). The fossil record of hydrothermal vents possibly represents the earliest direct evidence of life on Earth, highlighting their significance as biological habitats throughout Earth's history. Hydrothermal vent microbial communities consist of relatively high concentrations of a few species that rely on chemosynthesis for survival such as Proteobacteria and Campylobacterota (Georgieva *et al*., 2021).

Syngenicity and indigenousness

All the observed biomorphs, and especially the filaments and the globules, originate from the surface of the minerals present (As-Pyrite, Pb-Sb-sulfosalts, orpiment) at the chimneys and/or the surface of diatoms. The transition from the mineral surface to the filaments are smooth and undisturbed (Fig. 6) indicating that the filaments grow out of the surface of minerals. In cases, the open pore space has been colonized from a biofilm which filamentous net-like and globular grape-like structures grow (Fig. 3). The existence of the biomorphs on the outer layer of the chimneys and their close association with the primary sulfide minerals indicates that microbial activity was synchronous with the arsenic mineralization. These observations coupled with high counts of genes associated with arsenic oxidation (Papoutsa *et al*., 2024) suggest that the filamentous and globular biomorphs are indigenous of the chimneys and syngenetic with the As-sulfide deposition. Diatoms are not usually inhabiting hydrothermal vents, rather they accidentally sink from the upper levels of the water column onto the diffuser chimneys.

Morphology

The occurrence of filaments and globules as whole clusters resemble the culture media precipitates of As-respiring bacterial strain (Hu *et al*., 2020). The growth of clusters over diatoms, orpiment and other As-rich phases, achieved by penetrating and dissolving the mineral surface, mirrors microbial strategies for colonizing mineral surfaces to extract nutrients.

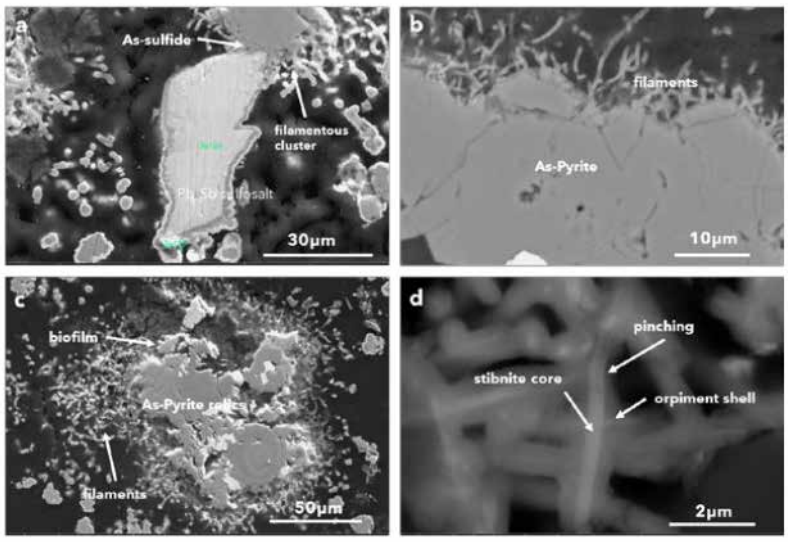

Figure 6. FEG-SEM photomicrographs of filamentous structures. a) Filaments growing on primary As-sulfides showcasing a smooth and undisturbed transition. b) Filaments growing on the surface of As-pyrite. c) Filaments colonization initiated by a biofilm formation around dissolved pyrite crystals. d) Microphotograph of thin filaments exhibiting pinching with a distinct stibnite (brighter color) core and an orpiment shell.

Composition

Despite the filamentous and globular biomorphs being embedded in epoxy resin, Raman spectroscopy revealed distinct CM within their structures. Comparisons with the spectra of the epoxy rule out contamination and confirm

that the carbonaceous matter is indigenous to the structures. Raman mapping (Fig. 7) revealed that CM is localized in specific areas such as the As-rich shell of the filaments rather than the stibnite core (Fig. 8). This suggests that indigenous CM is preserved in the late stages of the mineral paragenesis. The presence of CM in the shell of the structures agrees with other studies arguing about biogenic origin of As-sulfides (Hu *et al*., 2020) and it suggests that microbial activity was synchronous to As-sulfide deposition. Synchrotron X-ray absorption near edge structure analysis has shown that the As-

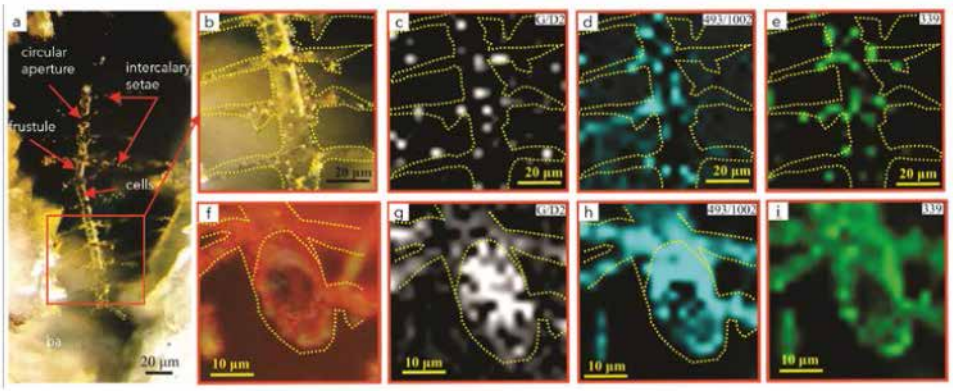

Figure 7. a) site of study b) zoomed area of Raman mapping c) distribution of CM on diatom frustule d) distribution of silica on diatom frustule e) As-Sulfide mineralization f) valve view of a diatom, another site of Raman mapping g) distribution of CM h) distribution of silica on diatom frustule i) As-Sulfide mineralization on diatom frustule and setae, it is also visible that the site in f) is more mineralized than diatom in a) (Papoutsa *et al*., 2024)

sulfides in the diffusers contain a mixture of As (II) and As (III). These heterogeneities in the valence of As can be credited to microbial activity. Metagenomic libraries constructed from the Kolumbo vents, which revealed high counts of functional genes involved in microbial oxidation of As (II) to As (III) (Papoutsa *et al*., 2024) further prove this point.

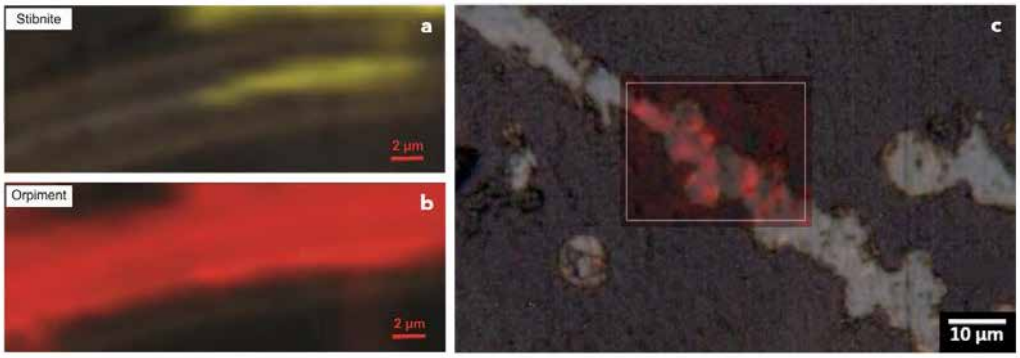

Figure 8. a) Raman map showing the distribution of stibnite in the visible core of a filament b) distribution of orpiment in the outer shell of filament (Papoutsa *et al*., 2024) c) distribution of CM on a string of beads.

Conclusions

In this study we report observations of different biomorphous structures associated with As-sulfides mineralization. Three types of biomorphs have been identified; Type 1) Diatoms, Type 2) Filaments and Type 3) Globules. The morphological features of the studied biomorphs, combined with their distinct spectroscopic characteristics and their geochemical composition along with the metagenomic data suggest that As mineralization was contemporaneous with microbial activity. The lack of diatom related gene counts in the metagenomic libraries shows that diatoms are not directly involved in the mineralization of As, rather they exist as the substrate for microorganisms to develop, providing CM and nutrient from the shallow waters to the deep sea. This theory is further supported by the fact that filamentous and globular structures seem to grow over the diatoms resembling microbial strategies for colonizing mineral surfaces.

Acknowledgments

We are thankful to NKUA for granting us access to Raman Spectroscopy at Core Facility of the School of Science. We are grateful to the Electron Microscopy Facility of the Materials Treatment Centre in VITO (Mol, Belgium) for the use of FE-SEM and the citizen

science Horizon funded project nexus-monARC for fully supporting the analyses that took place in VITO. Also, to Maria-Despoina Chrysafeni for her FE-SEM images.

EXTENDED ABSTRACT 061

Microfacies and species richness analyses of middle-late Eocene western Thrace Basin (Neotethys Ocean, Greece): Paleoenvironmental evolution and species-richness hotspot revealed

Dimou V.-G.[1], Koukousioura O.[1,2], Less G.[3], Triantaphyllou M.[4], Dimiza M.[4], Syrides G.[1], Langer M.R.[5]

(1) Aristotle University of Thessaloniki, Thessaloniki, Greece, dimouvaso@geo.auth.gr (2) University of Cologne, Cologne, Germany (3) University of Miskolc, Miskolc-Egyetemváros, Hungary (4) National and Kapodistrian University of Athens, Athens, Greece (5) Rheinische Friedrich-Wilhelms-Universität Bonn, Bonn, Germany

The Thrace region is a large Paleogene-Neogene molassic basin in the northern Aegean (Greece, NW Turkey, Bulgaria). Basin architecture is linked to middle-late Eocene NE-SW extension events, that led to the formation of a supra-detachment basin divided into three sub-basins (Alexandroupolis, Orestias and Petrota) that are characterized by a complex stratigraphy (Kopp, 1965; Papanikolaou and Triantaphyllou, 2010; Kilias *et al.*, 2013). The paleoenvironmental evolution and reconstruction of the Thrace basin (Neotethys Ocean, Greece), were carried out with the help of sedimentological, thin section and microfacies analyses (based on e.g., Flügel, 1982) and, above all, the analysis of larger benthic foraminifera (LBF) as proxies for the middle to upper Eocene carbonate deposits and their species richness.

The studied material derived from a total of 7 new sites (sub-basins of Alexandroupolis and Orestias), covering localities on the mainland [Maronia (MAR-1.2), Palagia (S1-3.2), Avantas (AVT1-15.1), Pylaea (PYL1-10) and Didymoticho (DDM1-5)] and the northeastern Aegean islands of Samothraki (SAM1-2.1) and Lemnos (LM1-2.1) (Fig. 1). In addition, results from the Kirki and Fanari sites were included in the present study (Dimou *et al*., 2021, 2023).

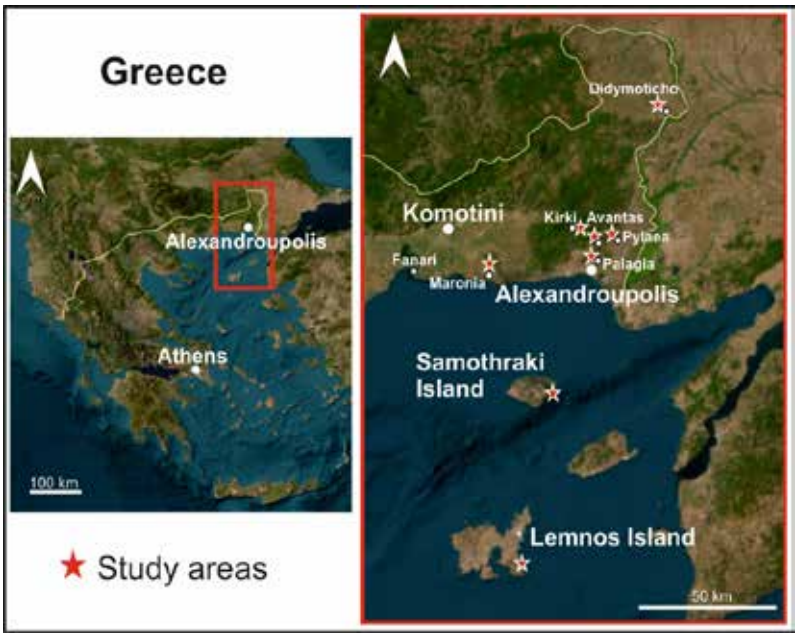

Figure 1. Overview map of Greece with the location of sampled sites marked by red stars (modified from Google Earth, Dimou *et al*., 2024).

In total, nearly 100 species have been identified. The observed foraminiferal taxa are characterized mainly by benthic foraminifera, while a few planktonic ones were obtained. The assemblage is strongly dominated by calcareous-perforate forms throughout the sequence and less porcelaneous and agglutinated. The calcareous forms are represented by the perforate orders of Rotaliida (>45 species), Vaginulinida (7 species), Polymorphinida (4 species) and Nodosariida (11 species), while porcelaneous forms are represented by *Quinqueloculina* spp. and miliolid casts, that probably belong to more than three genera. Finally, the agglutinated (10 species) forms are represented by the orders of Astrorhizida (4 species), Spirillinida (1 species), Lituolida (2 species) and Textulariida (3 species).

Among them the LBF were very diverse (43 species), with the most abundant *Nummulites fabianii*, *N. incrassatus*, *Heterostegina reticulata*, *Spiroclypeus carpaticus*, *Pellatispira madaraszi*, orthophragmines and *Asterigerina* spp.
The combination of sedimentological features and biogenic components led to the distinction of 5 microfacies types (Table 1). These can be attributed to a sequence of inner to outer shelf environments and support a model of a rimmed carbonate shelf with isolated platforms. Water circulation patterns on and between the platforms were both open and restricted. In particular, the inner shelf is characterized as a restricted environment with vegetation cover and limited water circulation (back-reef settings, MF1 and MF2). The middle shelf refers to the reef-core and platform margins with high energy conditions (MF3a-d), that passes to a lower-energy regime at a fore-reef setting (MF4). Finally, the outer platform refers to its proximal part with maximum depth of 60 m (MF5).
The Thrace Basin region represents a shallow carbonate platform during the middle-late Eocene and comprises two stages of development. Based on the remains of a late Lutetian/early Bartonian assemblage (samples from Kirki; Dimou *et al*., 2021), the existence of an older platform has been suggested, which is either demolished due to the tectonics or underlies a new transgression. The second stage refers to the onset of a late Bartonian to Priabonian platform. The Bartonian is assigned to middle / outer shelf settings and is reported only from Lemnos Island. Unlikely, Priabonian is widespread into the mainland and comprises all three main environments.
During this time interval, the dynamic syn-rifting led to the development of topographic highs, that represent favoring regions on which productive and species-rich reef structures could flourish. Based on an extensive compilation of LBF species richness from the Western Tethys (e.g., Pignatti, 1995; Less *et al*., 2011; Ferràndez-Cañadel *et al.,* 2023), we document in the carbonate deposits of western Thrace basin, well preserved and hyperdiverse, late Eocene assemblages of larger symbiont-bearing foraminifera, characterizing the study area, with 60 species, as a hotspot of LBF diversity in the Neotethys ocean.

Table 1. Summary of distinguished facies and their interpretation.

Major Microfacies (MF) Type	Texture	Main components	Minor components	Age	Paleoenvironmental interpretation
MF1: encrusting and other rotaliids-miliolids grainstone (PYL10, S3.1.1-S3.1.3)	Sparitic matrix	Encrusting and other rotaliids, coralline red algae, textulariids, miliolids	*Nummulites*	Priabonian (SBZ20)?	Protected environment, lagoon
MF2: Heterosteginid-orthophragminid packstone (AVT5-13.1)	Micritic matrix	Heterosteginids, orthophragminids, coralline red algae	Other nummulitids, small rotaliids, miliolids, agglutinants, bryozoans, corals, molluscs, worm tubes	Priabonian (SBZ20)?	Back reef, close to the reef or as a reef flat
MF3a: coral, coralline red algae, gastropods, aragonite/ magnesian calcite cemented wackestone/ packstone (AVT3-4/14-15, SAM2)	Micritic matrix	Corals, coralline red algae, gastropods, radial fibrous cement	LBF, miliolids, small rotaliids, bryozoans, bivalves, echinoids, ostracods	Priabonian (SBZ20)	Reef core, platform margins
MF3b: Corraline algae, nummulitic, bivalve wackestone/ packstone (MAR1.1, DDM1-5)	Micritic matrix	Coral patches, coralline red algae, nummulitids	Other LBF, small rotaliids, miliolids, planktonic foraminifera, bryozoans, echinoids	Priabonian (SBZ20)	Platform margins, shoal reef areas, patch reef

MF3c: Nummulitic grainstone (MAR, S2F)/ *Assilina alpina*-coral packstone (SAM1)	Sparitic matrix	*Nummulites fabianii, Assilina alpina*	*Operculina* ex. *gr gomezi, Discocyclina* sp., small rotaliids, coralline red algae, molluscs / other nummulitids, *Discocyclina* sp., small rotaliids, *Silvestriella tetraedra*, corals, echinoids, bryozoans	Priabonian (SBZ19)?/ Priabonian (SBZ19B-20)	Platform margins
MF3d: Coralline-LBF wackestone (PYL5-8)	Micritic matrix	Coralline red algae, corals, *Silvestriella tetraedra*	Other LBF, small rotaliids, miliolids, planktonic foraminifera, molluscs	Priabonian (SBZ19-20)	Distal outer platform
MF4: FAN1-16	Micritic matrix	*Nummulites*, small rotaliids	Other LBF, miliolids, planktonic foraminifera, corals, coralline red algae, echinoids, bryozoans, molluscs	Priabonian (SBZ19-20)	Fore-reef
MF5: LBF packstone (PYL1-4,9, LM1-2, AVT1-2, FAN17-21)	Micritic matrix	Orphophragminids, nummulitids	Other LBF, small rotaliids, miliolids, planktonic foraminifera, coralline red algae, echinoids, bryozoans, molluscs, worm tubes	Priabonian (SBZ19-20)	Outer platform

BULLETIN OF THE GEOLOGICAL SOCIETY OF GREECE, SP. PUBL.

EXTENDED ABSTRACT 062

Using alternative methods to promote geoheritage: the Koziakas Mt., central Greece, case study.

Dittopoulos Panagiotis Sotirios[1], Chatzipetros Alexandros. [1]
Bsc Geologist
(1) School of Geology, Department of Structural, Historical and Applied Geology, Aristotle University of Thessaloniki, 54124, Greece, geo.dittopoulos@gmail.com

***Research Highlights*:** This study demonstrates how GIS software, specifically QGIS, can effectively communicate geological research results to both the scientific community and the general public, enhancing data accessibility and interpretation while promoting geoheritage.

Introduction

Greece is renowned for its rich geological history, characterized by complex tectonic processes, diverse rock formations, and a plethora of geosites that possess scientific, educational, and cultural value. Among these, Koziakas Mt. in central Greece is an example of impressive geological formations, offering significant opportunities for both scientific research and the promotion of geoheritage. Its mountain range forms the edge of Pindos in the western part of Thessaly and rises imposingly from North to South. It covers a total area of about 400 km², making it an important landmark of the area. Geologically, the area is located at the eastern boundary of the Pindus zone and at the western boundary of the Sub-Pelagonian zone, including the important ophiolitic formations of Koziakas. The Koziakas unit, belonging to the Sub-Pelagonian, is the transitional stage from the Pindus to the Pelagonian zone.

The advent of GIS software suites has revolutionized the way geological data is collected, analyzed, and visualized. Open-source GIS programs, provide cost-effective, efficient and user-friendly platforms to create models and visualizations. These tools are instrumental in overcoming challenges associated with communicating geological information. Nonetheless, the effective communication of such data frequently encounters obstacles, such as the complexity of geological concepts, the limitations of impractical and intricate visual editing software, and the absence of user-friendly scientific data presentation platforms. The latter is of particular importance for the effective promotion of geoheritage. QGIS is the most renowned open-source GIS suite, supported by the largest community of users. This community has developed various methods, including the use of plugins, to address a range of challenges. However, the absence of geological modeling features in existing tools, hinders its adoption for geological 3D applications and visualisations. This paper explores how open-source tools, plugins and innovative visualisation techniques can address these challenges, using Koziakas Mt as a case study.

Methodology

The initial input to the area analysis is the geological maps and field data. For selected study areas, field data are collected, consisting of rock samples, images, linear, planar and point data such as rock formation dip planes, faults and locations of fossil finds. In addition, the input includes satellite orthophotos and Digital Elevation Models from the Hellenic Cadastre (Digital Elevation Model -DEM from the LSO25 project 25 m and LSO25 25 cm orthophotos, Hellenic Cadastre), the paths of the area from hellaspath.gr and OpenStreetMap for accessibility purposes (OpenStreetMap contributors, 2015).

The above, combined with the pre-existing geological knowledge for the area, results in the geological output data consisting of the West to East geological cross sections across the mountain, smaller scale flysch cross sections along the western valley, and fault raster and vector layers. Processing the data in QGIS results in the creation of background layers such as hillshade, slope aspect, contours and multispectral satellite layers, as well as vector layers such as the hydrology network.

For the visual results, the input data consists mainly of the above geological and geomorphological outputs. This is followed by processing through QGIS to create well presentable information layers, and later through the qgis2threejs plugin to structure the data using the three.js JavaScript framework and WebGL technology into a locally running 3D web view model. The layers containing the model's data were selected via the plugin's menu, utilising also the data from the National Cadastre. Furthermore, a custom plane was incorporated to facilitate altitude experiments, concurrently serving as a water level surface to simulate local flooding scenarios. To enhance comprehension of the broader area's orientation, geological planes, and azimuth measurements, the north arrow option was enabled. The map's boundaries were defined using a polygon layer, and the model's background was set to resemble the sky. To enable the user to have multiple layers open simultaneously, one focused on the specific study area and

another providing a broader context, the background raster images were separated into two layers: surroundings and background.

The visual outputs are divided into two categories: static and dynamic. The static output comprises 2.5D perspective images, which interpret the geological setting and geomorphology. These images can be used to accompany a digital or printed file. The dynamic output consists of a 3D interactive web model, which showcases all the study's data in multiple layers. This model can be accessed either locally or on the web (as outlined below). The 3D web model can be uploaded for online access, facilitating optimal practicality, via export to an HTML file. Uploading to OneDrive or a similar online drive service platform is then required. The model can be published via Drive2web's free serverless hosting website and viewed through a link on any web browser. The use of a link shortening website can achieve a better optical result. The workflow involved in the publication process can be seen in Figure 1.

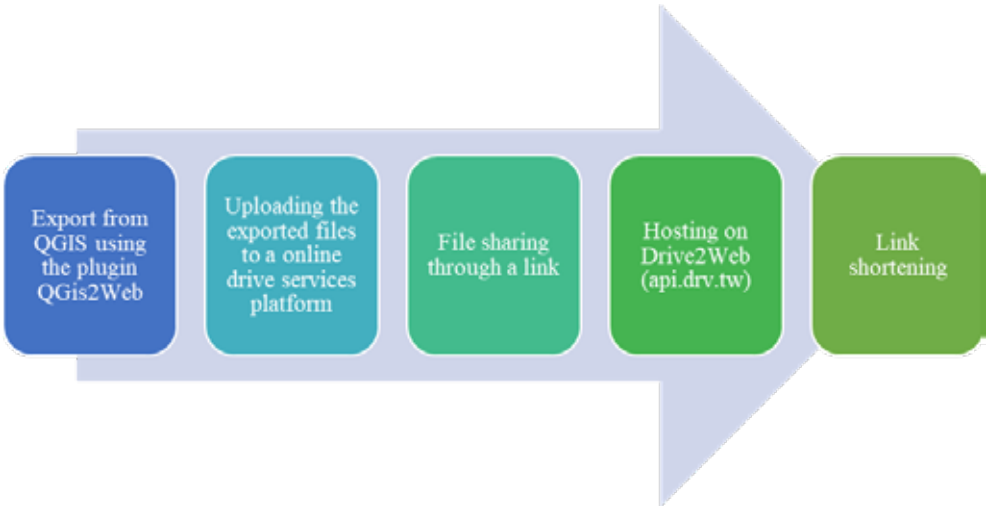

Figure 1. Illustration of the process that was followed from exporting using Qgis2threejs, to the hosting of the model.

Results and conclusions

The geological outcomes of the implemented methodology, which are directly associated with the geological aspect of the study, consist of the 2.5D static images, incorporating the geological cross-sections, as seen in Figure 2. As demonstrated in Figure 3, the integration of the two 2.5D static images in a single illustration serves to emphasize their position in relation to the Koziakas mountain range. The visual results include the most significant element of this study, the 3D web model (Figure 4). The link for the model is the following: https://koziakas-3d-model-qgis2threejs.on.drv.tw/Koziakas%20Website/KoziakasComplete7.html.

Accessible via any web browser, the interactive 3D model provides a detailed visual representation of scientific data while highlighting the geological features of the Koziakas study area. The final model integrates various layers, including geological maps, cross sections, hydrology data, field observations (e.g. fault strike and dip, fossils, faults, and folds), contours, slope aspect maps, hillshade maps, satellite imagery, and nearby hiking trails. The user can create numerous combinations by utilizing all the layers and background data to extract the required information. Background layers, by lacking 3D morphology, place more emphasis on the study region. Hillshade and slope-aspect maps, products from DEM processing from the National Cadastre (Digital Elevation Model -DEM from the LSO25 project (25 m), Hellenic Cadastre), geological maps of IGME (Savoyat and Lalechos, 1972; Karfakis, 1993) and contour topographical map are some of the additional raster layers. Figure 4 displays the model with all information layers activated and Figure 5 demonstrates a different layer combination, showcasing the diverse range of potential applications.

Although not of great significance, the limitations of the plugin have led to the adoption of an alternative visualisation strategy for certain information layers. To address the constraints of the selected plugin and ensure that crucial data remains visible, line elements such as hydrology, faults, and paths have been slightly elevated. Additionally, some product types, like the hillshade-fault map, have been separated into raster and vector layers. This approach mitigates the lower resolution projection caused by the plugin, resulting in improved visualisation. Moreover, the satellite image is observed to exhibit a markedly higher level of clarity when viewed in 3D view within QGIS, in comparison to the final output produced by the Qgis2threejs plugin. Furthermore, it has been demonstrated that the model is efficacious in capturing screenshots, which were subsequently utilized to generate the 2.5D static images.

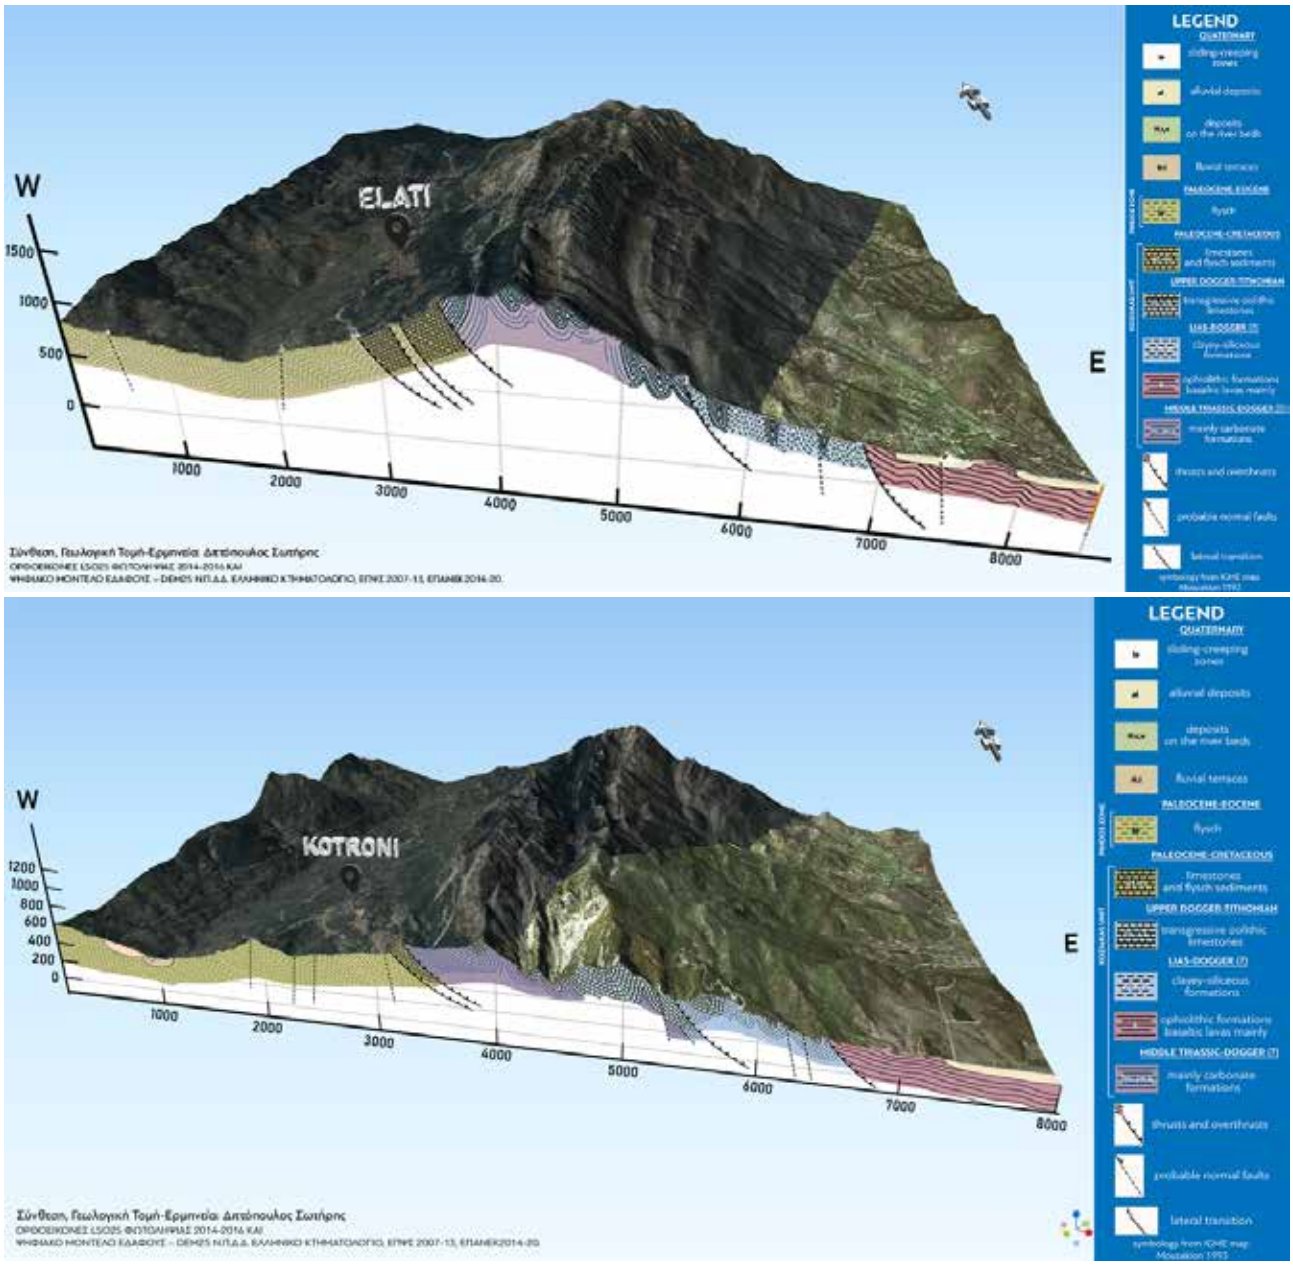

Figure 2. Illustration of the two 2.5D models featuring the geological cross-sections and their respective geological legends. Top: the northernmost geological cross section, located near the settlement of Elati. Bottom: the southernmost geological cross section, located near the settlement of Kotroni. The Qgis2threejs plugin model was utilized to capture the screenshots (Digital Elevation Model -DEM from the LSO25 project (25 m) and LSO25 (25 cm) orthophotos, Hellenic Cadastre).

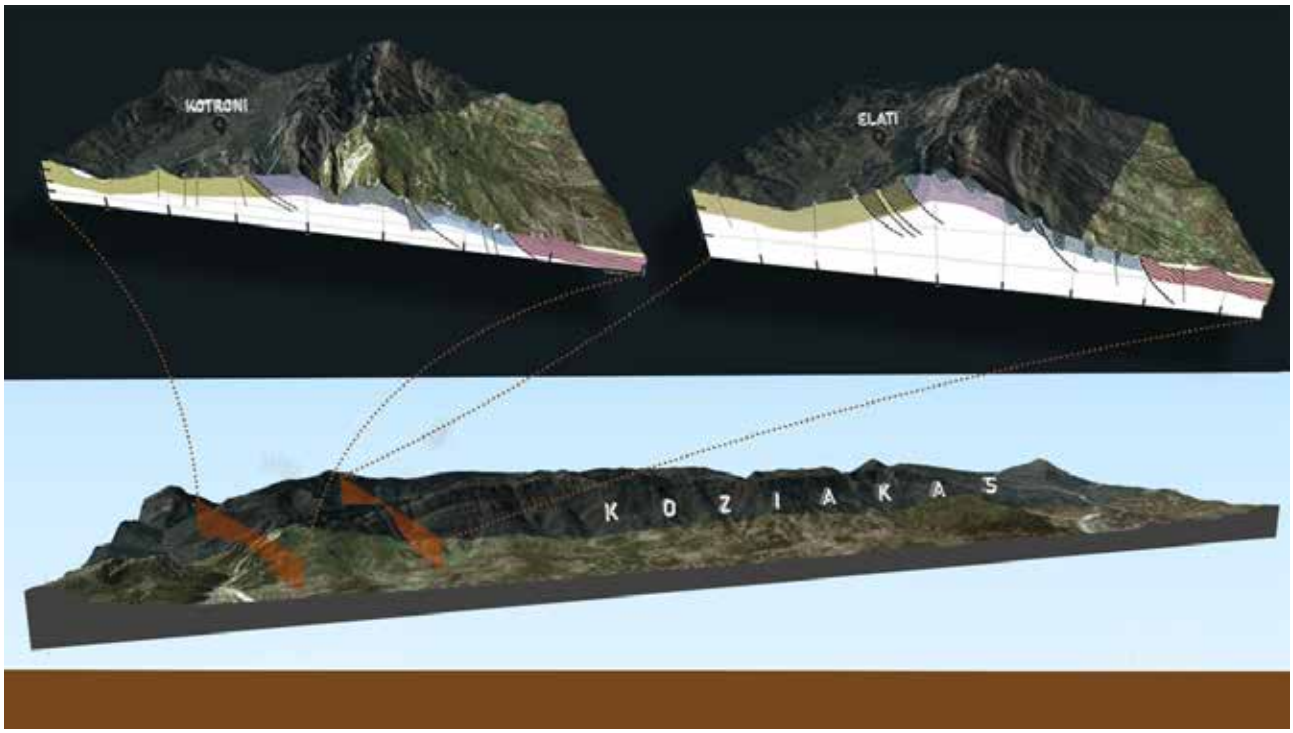

Figure 3. Illustration of the two 2.5D models featuring the geological cross-sections and their position in relation with the Koziakas mountain range. The Qgis2threejs plugin model was utilized to capture the screenshots (Digital Elevation Model -DEM from the LSO25 project (25 m) and LSO25 (25 cm) orthophotos, Hellenic Cadastre).

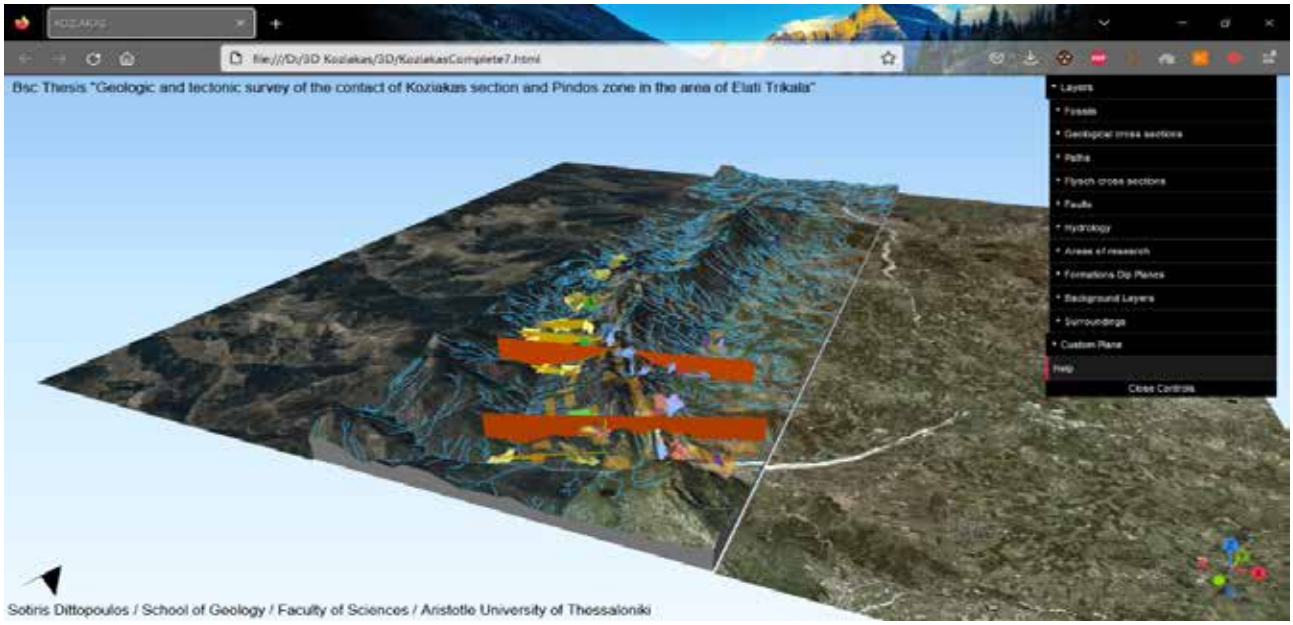

Figure 4. Screenshot of the model, illustrating the information of three layers: locations of geological cross sections (orange), locations of flysch cross sections (yellow), background layers: high resolution satellite image from the Hellenic Cadastre (Digital Elevation Model -DEM from the LSO25 project (25 m) and LSO25 (25 cm) orthophotos, Hellenic Cadastre).

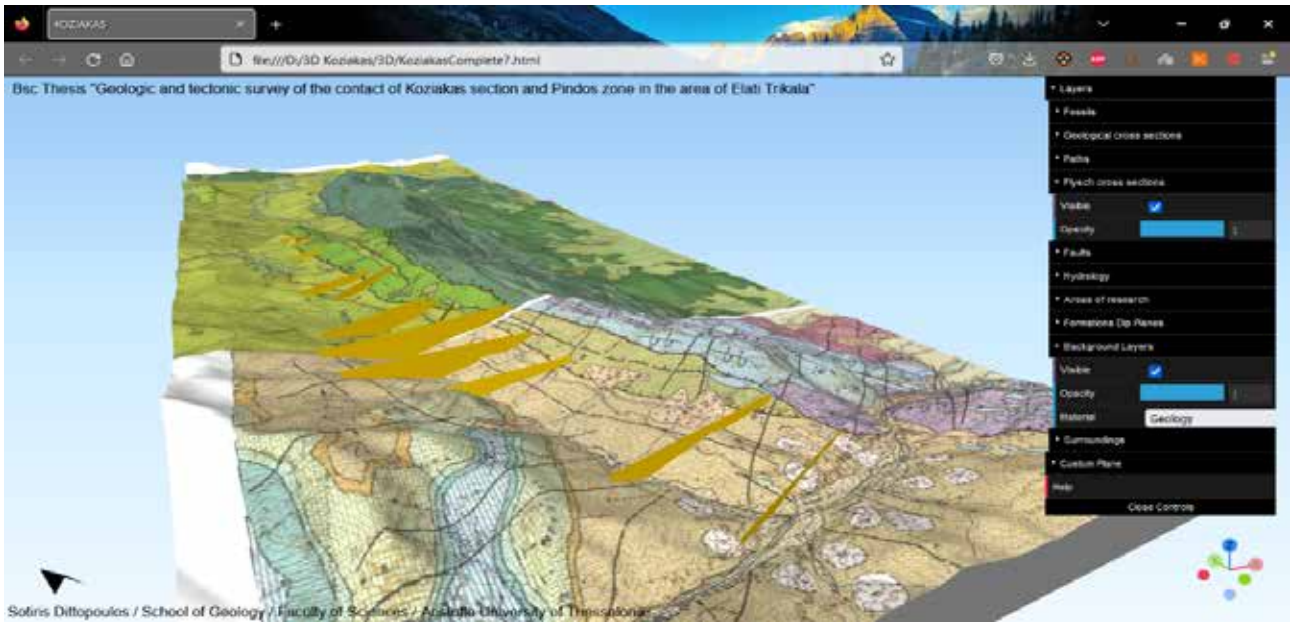

Figure 5. Screenshot of the model, illustrating the information of two layers: locations of flysch cross sections and background layer: geological map of IGME (Mouzakion and Kalambaka sheets, Savoyat and Lalechos, 1972; Karfakis, 1993).

Discussion

The process of transforming complex spatial data into clear, visually engaging outputs is often challenging, particularly when using specialized tools such as the Qgis2threejs plugin. Despite its versatility, the plugin requires experimentation to achieve the intended visualizations, as its performance can be heavily influenced by the underlying hardware. Exporting data, especially in high-resolution formats, can take several hours on systems with outdated or insufficient processing power. To enhance the workflow and optimize efficiency, it is essential to ensure that the hardware capabilities are in alignment with the demands of QGIS and its extensions.

Regarding the enhancements that could be made to improve the end result, one of the primary concerns is the potential to incorporate a geological cross-section illustration within the interactive model. Furthermore, the hydrographic network could be segmented into branches (for example, according to Strahler's classification), integrated into the river basins and accompanied by river name labels. Another significant enhancement would be the capability to include images of the features, visible upon selection. To optimise the presentation for educational purposes, a camera flight plan could be devised to guide the viewer upon entering the model. Faults could be accompanied by arrows, indicating the movement direction, and paths could be equipped with additional information such as distance and estimated walking time. The incorporation of videos and descriptions could further augment the model, resulting in a comprehensive interactive webpage that offers a detailed exposition of the study area.

The Qgis2threejs plugin offers a significant advantage in its ability to export 3D models in the glTF format. This format is a widely recognized standard for 3D computer graphics (3DCG) and 3D printing. This capability opens opportunities for users to move beyond traditional GIS applications, enabling the creation of interactive 3D visualizations or detailed physical models. The potential of these models is significant for the effective promotion and preservation of geoheritage through digital innovation. The visualizations created with this tool facilitate a deeper engagement with geological and cultural heritage sites, providing users with virtual access to areas that may be difficult to visit physically due to geographic or environmental constraints. Moreover, this creates a dynamic way to educate the public about their geological history. Studies have shown that dynamic visualization has a greater positive impact on educational outcomes compared to static visualization. This effect is particularly evident in the learning results and intrinsic motivation of science students, especially in subjects like Biology, Chemistry, and Geology. As highlighted by e.g. Berney & Bétrancourt (2016) and Teplá et al. (2022), dynamic visualization can enhance attention and more effectively demonstrate abstract procedures (Ayres et al. 2009; Schwan & Riempp 2004; Teplá et al. 2022) and processes that change over space and time (Ainsworth & VanLabeke 2004; Rieber 1990; Schnotz & Lowe 2003; Teplá et al. 2022). Furthermore, the 3D printing allows the physical replicas of geoheritage, and features such as

rock formations, fossil sites, faults and folds, to be produced and displayed in educational institutions, museums, or cultural centres. The potential for these models to foster appreciation and awareness is significant, and their capacity to aid in conservation efforts is equally noteworthy.

Acknowledgements

We would like to express our gratitude to the local community of Elati, for their collaboration and the valuable information provided regarding the accessibility of the area. Additionally, we would like to thank the Legal Entity of Public Law Hellenic Cadastre for providing the Digital Elevation Model and Orthophotos used in our analysis.

of the Geological Society of Greece

BULLETIN OF THE GEOLOGICAL SOCIETY OF GREECE, SP. PUBL.

EXTENDED ABSTRACT 063

Assessment of fault hazard in the broader area of Sitia, Eastern Crete

Dretaki A.[1], Chatzipetros A.[1]
(1) School of Geology, Aristotle University of Thessaloniki, , Greece, antoniadret@hotmail.com

Research Highlights: Potential earthquake magnitudes for fault zones in Eastern Crete were determined using empirical relationships, highlighting significant seismic hazards. The Ierapetra, Mesa Mouliana, Sitia, and Xerocampos-Goudouras Fault Zones are identified as the most active and hazardous in the area, indicating the need for further research.

The area of Crete is one of the most tectonically active in Greece and its study has been at the centre of interest of many researchers. Eastern Crete is considered to be the area where 80% of the future normal fault earthquakes will occur (Nicol *et al.,* 2020), so seismic hazard assessment is a necessity. The Ierapetra fault zone is considered the most dangerous and important, as two major earthquakes have occurred in the past, destroying completely the city of Ierapetra. Therefore, the mapping and analysis of the area's major fault zones can provide substantial insight into the seismic hazard of the region.

The study area is located in the eastern part of Lasithi and includes the municipality of Sitia and part of the municipality of Ierapetra. It is characterised by a relatively mountainous landscape with numerous gorges formed in the limestone bedrock. The geological structure of the area, from the lowest to the highest units, consists of the following units: Plattenkalk unit, Tripali unit, Phyllite-Quartzite unit *s. str.,* the pre-alpine basement, the Tyros Unit, the Tripoli Unit, the Pindos Unit and then, above all, the younger post-alpine sedimentary series (Fassoulas, 1995, ten Veen and Postma, 1999, Seidel, 1968; Krahl *et al.*, 1983; Zulauf *et al.,* 2008, Klein *et al.,* 2008, Mountrakis, 2010, Krahl *et al.,* 1986; Zulauf *et al.,* 2013, Robertson, 2006; Robertson, 2008; Robertson, 2022).

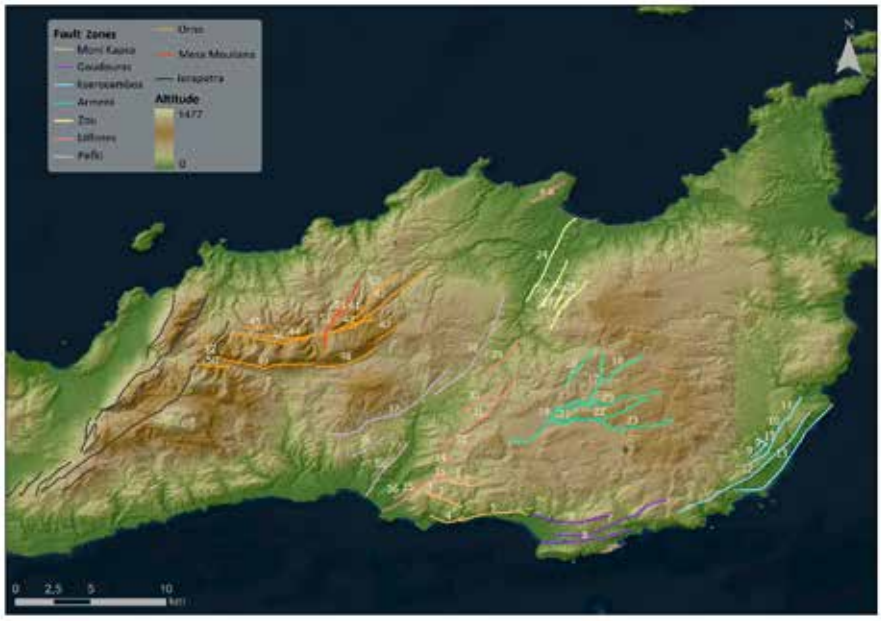

Figure 1. Neotectonic map of fault zones and numbered segments referred on Tables 1 to 3 (Dretaki, 2024). For source of the DEM see text for details.

Active faults in the area are normal or normal-oblique ones. They are numerous and can be grouped into two main trends: the NNE-SSW trending fault group and the E-W to ESE-WNW trending fault group. The Ierapetra Fault Zone, as mentioned above, has been mapped and analysed in detail. Other fault zones mentioned in previous research include the Sitia Fault Zone and other minor offshore and onshore structures, such as the Goudouras Fault, the Mouliana Fault and the Orno Fault (ten Veen and Postma, 1999, Caputo *et al.,* 2010, Caputo and Pavlides, 2013, Mason *et al.,* 2016, Pavlides *et al.,* 2018, Veliz *et al.,* 2018, Mechernich et *al.,* 2023). On 12 October 2021, an M 6.3 earthquake occurred on an offshore NNE-SSW fault, its focal mechanism (data from the National Observatory of Greece, Dretaki *et al.,* 2022), showed that the active stress field is compatible with several onshore fault zones and indicating the need for further research into the tectonic activity of the area.

To estimate the seismic hazard, empirical relationships are used that relate the surface rupture (L) to the energy released by the earthquake (magnitude Ms) (Pavlides, 2016). Many researchers have already calculated the possible magnitudes of some faults

in the area and the results are shown in Table 1.
During the field mapping, measurements of faults and structures were taken where possible. Then, using ArcGIS Pro software, they were analysed and correlated with the satellite imagery and DEM in order to better map them in the field. From the above analysis, the structures were divided into five fault zones, Xerocampos - Goudouras, Sitia, Orno, Mesa Mouliana and Ierapetra (Figure 1). Each was divided into individual fault subzones based on their segmentation and correlated with the satellite data, Digital Elevation Model (Data Source: Legal Entity of Public Law Hellenic Cadastre, Operational Programme Competitiveness, Entrepreneurship and Innovation 2014-2020 (EPAnEK)) and digitized geological map (IGME 1959). The hydrographic network was also used, since the way it develops can be strongly influenced by the tectonic regime of a region.
All of the above, combined with the analysis of morphotectonic indices and data published in the literature, led to the assessment of the activity of each zone. Then, the seismic hazard was calculated, using empirical relationships, for each segment of sufficient length, combinations of segments, the entire fault zone, combinations of fault zones and the entire deformation zone. For the calculation of the Ms magnitude of the faults the empirical relationships of Wells & Coppersmith (1994), Papazachos *et al.* (2004) and Pavlides & Caputo (2004) were used
First, the surface length L or SRL (Surface Rupture Length) of each section was calculated separately in km using the ArcGIS Pro application for the mapped sections. Then the values of the potential magnitudes and the Maximum Vertical Displacement (MVD) were calculated. The values were calculated for each individual segment, combinations of segments and the whole zone and the results are shown in Tables 1, 2 and 3.
Previous work in the area (Dretaki, 2024) confirmed that both groups are active, with the NNE-SSW faults being more active than the E-W ones. The above analysis, in addition with previous studies, shows that the Ierapetra, Mesa Mouliana, Sitia and Xerocampos - Goudoura Fault Zones are the most active in the region. In the Ierapetra Fault Zone there are historical records of its activation. Segment 52 (Figure 1), which was recently mapped during fieldwork (Dretaki, 2024), shows evidence of activity as it deforms recent deposits and has the potential for a magnitude Ms 5.7 event (Pavlides and Caputo, 2004). Further investigation of this fault segment is considered important. The Mesa Mouliana Fault Zone is considered to be as active as the Ierapetra one, with potential similar to that of Lastros fault (Mechernich et al. 2023), with calculated Ms 5.7 (Pavlides and Caputo, 2004). It intersects the Orno Fault Zone, which is also considered to be active, creating strong relief and slope debris have been deposited in the hanging wall. Orno fault has a potential magnitude of Ms 6.8 (Pavlides and Caputo, 2004). Sitia Fault Zone is an active zone with signs of activity migration towards the centre of the basin. The younger parts of it intersect the Neogene deposits, but more importantly they intersect the beachrocks of Sitia beach, indicating that it was active during the Holocene. The activation of the entire fault zone could cause an earthquake of Ms 7.1 (Pavlides and Caputo, 2004), similar to Ierapetra and Xerocambos-Goudouras Fault Zones. Xerocampos Fault Zone, as well as the large expected earthquake magnitude derived from empirical relationships, appears to be part of the same system as the 12 October 2021 earthquake.
Based on the above, as well as the results from Tables 1 to 3, we can conclude that further research on each area is mandatory. This research could include the monitoring of micro-movements by installing instruments in the most active sections, geophysical surveys and paleoseismological trenching. Although the study area is the least developed in terms of tourism compared to the rest of Crete, it receives many visitors each year. Combined with the permanent population, especially in the settlements close to the fault zones, the seismic risk of the area is greatly increased due to the age of most of the settlements, the short distance from the seismic sources and the permanent human presence.

Acknowledgements

The authors would like to acknowledge the invaluable support and contributions that made this research possible. The first author is grateful to Sotiris Dittopoulos, BSc geologist, for his collaboration and assistance. The authors would also like to thank the *Geositia project* for Sitia UNESCO Global Geopark, during which many field data were collected and presented as part of the project deliverables. The administration of the Geopark, as well as the Municipality of Sitia through MADES S.A. provided financial support for part of the research, and their contribution is greatly appreciated. The Digital Elevation Model used in the analysis was kindly provided by the Legal Entity of Public Law Hellenic Cadastre. This paper summarizes part of the first author's MSc Thesis at the University of the Aegean, completed under the Inter-Institutional «Natural Hazards and Disaster Mitigation» Master Course programme. The contributions of Professor Emeritus Spyros Pavlides (Aristotle University of Thessaloniki) and Dr Charalambos Fassoulas (Natural History Museum of Crete of the University of Crete) were crucial, pivotal and greatly improved the Thesis text; the authors would like to express their sincere gratitude towards them.

Research Highlights: The Sitia Geopark caves, including Pelekita, Kato Peristeras, Ano Peristeras, Chonos, and Vreiko, demonstrate significant tectonic influences on their formation. The tectonic setting, marked by E-W and NNE-SSW faults, shapes the orientation and development of these caves.

Introduction and background

The region of Sitia, distinguished by its topography marked by rugged mountains, intense tectonic activity, and a rich karst landscape, hosts several caves that are of significant historical importance in Greece. Consequently, the area has become a focal point for speleological studies, with numerous teams dedicating their efforts to mapping and exploring the region's cave systems. The caves of the Sitia Geopark include five caves in the Lassithi region, which were studied during a project targeted towards documenting the Geopark's geotopes (Geositia project): Pelekita, Kato Peristeras, Ano Peristeras, Chonos and Vreiko. The formation of these subterranean karst formations is attributed to the combined effects of erosion and chemical dissolution, resulting from the movement of groundwater through fissures in the rock formations. The structural characteristics and three-dimensional patterns of these caves are influenced by the rock type in which they were formed. The hydrochemical factors that influence them depend on petrological, tectonic, climatic, and other conditions. Whether cave forms are composed of active, under-formation or residual features, there is a possibility that they will diversify in the future under completely different conditions (Ford and Williams 2007).

The caves of eastern Crete were primarily formed within limestones and dolomites belonging to the Tripoli and Pindos Units, and along their contact with the Phyllite-Quartzite Unit s.l. (IGME, 1959). This process occurred under the influence of intense tectonic uplift conditions prevailing on the island, caused by the northward subduction of the African plate beneath the Eurasian one (Fassoulas, 2017).

The tectonic history of Crete is marked by significant extensional and compressional episodes. Since the Neogene, the island has experienced three major faulting events that have dissected the island in several blocks. The earliest fault group, formed during the Early Messinian (7-6 Myr), is characterised by E-W trending faults resulting from the southward roll-back of the subduction zone. This was followed by the Late Messinian to Early Pliocene (5 Myr) stage, characterised by N-S trending faults due to the extrusion of the Anatolian plate and regional stress field perturbations. The most recent fault group, dating from the Middle Pliocene to the present (4 Myr), comprises NE-SW and NW-SE trending faults driven by ongoing geodynamic processes (Fassoulas, 2017). More specifically, the active normal faults in the area are numerous and can be grouped into two main trends: the NNE-SSW trending fault group and the E-W to ESE-WNW trending fault group. They can be divided into the following Fault Zones: Ierapetra, Sitia, Orno, Mesa Mouliana and Xerocambos-Goudouras (Dretaki, 2024).

The above tectonic setting can influence the development of the topography of the area, and more precisely, the orientation of the drainage network, which includes the underground network of rivers and caves. The cave structures tend to develop inside fragmented limestone, along pre-existing fractures and faults. The present study is focused on investigating the influence that these intense tectonic settings had on the formation of the caves within Sitia Geopark. Furthermore, the study explores how caves contribute to the unravelling of tectonic structures that remain hidden beneath the surface, leading to a better mapping and understanding of the tectonic setting.

Methodology

Cave mapping is a fundamental aspect of speleology, providing a detailed and accurate representation of the underground environment. These maps are essential tools for understanding the spatial layout, geological features and environmental conditions of caves. The mapping process combines traditional surveying techniques with modern technology to capture the intricate details of cave systems. Cave mapping is carried out by dividing the cave into small imaginary rectilinear sections. In each section, the length, direction relative to magnetic north and inclination relative to the horizontal plane are measured. At the end of each section, the distances from the cave walls are measured to record the dimensions of the

cave. These measurements are processed by a computer program, producing a map in Cartesian coordinates.
The hardware used for mapping included the BRIC5 and DistoX1, an analogue compass, an analogue inclinometer, a tape measure and a laser rangefinder. In terms of software, the BRIC5 measurements were accompanied by the Topodroid app for Android and the processing was done using Visual Topo for Windows.
During the fieldwork of the GeoSitia project and the thesis of Dretaki (2024), fault measurements were obtained using a geological compass and the Android program FieldMove. Further processing and analysis of the data was carried out using QGIS and ArcGIS Pro. The rose diagrams were created using the QGIS plugin “Line direction histogram”. Furthermore, for the creation of the drainage network as well as the hillshade of the study area, the Digital Elevation Model of the Legal Entity of Public Law Hellenic Cadastre was used [Operational Programme Competitiveness, Entrepreneurship and Innovation 2014-2020 (EPAnEK)]. To achieve a more comprehensive interpretation of the landscape, the Digital Elevation Model (DEM) was used in combination with Google Earth Software.

Field data

The cave of Ano Peristeras is located west of the settlement of Karydi and is among the most significant and largest caves in Greece (Figure 1). It is situated within the limestones of Tripoli Unit (IGME, 1959). The cave’s entrance, shaped as a semi-circular doline with a radius measuring approximately 24 m, is situated at an altitude of 600 m. The broader area of the doline exhibits the contact between the Tripoli Unit and the Phyllites-Quartzites Unit. The first chamber is notable for its substantial dimensions, measuring 30 m in width and 90 m in height. This is followed by a second chamber that is comparatively smaller in size, with dimensions of 35 m in width and 13 m in height. Its total length is 8,250 m, making it the third longest cave in Greece. Through hydrologic data and pressure gauges, it is assumed that the Ano Peristeras Cave discharges to the Flega spring (Chailloux, 2015). The entrance of the cave is developed in a SSW-NNE direction, and another branch follows the same direction upstream, to the west of the entrance. The main branch develops in a W-E direction until the central part, where it turns NW-SE. These directions are due to the tectonics of the area and the NNE-SSW fault zone trending (as shown in yellow, Figure 1), as well as the older E-W faults (as shown in orange, Figure 1), which is confirmed by the correlation of the fault trend and cave branches rose diagrams (Figure 5). The dashed yellow lines indicate possible faults along which several branches of the cave were developed, parallel to the younger active Sitia Fault Zone (as shown in yellow, Figure 1). The tectonic stress of the limestone accelerates its disintegration and thus the formation of the cave along the fault zone. In addition, a large part of the cave is situated at the tectonic contact (thrust) of the limestones of the Tripoli Unit, which overlie the phyllites of the Phyllite-Quartzite Unit. A smooth limestone surface appears on the roof of the cave, in the part of the cave that develops within the red phyllites.

Figure 1. Map showing Ano Peristeras (lower, longer red line) and Chonos (upper, shorter red line) cave systems and their correlation with faults in the area. DEM Source: Legal Entity of Public Law Hellenic Cadastre, Operational Programme Competitiveness, Entrepreneurship and Innovation 2014-2020 (EPAnEK).

The cave of Chonos is located south of the homonymous settlement, a term employed in the Cretan dialect to denote a sinkhole (Figure 1). It has been determined that the cave develops at the point of contact between the upper layers of the Toplou beds of the Tyros Unit and the limestones of the Tripoli Unit (IGME, 1959, Klein *et al.*, 2008, Zulauf *et al.,* 2018). The cave's entrance, measuring 120 by 130 m and 25 m in depth, is a doline that appears to have been influenced by probable NE-SW trending faults. The cave development extends for approximately 700 m and reaches a depth of 90 m The first section of the cave is vertical, and then it transitions parallel to the contact between the Tyros Unit and the limestones of the Tripoli Unit. It is plausible that the cave discharges in the same underground drainage system as Ano Peristeras, and the presence of water is seasonal. The presence of speleothems, formed through the accumulation of mineral deposits, indicates that the cave is periodically filled with water, which then escapes through fissures at the cave's end. Mapping of the cave reveals the presence of two branches, which later connect. The main branch of the cave exhibits a WNW-ESE direction (as shown in orange, Figure 1), aligning parallel to the fault zone that brings the Tyros Unit into contact with the limestones of the Tripoli Unit (Klein *et al.,* 2008). The disintegration of limestone is accelerated by tectonic stress, leading to the formation of caves along the fault zone. The second branch, located a short distance west of the entrance and originating at the contact of the two Units, exhibits an NNE-SSW orientation and appears to develop within the same zone as certain branches of the Ano Peristeras (as shown in dashed yellow, Figure 1). The main branch exhibits a bend with a NNE-SSW orientation in its western segment, indicative of its influence by NNE-SSW trending faults (as shown in yellow, Figure 1). The above is confirmed with the correlation between the fault trend and the cave branches' rose diagrams (Figure 5 and 6).

Figure 2. Map showing Kato Peristeras and its correlation with possible faults in the area. Legend as in Figure 1. Basemap: Google Satellite.

The cave of Kato Peristeras is located 1.5 km from the settlement of Karidi, on the road to the settlement of Adravasti (Figure 2). It is located north of the road and can be reached by following a path for 350 m. The cave is developed in limestones of the Pindos Unit (IGME, 1959, Klein *et al.,* 2008). It is a horizontal cave with its entrance at an altitude of 615 m, in the area of Kato Platyvolo. Its entrance is a doline measuring 45 by 25 m and 20-25 m deep, which collapsed to reveal the cave. According to the primary mapping of the E.S.E. (Hellenic Speleological Society) it has a length of 100 m, a maximum ceiling height of 12 m, a depth of 63 m and a total area of 2800 m² (Petrochilou, 1970). The main chamber of the cave measures 75 by 35 m and is 3-10 m high. It is quite steep, with several limestone blocks sloping down towards the interior. At the end of this chamber, water escapes through fractures and discontinuities in the rock. To the left of the main chamber, there is a much smaller one, 19 by 11 m and 1.5-6 m high, with stalagmite speleothems, which joins the main chamber at two points. The cave develops primarily towards the W, in the direction of the NW-SE shear zone (as shown in dashed yellow, Figure 2). Inside the cave, especially in the left part of the chamber, several fault surfaces of a second NW-SE fault zone can be found during the descent. As shown in the rose diagrams (Figures 5 and 6), some smaller branches of the cave follow the NNE-SSW and the E-W trending faults. The tectonic stress on the limestone creates the conditions for faster dissolution and formation of the cave along this zone.

The geotope of the cave of Pelekita is located 3 km away from the settlement of Kato Zakros, following the E4 path to Karoumes beach (Figure 3). The cave is developed in limestones and dolomites of Tripoli Unit (IGME, 1959). The

cave of Pelekita, named after the nearby ancient quarry, is located at an altitude of 100 m in the foothills of Traostalos. According to the primary mapping conducted by the Hellenic Speleological Society (E.S.E.) in 1970, the cave's length is 310 m (Ioannou, 1970). However, more recent mapping by FORS Sitia has revealed a length of 370 m and a depth of 95 m The cave's entrance, measuring 15 m in diameter and 8 m in height, is oriented towards the east (Bruins *et al.,* 2019). The first chamber measures 20 m in length, 20 m in width, and 7.5 m in height. It is a horizontal cave that is developed sub-parallelly to the coastline, oriented NW-SE. The total number of chambers in this cave is four, including the entrance. The second chamber is considered the largest cave chamber in Crete and one of the largest in Greece, with a volume of about 300 m². It is characterized by a rich variety of speleothems, with an abundance of stalactites and stalagmites. At the base of the third and fourth rooms, there are small brackish water ponds, which are at the same altitude as the sea level. Between the last two chambers, there is a pile of limestone fragments, coming from the roof, due to the angle of the limestone bedding, which favours their collapse. In the eastern part of the cave, a relatively smooth surface is found, exhibiting characteristics of a fault surface, which extends to the south and is likely associated with an older possible NW-SE trending fault (as shown in dashed yellow, Figure 3). Based on the rose diagram (Figures 5 and 7), the mean trending direction is similar to Vreiko's cave, while smaller branches follow the NNE-SSW to N-S direction.

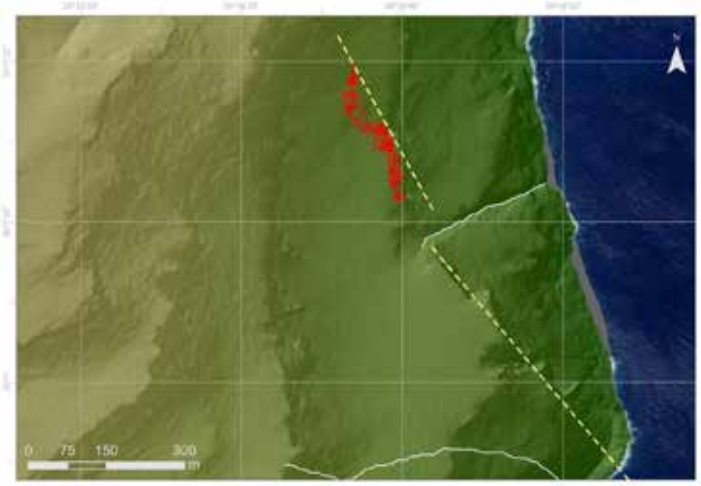

Figure 3. Map showing Pelekita and its correlation with possible faults in the area. Legend as in Figure 1. DEM Source: Legal Entity of Public Law Hellenic Cadastre, Operational Programme Competitiveness, Entrepreneurship and Innovation 2014-2020 (EPAnEK).

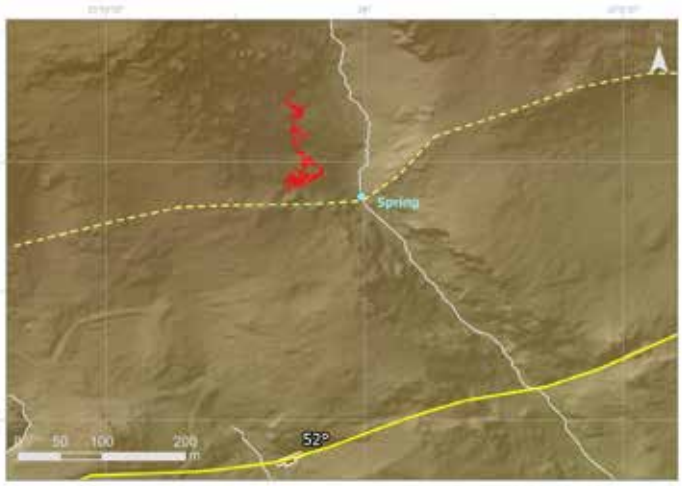

Figure 4. Map showing Vreiko and its correlation with faults in the area. Legend as in Figure 1. DEM Source: Legal Entity of Public Law Hellenic Cadastre, Operational Programme Competitiveness, Entrepreneurship and Innovation 2014-2020 (EPAnEK).

Vreiko Cave is located about 2 km north-east of the village of Pefki, following the road first to Makri Gyalos and then further north to the church of Estavromenos near the peak of Sarakinika (Figure 4). A 300 m path leads to the entrance of the cave. The cave develops within the limestones of the Tripoli Unit (IGME, 1959). The cave entrance is located at an altitude of 565 m and is a 7 m deep depression (Georgiakakis *et al.,* 2006) created by the collapse of the cave ceiling. It has a total length of 277 m and a maximum decline of 47 m. There is one entrance to the NW and two entrances to the south. In the northern part of the cave there are two chambers, the first measuring 60 by 5-22 m with a maximum height of 11.5 m (Georgiakakis *et al.,* 2006). The two chambers are separated by a pile of talus and surface sediments, above which there is an opening at a height of 9.5 m (Georgiakakis *et al.,* 2006), which is the second entrance to the cave. Continuing north, there is a second room leading to an outer porch and the third entrance to the cave . In the southern part of the cave there is a wide opening that leads to the deepest part of the cave, which is 34 m lower. The chamber measures 50 by 22.5-27.5 m and is 3-5.5 m high, with a shallow lake 3-5 m in diameter at its deepest point (Georgiakakis *et al.,* 2006). It has more impressive cave landforms than the northern room, with large stalactite columns and speleothems on the walls. To the left is another room measuring 31 by 7.5 m and 7.5 m high, at the end of which, in a small chamber, Byzantine pottery has been found consolidated with calcite material (Georgiakakis *et al.,* 2006). Just below the entrance to the cave, a spring flows near the vegetated area, which is in line with the southernmost point of the cave. There is a possible ENE-WSW trending fault that contributes to the surface discharge of water, inside the limestone bedrock (as shown in dashed yellow and blue dot as the spring, Figure 4). The fault is indicated by the topography, but also by the parallel development of a synthetic fault structure further south (Dretaki, 2024). The end and lowest part of the cave follows the direction of the above possible fault (Figure 4), which is also evident from the rose diagram (Figure 5 and 7).

Results and conclusions

In most cases, the development of the caves has been directly influenced by the local tectonic setting, including both older and newer faults and lithology. This phenomenon was clear through the correlation of fault zones and cave branch trends, the change in direction of the local drainage network, and in some cases, the existence of springs indicative of fault activity. The major E-W trending development of the caves corresponds with the same trending faults in the area as well as the NNE-SSW trending faults, but to a lesser extent. This finding suggests that the former were active for a longer period than the latter, indicating that the latter are more recent. The data gathered through field measurements offers further evidence to support this interpretation. However, additional field research is necessary to ensure more accurate conclusions. Such research could involve creating a more extensive network of measurements, which would allow for the confirmation or rejection of potential faults and thus correlations. To achieve this, a more in-depth caving mission would be required, with a skilled team that possesses a multidisciplinary understanding of speleology and geology. Regarding the deeper data interpretation, an analysis of 3D models through the software of Visual Topo could also lead to more detailed examination of underground tectonic formations, while experimenting with area proportional and no weighted-on length options in Line Direction Histogram could lead to a safer multivariate rose diagram data analysis.

EXTENDED ABSTRACT 065

Enhancing Geoheritage through GEOAM: A Case Study of Tinos Island, central Aegean Sea, Greece

H. Drinia[1] G. Zafeiropoulos[1],
(1) Faculty of Geology & Geoenvironment, National and Kapodistrian University of Athens, Panepistimioupolis 15784, Zographou, Greece, cntrinia@geol.uoa.gr

Introduction

Geoheritage encompasses the recognition, conservation, and promotion of geologically significant sites and their cultural, educational, and ecological value. In this context, Tinos Island in the Cyclades stands out as a remarkable locale due to its complex geological history and the coexistence of geological formations with architectural features tied to human activity. This study employs the GEOAM (Geoeducational Assessment Method), an innovative framework proposed by Zafeiropoulos and Drinia (2023) and Zafeiropoulos (2024), to evaluate the geoheritage potential of Tinos Island and explore the interplay between its natural and built environments.

Tinos Island belongs to the Atticocycladic geological mass and is characterized by its complex metamorphic history and structural geology, deeply influenced by tectonic activities in the Aegean region (Figure 1). This geological mass comprises several distinct metamorphic units, including the Upper Unit, the Cycladic Blueschist Unit, and the Basal Unit. The Upper Unit, which has undergone greenschist-facies metamorphism, consists of serpentinites, meta-gabbros, and phyllitic rocks. The Cycladic Blueschist Unit, notable for its high-pressure metamorphism, includes marbles, calcschists, and various metasediments, reflecting the intense subduction processes that have shaped the region. At the lowest stratigraphic level, the Basal Unit contains a diverse array of metamorphic carbonate rocks. These units collectively highlight a dynamic tectonic environment with multiple detachments, showcasing the geological complexity and ongoing metamorphic processes defining Tinos within the Cyclades complex. Further illustrating this complexity, the island's stratigraphy includes additional divisions such as the Akrotiri Unit, predominantly in the southern region, comprising amphibolites, paragneisses, and minor silicate marbles. This unit is separated from the Upper Unit by the low-angle Vari detachment, emphasizing distinct tectonic settings (Bröcker and Franz, 1998). Beneath the Akrotiri Unit, the Upper Unit presents a metamorphic history shaped by diverse rock types and intricate tectonic interactions. Below these lies the Cycladic Blueschist Unit, marked by high-pressure metamorphism at approximately 450–500°C and pressures around 4–7 kbar. At the lowest level, the Basal Unit, mainly found in the northeastern part of the island, reveals a history of geological transformations influenced by regional metamorphism and magmatic intrusions. The presence of multiple detachments, discussed by Brichau et al. (2007) and Jolivet et al. (2010), underscores the dynamic tectonic regime of Tinos, with the North Cycladic Detachment System reactivating older geological structures such as the Vardar oceanic suture zone. Mapping and analyzing these geological units, based on fieldwork and historical data, provide a comprehensive understanding of Tinos Island's geological framework, offering valuable insights into the Cycladic region's tectonic and metamorphic history while aiding in the prediction of future geological developments in this seismically active area.

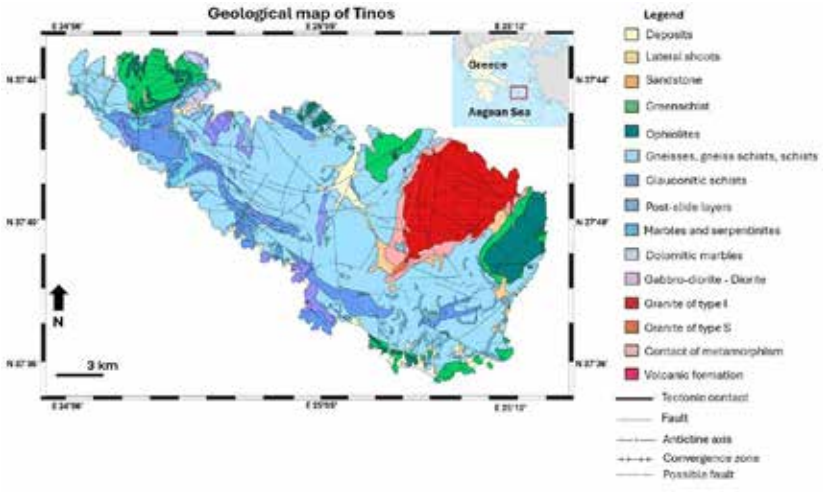

Figure 1. Geological Map of Tinos island after Lamont et al., (2000) and Leonidopoulou (2004), modified

Methodology

To assess and enhance the geoheritage of Tinos, the Geoeducational Assessment Method (GEOAM) was employed. The GEOAM assessment method is a comprehensive framework designed to evaluate the educational value, conservation status, and overall potential of geosites. By applying eight key criteria—Site Management and Visitor Experience (SMVE), Natural Resource Management (NRM), Environmental Education and Interpretation (EEI), Cultural and Historical Significance (CHS), Geoethics (GE), Economic Viability (EV), Community Involvement and Engagement (CIE), and Sustainable Development (SD)—along with their respective subcriteria, GEOAM provides a detailed scoring system that assesses various aspects of a geosite, such as accessibility, biodiversity conservation, interpretive resources, cultural importance, and sustainable practices. Scores are assigned on a scale of 1 to 5 for each subcriterion, weighted according to their importance, and combined to calculate an overall score using a specific formula. The final score categorizes geosites into five levels, from Low Implementation (LI) to Extremely High Implementation (EHI), offering a measurable and adaptable tool for enhancing the geoeducational value and sustainable development of geosites.

The application of GEOAM involved selecting six representative geosites on Tinos, including marble quarries, tafone, alveoles, tors, core stones and the iconic granite outcrop of Exombourgo (Figure 2). Each site was evaluated using a weighted scoring system, highlighting their strengths and areas for improvement. The methodology's focus on education and community involvement ensures that conservation efforts are both inclusive and impactful. This approach is particularly valuable in addressing the dual goals of heritage preservation and tourism promotion according to sustainable principles.

Figure 2. The selected geomorphosites in the island of Tinos

Results

The evaluation of the criteria using the GEOAM intricately revealed the following results (Table 1):

Table 1. Final scores for the geosites of Tinos

Criteria	Weight	GS.T1	GS.T2	GS.T3	GS.T4	GS.T5	GS.T6
SMVE	10%	2.66	2.83	2.5	3.16	2.5	2.66
NRM	10%	2.4	3.2	3	3.4	3	3.4
EEI	30%	2	2.4	2.2	2.4	2	2
CHS	10%	3.25	3	2.5	3.75	2.25	3.5
GE	20%	3.4	3.8	2.6	4	2.4	4
EV	5%	3.6	3.8	2.4	4	2.2	3.8
CIE	5%	3.5	4	2.25	4.5	2.25	4
SD	10%	3	3.33	2.33	3.33	2.66	3
Final Score		2.76	3.10	2.44	3.30	2.34	3.04
Characterization of score		MI	HI	MI	HI	MI	HI

Discussion

According to Table 1, it is evident that all geosites demonstrate significant importance, as none received a low score. Notably, three out of six geosites are classified under High Implementation (HI) in the final score characterization. Specifically, GS.T4 achieves the highest score of 3.30 (Table 10), indicating its strong potential for further development and the initiation of more community-driven strategies for its rational management.

Additionally, GS.T2 and GS.T6 showcase their geoheritage value, offering opportunities to drive collective management efforts. This approach could enable the local community to reap the benefits of their geosites within a sustainable development framework. On the other hand, GS.T1, GS.T3, and GS.T5 record the lowest scores of 2.76, 2.44, and 2.34, respectively. These lower scores highlight a lack of geoenvironmental activities and initiatives to enhance the visibility and value of these geosites. This is further reflected in the fact that the Environmental Education and Interpretation (EEI) criterion consistently receives the lowest scores across all geosites.

To address this issue, collaboration among the local community, stakeholders, and policymakers is essential. Such cooperative efforts would enable a holistic approach to enhancing the geoheritage value of these areas. At the same time, this would safeguard the cultural dynamics of the region, which, according to a European study, face certain threats. Geo-education, through organized geoeducational activities or recreational initiatives, could play a constructive role in benefiting society, delivering economic, social, and environmental advantages.

Furthermore, promoting structured geoeducational activities can foster a geoethical mindset and instill sustainable values in participants. By aligning with the principles of sustainable development, such initiatives would create a society that exists harmoniously with the natural environment..

Conclusions

Tinos Island showcases a remarkable intersection of geology, culture, and geotourism potential. The island's unique geomorphology, shaped by its dynamic tectonic history, offers diverse features such as granitic tors, core stones, and tafoni formations, which contribute to its high geoheritage value. Additionally, Tinos' cultural identity is enriched by its marble craftsmanship, recognized by UNESCO, and its rich tradition of artistic expression.

Evaluating its geosites using the GEOAM method highlighted both strengths and areas for improvement. Geosites like GS.T4 exhibit high implementation potential for geoeducational activities, while others lack necessary infrastructure and environmental education elements. Integrating local communities, stakeholders, and policymakers is critical for sustainable development of the island.

By fostering geoethical awareness and promoting alternative tourism, Tinos can balance cultural preservation with economic and environmental benefits, ensuring its legacy as a dynamic and sustainable destination.

Introduction

Tinos Island, part of the Cyclades in Greece, boasts a remarkable granitic landscape with geomorphs of significant geological, cultural, and educational value. These geomorphological features, shaped over millennia, are increasingly vulnerable to the impacts of climate change, which can accelerate erosion, alter landforms, and threaten the preservation of the island's natural heritage. This study explores the feasibility of establishing a Geopark on Tinos Island, with a central mission to protect, promote, and utilize the island's natural and cultural heritage. Special emphasis is placed on addressing climate change and advancing geoconservation practices to mitigate the effects of environmental changes on these unique geomorphs. Unlike existing Geoparks, this project stands out by integrating the unique geological features of Tinos with the island's cultural narratives, offering an innovative approach to linking geoconservation with sustainable development and community engagement.

Geological Setting and Cultural Significance

Tinos Island, part of the Cyclades plateau in the Aegean Sea, boasts a complex geological setting shaped by tectonic processes associated with the Alpine orogeny. It lies within the Attic-Cycladic Metamorphic Complex, a region that showcases the dynamic interplay of subduction, high-pressure metamorphism, and subsequent extensional tectonics during the Tertiary period (Figure 1). These processes have given rise to a diverse range of geological features, making Tinos a natural laboratory for understanding Earth's dynamic systems.

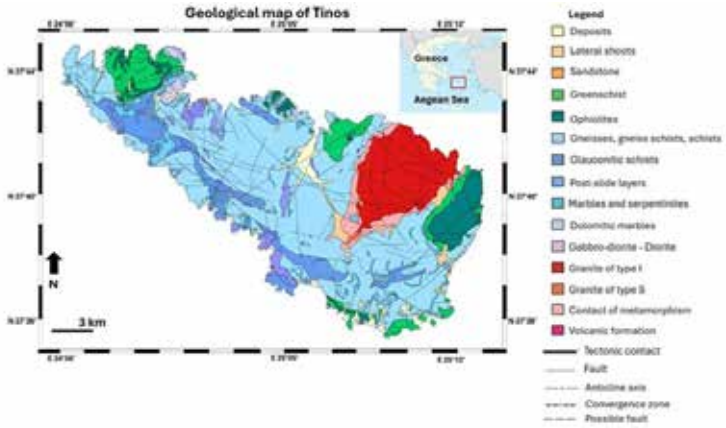

Figure 1. Geological Map of Tinos island after Lamont et al., (2000) and Leonidopoulou (2004), modified

The island's lithology is dominated by metamorphic rocks, including schists, marbles, gneisses, and amphibolites. These rocks were formed under high-pressure, low-temperature conditions during subduction. Tinos is particularly renowned for its high-quality marbles, which have been used extensively in art and architecture since antiquity. Schists and gneisses, characterized by their foliated textures, also contribute to the island's distinct geological character. Adding to this diversity are granitic and granodioritic intrusions from the Miocene period, dated to approximately 18–13 million years ago. These granitoids, formed during post-orogenic extension, are a hallmark of the Cyclades and play a crucial role in shaping Tinos' geomorphology (Stournaras 2006). This granitic landscape, covering 22.6 km², forms a triangular pattern with vertices at Exomvourgo, Livadia Bay, and Kakia Skala. Notable geomorphs, including tors and tafoni, have developed due to spheroidal weathering, creating a visually striking terrain. The area around the village of Falatados, located in the semi-mountainous Pano Meri region between Tinos' highest mountains, Exomvourgo and Tsiknias, contains significant clusters of these geomorphs (Figure 2). These geological features, intertwined with local folklore, architecture, and agricultural traditions, add layers of cultural and social value to the landscape.

Figure 2. Granitic geomorphs around the village of Falatados

Tinos' geology holds significant cultural, scientific, and economic value. Its marbles, known for their exceptional quality, have been used in iconic structures like the Parthenon. The island's geological features attract researchers and geotourists, offering insights into tectonic and metamorphic processes while showcasing the interplay between geological heritage and human history. The unique geomorphic features and the island's potential as a Geopark underscore the importance of integrating geoconservation with sustainable development

Climate Change and Geoconservation Focus

Climate change poses challenges to the preservation of Tinos' granitic landscape. Rising temperatures, shifting precipitation patterns, and increased weathering rates threaten the stability and appearance of the granite geomorphs. The proposed Geopark aims to serve as a hub for studying these impacts while implementing adaptive geoconservation measures. This project is original in its commitment to directly addressing the intersection of climate change, geological heritage, and community well-being, setting a benchmark for future initiatives in similar environments. Key initiatives include a) the establishment of research programs to monitor weathering rates and the effects of climate variability on the granitic formations, b) the development of techniques to stabilize vulnerable geomorphs and preserve traditional stone buildings against climatic impacts, c) the assessment of how climate change influences the surrounding ecosystems and integrating findings into conservation strategies.

To achieve its objectives, the following interventions are proposed:

- Creation of new paths and improvement of existing ones to enhance accessibility while minimizing environmental impact.
- Development of information and visitor service infrastructure, including a central information center.
- Promotion and protection of granite massifs and geomorphs, emphasizing their vulnerability to climate change.
- Restoration, promotion, conservation, and protection of traditional stone buildings as part of the island's cultural heritage.
- Establishment of rest areas and educational zones for visitors.
- Installation of interpretative signs to provide information about the geological, ecological, and cultural significance of the sites.
- Organization of educational and cultural events to raise awareness of climate change and geoconservation

Discussion - Conclusions

The proposed Tinos Island Geopark will serve as a catalyst for addressing climate change and promoting geoconservation while celebrating the island's unique geological and cultural heritage. By combining research, education, and sustainable tourism, the Geopark will enhance the resilience of the local landscape and community, ensuring its preservation for future generations. Its originality lies in its innovative integration of climate change research, community-driven geoconservation, and the sustainable promotion of one of Greece's most distinctive geological landscapes.

Research highlights

- Strong lithological control on dissolved constituents in surface waters, influenced by regional geology.
- Nitrogen species mainly originate from sewage inputs from Megalopolis, with minimal lignite mining impact on Alfeios River water quality.

Abstract

This study aims at the hydrogeochemical evaluation of surface waters and the possible anthropogenic impact affecting the surface water quality in the complex environment of the Megalopolis basin, including over 50 years of lignite mining. The results can guide sustainable restoration strategies and environmental policies in the transition era of mine closure. In March 2024, 24 surface water samples were collected from upstream to downstream locations along the Alfeios River and its tributaries, which flow near the lignite operations. The chemical parameters of NH_4^+ (maximum 3 mg/L), SO_4^{2-} (range from 3 to 1010 mg/L), Mn (range from 1 to 338 μg/L), and Mo (range from 0.2 to 1027 μg/L) were identified as the most of environmental concern, exhibiting significant variability among samples. The presence of SO_4^{2-}, Mn, and Mo in the water samples indicates a geogenic origin, strongly influenced by the regional lithology, including lignite deposits, postAlpine sediments, and geological formations within the Pindos zone. The samples were categorized into three clusters (C1, C2, and C3) according to Hierarchical Cluster Analysis (HCA). Samples in Cluster 3, located near the old mining area, showed the highest concentrations of major and trace elements, exceeding the EU limits for Mn (50 μg/L) and SO_4^{2-} (250 mg/L) and were classified as Ca_2^+-SO_4^{2-} type waters. In contrast, C1 and C2 samples had a Ca^{2+}-HCO_3^- hydrochemical type. The scatter plot of NO_3^-/Cl^- ratios vs Cl^- indicated that the dominant source of NO_3^- was sewage from the town of Megalopolis. The Alfeios River appeared to be minimally affected by lignite activities, with no significant changes in water chemistry observed before and after the mining area, except for slightly elevated Mn and Mo levels, most of which remained below WHO and EU limits.

Keywords: Hydrogeochemistry, Surface Water, Lignite Mining, Post Mining

Introduction / Background

Lignite mining has been a major source of energy, significantly contributing to local and national economies, including that of Greece. Many studies have extensively examined the contamination and geochemistry of surface and groundwater resources near coal mines across various locations and different geological environments (GonzálezMartínez et al., 2019; Yang et al., 2023). However, environmental concerns related to coal mining activities and water resources will remain significant, even after the closure of mines (Liu et al., 2020). The geology of a region is a primary factor influencing the chemical composition of waters and the release of different types of contaminants, including metals and major ions, due to the geochemical conditions and anthropogenic activities (Kelepertzis et al., 2023; Yang et al., 2023). Coal mining can potentially contaminate surface and ground waters with pollutants such as sulfates and metals, resulting from coal processing and the exposure of sulfide minerals in atmospheric conditions (An et al., 2024). Also, various types of wastes affect water quality, including acid mine drainage, waste disposal (e.g. dumping sites), waste rocks, tailing storages, and liquid industrial wastes from power plants (Welch et al., 2021). The post-mining reclamation process has also been shown to affect geochemical conditions in abandoned or closed areas. Studies have shown that exposure of mineral residues and waste from lignite could potentially affect heavy metal and ion concentrations in surface water for many years after mine closure, making monitoring necessary (Liu et al. al., 2020; An et al., 2024). Lastly, differences in the chemical composition of the river are associated with various land uses and activities such as agricultural (fertilizer leaching etc.), domestic sewage, and industrial wastes

(Kypritidou et al., 2024).

Surface water quality of the Alfeios River in Megalopolis has shown elevated concentrations of some ions, e.g. Ca^{2+}, Mg^{2+} and SO_4^{2-} in the river water (Dimitrakopoulos et al., 2007). Louloudis (2017) applied Principal Component Analysis (PCA) to determine the correlation between different types of water in the region, such as surface waters, groundwaters, aquitards, and pit lakes. It was found that karstic waters, surface waters, and aquitard waters are not affected by mine waters in the region. Despite the above studies, there is no comprehensive systematic environmental monitoring of surface water quality in the region. The aim of this study is to cover this gap by sampling all rivers and tributaries flowing through the lignite mining area to define the pollution sources that influence the water hydrochemistry. The findings of this research aim to provide useful information regarding the hydrogeochemical status of surface waters, the geological influence in water geochemistry and imprint the environmental pressures from the human activities in the region. The geochemical stability of the region is one of the main key criteria to consider for the environmental rehabilitation of the Megalopolis Lignite Center (Sokratidou et al., 2018).

This study can establish geochemical baseline conditions before post-mining activities and help for a better understanding of the hydrogeochemical status of the area and support environmental rehabilitation and monitoring plans. The specific objectives are: a) To determine the hydrogeochemistry of all surface waters in the area and their effect on the Alfeios River and, b) to investigate the influence of the regional geological structure and any anthropogenic contamination on major ion and trace element concentration.

Description of the study area

Megalopolis region is located in the center of the Peloponnese peninsula Greece. The basin exhibits an elliptical form, with its major axis oriented in an NNW–SSE direction, stretching over a length of 18 km. The study area could be characterized as small hydrological basin due to the complicated hydromorphology of the region where many small tributaries flow near the Megalopolis town, the lignite mining works and the sites of the external waste dumps. The main river of the area is Alfeios River flowing from the south to Northwest direction, spanning 127 km before discharging into the Gulf of Kyparissia. This study focuses on the Southern part of the basin, where the river traverses the lignite basin of Megalopolis. The biggest tributaries are Elissonas and Xerilas, which flow from East to West and South to North direction and finally flow into Alfeios River.

The geology of the region is shown in Fig. 1. The Pindos unit is the main geological unit in surrounding mountains with limestones, cherts, dolomites, and flysch. In the eastern part of the basin, the Gavrovo-Tripolis Unit appears mainly with limestones, dolomites, Flysch and the Volcano-sedimentary unit (Tyros Beds). Only in small exchanges northeast of the basin does the quartzite-phyllite series show up with marble, schist, and phyllites (IGME, 1997). Lastly, Mesozoic ultramafic rocks also occur in small extensive throughout the basin's marginal rocks. The central part of the basin is covered by different ages of post-alpine sediments from the upper Pliocene with Makryssion formation up to the Holocene Alfeios river terraces with clays, marls, red loam, coarse clastic sediments and lignites.

Figure 1: Geological map of the study area with the sampling locations.

Land use and Mine activity

The main economic sectors are primary (7% of the population) with cultivated land, secondary (36%) by limited industrial and artisanal activity, and tertiary (40%) tourist and economic centres (Energy and Climate Action Plan, 2021). The dominant economic activity was lignite mining by the Public Power Corporation (PPC), starting with the Thoknia mine in 1970. The other lignite fields include: Marathousa (started at 1989) ceased the exploitation in-2015, Kyparissia lignite field (started 1987) finished in 2012 and Choremi lignite field, which was the only active mine site since 1970 until the end of 2024. In the area two (2) Power Plans (PP) exist, with a total of four lignite power units: I and II (19702011), III (1975-2022) (PP A), and IV (1991- end of 2024) (PP B), with a total installed capacity of 850MW. There is also a natural gas Unit V with 811 MW total capacity. In March 2024, only two factories remained operational: a lignitefired power plan (Unit IV), which works when the energy demand is high, and the fully operational natural gas factory (Unit V). By the end of 2024, all lignite power plants were ceased, leaving only the gas unit. New activities like agriculture, renewable energy, and environmental projects will replace lignite operations (Louloudis et al., 2024) considering the master plan for the post mining areas.

Methods

The sampling campaign took place during March 2024 (wet period), collecting 24 surface water samples; ten samples from the Alfeios River (A0-A9) and 12 water samples from tributaries (ZR1, X1, KF1, ZG1, E1, E2, K1, LG1, ZT1, P1, ZM1, T1, SIK1) that discharge directly or indirectly into Alfeios River (Fig. 1). The physicochemical parameters (pH, EC, TDS, Eh, and Dissolved Oxygen) were determined in situ with a pre-calibrated portable multiparameter. The samples were collected in triple-rinsed high-density polyethylene bottles for further analyses. All water samples for analysis of trace elements and major cations were filtered on-site through 0.45 μm membrane filters and acidified down to pH<2 with conc. HNO3 (65%). All water samples were stored at 4 0C or frozen condition until further analysis.

Laboratory analysis and treatment of data

All water samples were analyzed for major cations (Ca^{2+}, K^{+}, Mg^{2+}, Na^{+}) with the ICP-OES (Agilent 5800), trace elements (B, Li, Be, Al, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Se, Sr, Mo, Cd, Sn, Sb, Hg, Ti and Pb) with ICP-MS/MS (Triple Quad 8900), major anions (Cl^{-}, NO_2^{-}, NO_3^{-}, PO_4^{3-}, SO_4^{2-}) with ion chromatography (DIONEX ICS-2000). Ammonium ion (NH4+) was analyzed only in the sampling sites of Alfeios (A0-A9) and Zarzakis (ZR1) with the HACK LANGE DR 3900. All water analyses were carried out in the PPC Innovation hub in the Laboratory of Environmental Chemistry and Special Materials (PPC) and standardized according to ELOT EN ISO/IEC 17025. Bicarbonate (HCO_3^{-}) was measured at the Laboratory of Economic Geology and Geochemistry at the Department of Geology and Geoenvironment (NKUA) by the acid titration method using H2SO4 (1.6 N) until a pH of 4.5. The ionic charge balance error (CBE%) was below 5% for all samples, except for P1 (8.6%) and ZT1 (7.2%). Statistical and graphical analysis of the acquired data was done with the Minitab 7 ® v 17.1 statistical software analysis. Elemental concentrations close to or below the method detection limits were excluded from further data processing. Statistical analysis was restricted to parameters that showed great variability (EC, Ca^{2+}, Mg^{2+}, K^{+}, Na^{+}, Cl, HCO_3^{-}, SO_4^{2-}, NO_3^{-}, Mn, Mo and Sr). The statistical methods that were used are: Hierarchical cluster analysis (HCA) with the Ward method and Boxplot of the parameters.

Results and Discussions

All water samples, except SIK1 (pH 6.5, slightly acidic), were near-neutral to mildly alkaline. Oxidationreduction potential (Eh) in most samples was indicative of oxidizing conditions, except for samples E2 and P1, where Eh values were slightly reduced (-47 and -26 mV, respectively). Electrical conductivity (E.C.) varied widely between 415 μS/cm and 2150 μS/cm, with an average of 788 μS/cm, indicating strong differences in chemical composition. Dissolved oxygen (DO) ranged from 6.6 to 10.3 mg/L. Calcium (Ca^{2+}) levels ranged from 63 mg/L to 421 mg/L, with a median of 115 mg/L; specific samples like P1, T1, SIK1, and ZT1 had elevated levels (>195 mg/L). Bicarbonate (HCO_3^{-}) was stable at 200–300 mg/L, except for SIK1, which exhibited a low value of 98 mg/L. Sodium (Na^{+}), K^{+}, and Mg^{2+} were generally low, except for T1, where Na^{+}, K^{+}, and Mg^{2+} were detected at higher levels 42 mg/L, 22 mg/L, and 44 mg/L, respectively. Sulfate (SO_4^{2-}) ranged from 3 mg/L to 1010 mg/L, with the highest values in SIK1 (553 mg/L) and T1 (1010 mg/L), P1 (274 mg/L) and ZT1 (318 mg/L), exceeded the acceptable drinking water for sulfate ions 250 mg/L(WHO 2022). Chloride (Cl^{-}) was generally below 20 mg/L, except for T1 (61 mg/L) and ZT1 (26 mg/L), both well below the acceptable limit for drinking water of 250 mg/L (WHO 2022).

Nutrient levels were low, with NO_3^{-} ranging from 8 to 16 mg/L in the Alfeios River, and most tributaries below 1 mg/L, except for ZR1 (13 mg/L) and T1 (11 mg/L), all within the WHO-acceptable drinking limit of 50 mg/L. Ammonium (NH_4^{+}) varied from <0.02 mg/L to 3.04 mg/L, with ZR1 showing the highest value above the drinking water

limits of 0.5 mg/L (EU, 2020; WHO, 2022). In the Alfeios River, NH_4^+ values were below 1.45 mg/L and decreased downstream (A8) to 0.34 mg/L. Phosphate (PO_4^{3-}) was generally undetectable, except for ZR1, T1, and ZT1, which had elevated concentrations (0.3 mg/L, 1.8 mg/L, and 0.5 mg/L, respectively). Trace elements such as Pb, Tl, Ag, Sb, Cd, and others were mostly below detection limits, but higher concentrations of Se, Ni, Fe, Mn, and Mo were observed in specific samples. Manganese (Mn) ranged from 1 µg/L to 338 µg/L, with several samples (P1, ZR1, T1) exceeding the WHO, (2022) limit of 80 µg/L. Molybdenum (Mo) had a median value of 3 µg/L, with three samples (E2, T1, ZT1) exceeding the WHO, (2022) limit of 70 µg/L.

Boxplot analysis (Fig. 2) revealed that Cluster 1 shows the lowest concentrations of all chemical parameters, with only a few outliers for Mn (PAN1) and Mo (E2). Cluster 2 exhibits higher concentrations than Cluster 1 across all parameters, especially for NO_3^- (>8 mg/L). Cluster 3 exhibited the highest variability and concentrations for most chemical parameters, except for NO_3^- (<8 mg/L). According to Piper classification diagram (Fig. 3) the water samples of Cluster 1 and Cluster 2 are of Ca^{2+} - HCO_3^- type. The samples from Cluster 3 are of Ca^{2+}-SO_4^{2-} type.

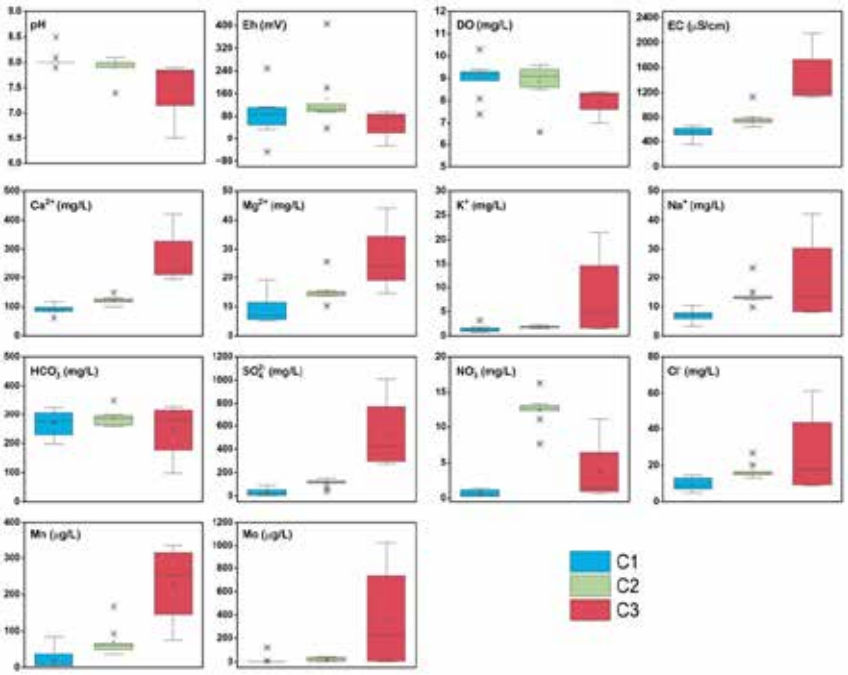

Figure 2: Boxplot of major chemical parameters based on the classification of surface water samples according to HCA.

The presence of Na^+, K^+, and Mg^{2+} in surface waters is associated with the dissolution of the clay minerals existing in the area. Kelepertzis and Kontis (1997) found that these elements have a strong association with clay minerals and plagioclase feldspar. Moreover, the sources of SO_4^{2-} are the geogenic factors of the region, as the composition of lignite is strongly associated with the geological environment of Megalopolis region. The low NO_3^-/Cl^- ratios and high Cl^- concentrations along the Alfeios river indicate sewage contamination from Megalopolis town as the main NO_3^- source (Fig. 4). High Mn content is primarily due to the presence of the Pindos zone in the Peloponnese, which contains high amounts of Mn, with Mn content ranging from 100 ppm to as much as 10,900 ppm, as well as localized small Mn deposits (Pe-Piper & Piper, 1989; Photiades & Perseil, 2002). Secondly Mn originated from the sediments of the area and lastly from the mafic and ultramafic rocks in the area. Mo is generally absent from local waters, except for two notable sources. The first is located downstream in Elissonas river (E2) and the second source of Mo enrichment is associated with the Gavros tributary (T1 sample). As suggested by Dimitrakopoulos et al. (2016), Mo shows high leaching potential because it is mobile and soluble in alkaline environment, and in Megalopolis, the geochemical composition of the lignite ore is particularly enriched in Mo.

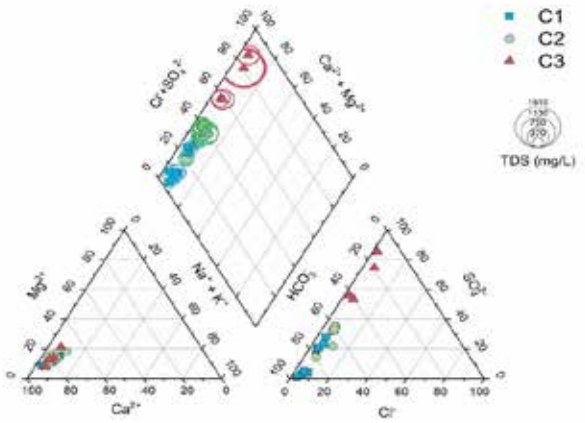

Figure 3: Piper diagram for the surface samples of the study area based on the classification of surface samples according to the results of HCA

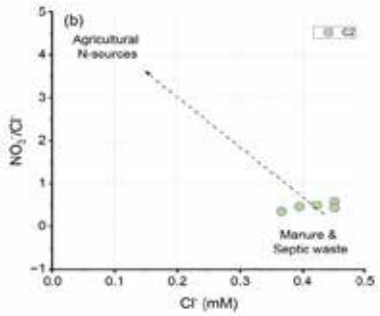

Figure 4: Scatter plot of NO3−/Cl− ratios and Cl−. The limits for agricultural activities and manure/sewage have been taken by Su et al., (2024).

Conclusions

- The Alfeios River appeared to be minimally affected by lignite activities, with no significant changes in water chemistry observed before and after the mining area.
- High Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}, and SO_4^{2-} concentrations are observed in tributaries flowing near the external waste dumps and near Thoknia mine.
- High NH_4^{+}, Cl^{-} concentrations and low NO_3^{-}/Cl^{-} ratios in the Zarzakis stream, point to septic waste from Megalopolis town as the main source of NO_3^{-} contamination that affects the entire length of the Alfeios river.
- Trace elements such as Mn and Mo exhibit distinct sources of enrichment. Manganese appears to originate both from the Chert series (Pindos zone) and post-Alpine sediments in the western basin. In contrast, Mo enrichment is observed in samples after the Elissonas River confluences with the Alfeios River. This enrichment could be attributed to the dissolution of material from the external waste disposal site. The influence of fly ash deposits potentially could be considered as an additional Mo source; however, the external trenches network in the mine perimeter, diverts the surface runoff into external and internal reservoirs, where the concentrated water is pumped and used for the rewetting of desulfurization and fly ash solid waste deposits inside the Thoknia mine area. Therefore, the surface water, that is in contact with the with fly ash deposits, is recycled inside the mine, and leaks in the outside are prevented.

Introduction

A Near Fault Observatory (NFO) is a natural laboratory undergoing active, and complex geophysical processes at or in proximity to densely populated urban areas. NFOs bound relatively small areas and provide researchers from various disciplines (e.g. geophysics, geodesy, and geochemistry) the opportunity to access and (re-)use a vast wealth of data and derive scientific products. This allows a better understanding of the multi-scale, physical/chemical processes, responsible for earthquake generation. This can only be achieved by the acquisition of continuous, long-term, high-resolution multidisciplinary data and the application of consistent, reliable state-of-the-art data processing. Six NFOs in Europe have been identified by the European Plate Observing System (EPOS), Figure 1, as long-term Research Infrastructures; three additional NFOs are in observer status. NFOs target the enhanced understanding of the mechanics of earthquakes to unravel the anatomy of complex seismogenic faults.

Figure 1: Map of the Near Fault Observatories (in red) and those being in observer status (in orange) across Europe.

Vision of TRANSFORM²

The TRANSFORM² project has the ambitious goal to improve and transform the existing NFOs, by integrating cutting-edge methodological and technological solutions, paving the way for the next generation of NFOs across Europe. This will be achieved by:

- Conducting tests, horizon scanning and feasibility studies, performing gap-analysis and assessing user needs in order to gain knowledge of the available state-of-the-art sensor equipment, evaluating its appropriateness and applicability for their deployment in the NFOs.
- Accelerating sensor development and testing where possible.
- Creating, developing, and applying workflows that will revolutionize the capacity of NFOs to detect and characterize seismicity and ongoing seismic sequences in real-time, leveraging machine learning as well as the existing and next-generation instrumentation.
- Establishing new paradigms in Earthquake Early Warning (EEW) that are optimized for the dense NFO networks. Assessing the developed workflow's suitability on EEW applications targeting the decision-makers and, consequently, society.
- Transforming the interaction with stakeholders and decision-makers, underpinned by a deeper understanding of their needs and demands and ultimately the benefits that they can gain from the RIs.
- Assessing the capacity and opening of new pathways for the existing NFOs to function as powerful test-beds for the development, calibration, and testing of new measuring equipment and systems.
- Identifying possible funding mechanisms and sources and providing recommendations to national administration authorities and the European Commission on potential calls for the long-term sustainability of the RIs.

Main Pillars

TRANSFORM² is based on the four pillars and on a coherent strategy for communication and liaison activities with researchers, scientists, and stakeholders, securing their active engagement, as well as the assessment and control of the project's outcomes, long-term scientific and socio-economic impact. These are:

Pillar I – New generation of sensors and analytical solutions in basic and applied research related to earthquake processes. These new technologies will contribute to the design of innovative studies and the opening of new perspectives to forecast natural disasters and mitigate associated risks and impact. The scientific and technological advancements of the last decade allowed the scientific community to use a new generation of sensors and analytical solutions in basic and applied research. Near Fault Observatories (NFOs) are the most suitable infrastructures to develop and test advancements in technology because they maintain the facilities and cover a large scientific knowledge to challenge the design, realization, testing, and use of innovative instrumentations. We aim to develop innovative instruments that will go beyond the state-of-the-art, improving NFOs capabilities for interdisciplinary (seismology, acoustics, geodesy, geochemistry) observational and monitoring purposes. We will exploit recent technological advancements (fiber optic-based systems, fully autonomous low-cost seismic devices, ferroelectric acoustic sensors, high-rate multi-constellation GNSS, automated geochemical sensors) to generate a new generation of multidisciplinary data that will allow for the first time to investigate earthquake nucleation processes in more details and from different perspectives.

Pillar II – Novel automatic workflow concept for enhancing detectability and characterization of earthquakes. Development of workflows for improving earthquake detection and source characterization across magnitude ranges. The emergence of Machine Learning (ML) algorithms and Digital Acoustic Sensing (DAS) of fiber optic cables are having a disruptive and transformative effect on seismology today, enabling new and fundamental insights into earthquake processes. The impact of NFOs can be expected to be particularly significant. We aim to exploit these technologies by exploring novel methodologies that will be transformed into operational-quality software, enabling application across the NFOs, with a focus on real-time applications. The first effort focuses on applying machine learning in order to deepen and enrich earthquake catalogues founded on traditional seismic instrumentation. A final effort will be focused on earthquake source characterisation - the elevated event-detectability provides new opportunities for this topic. The characterization of earthquakes might be supplemented by the HR-GNSS instrumentation solutions. Although accelerometers measure the waveform with orders of magnitude higher resolution and at higher frequencies than GNSS, they do not guarantee the representation of the overall event in a unique reference frame and may suffer from the so-called baseline shift (acceleration bias) and data clipping during large events.

Pillar III – New platforms for supporting decision-makers: Earthquake Early Warning concept, combining regional and on-site systems, new communication systems beyond telemetry, and tailored applications to citizens and

stakeholders. In the seconds following earthquake initiation, Earthquake Early Warning Systems (EEWS) can provide prompt notification of the incoming strong ground motion and estimate the potential damage, using real-time, modern information systems, leveraging fast telemetry and data processing from dense instrument arrays deployed in the source region of the event of concern. Despite this scientific and experimental effort, EEWS at the European scale are far from being considered a consolidated and standard technology. The real-time information released by EEWS often suffers from large uncertainties and inaccuracy of the predicted ground shaking amplitude. Additionally, the existing prototype EEWS at European scale are conceived to trigger a generic alert release and are often disconnected from the specific community and environment to be protected. Both factors complicate the effective implementation of EEW methodologies and prevent the use of real-time alerts for automatic decision-making processes during emergencies. Taking advantage of the recent progress in sensors and communication technologies, alongside new theories and observations on the earthquake nucleation process, here we want to set the grounds for the development of the new concept of EEWS, having the next-generation NFOs as backbone infrastructures.

Pillar IV – Next generation of accessibility: Test-bed concept, for testing and development of new cutting-edge measuring sensors. The raised research infrastructure will be exploited as a testbed for the equipment to be developed, workflows, early warning, and decision-making platforms, for demonstration and proof of concept purposes. The main goal is to use and test new measuring sensors and methodologies for studying natural systems at several sites (test-beds). These test-beds might be natural underground cavities, underground basements or even perpendicular escape branches of tunnels. A big challenging task is the in-situ demonstration of new instruments based on innovative optical recordings and processing. These new instruments and technologies, such as the commercial DAS or Brillouin Optical Time-Domain Reflectometer (BOTDR) systems, require long optical cables. For the EEW-ready NFOs, a difficult task will be represented by the improvement of EEW capabilities by extending the EEWS software and exporting the Decision Module, a platform that will be able to issue alerts from multiple locations that act independently. Several prototype applications will be developed to test the end-to-end chain going from data acquisition, and real-time processing of multiple algorithms to output combination and alert release. In several test sites we will involve stakeholders to evaluate the performance of the developed Decision Module.

Communication acivities

TRANSFORM² will focus on the active engagement of the stakeholders through targeted actions.

In the framework of TRANSFORM², industrial partners are given the opportunity to participate by interacting with the scientific and research community through the various planned initiatives. Towards this direction, we propose the development of the SolidEarth Innovation Hub (SEIH), the organization of two dialogue forums and two info-days dedicated to industry.

SolidEarth Innovation Hub is a web-based platform for exposing TRANSFORM²'s activities to stakeholders in a stakeholder-friendly manner and for evolving ideas to innovation and to realized outputs and services

Dialogue forums: Two dialogue forums will be organized by the Region of Western Greece with the participation of invited representatives from local authorities of the countries participating in the NFOs, industrial partners, researchers, scientists, and other target groups. Our aim is to trigger interest and promote the potential opportunities offered to the stakeholders through their active engagement.

Info-days for industry: TRANSFORM² will organize two info-days to engage stakeholders from the commercial world and communicate the projects and NFOs' potential involvement in their domains.

Last but not least, at the project's completion, a comprehensive **'White Book'** will be compiled which will document how associated data, products and services from the next-generation RI can be exploited for the benefit of different target groups among the research community, the stakeholders, and the society and propose ways for a sustainable funding of the RI in the future.

Acknowledgements

TRANSFORM² is funded by the European Union under project number 101188365 within the HORIZON-INFRA-2024-DEV-01-01 call. We would like to acknowledge all the TRANSFORM² colleagues involved in the proposal.

The Syros GeoPark Project

Engi M.[1], Gialoglou A.[2], Koutsabasis P.[3], Laurent V.[4], Mavrogonatos C. G.[5]
(1) University of Bern, Switzerland, martin.engi@unibe.ch (2) Syros, Greece agialoglou@mou.gr (3) University of the Aegean, Syros, Greece kgp@aegean.gr (4) Imperial College, London, UK v.laurent@imperial.ac.uk (5) University of Pisa, Italy konstantinos.mavrogonatos@unipi.it

Highlights

Apart from educational and cultural objectives, this project emphasizes the sustainable development of geo-tourism in Syros, with extended seasons, respect for sensitive areas, and supporting ecological preservation efforts.

Background and Motivation

Syros is renowned worldwide among geologists, mainly because its subduction / exhumation history is so well displayed. This realization has attracted countless Earth scientists to Syros since the 1960s, and people on the island have certainly noted these “odd tourists”, equipped with hammers and maps. But hardly any of the locals know what keeps attracting so many field geologists to their island. To this day, a general awareness of the outstanding significance of Syros – and the neighboring Cycladic islands – is lacking. Plenty of scientific research papers on Syros have appeared, but only scientists read these. Sadly, the plate tectonic spectacle evident in Syros remains obscure to most people!

The Syros GeoPark Project aims to change this : The public shall get the opportunity to recognize some of the many geological features visible in Syros and find out how these formed. Interested visitors of the Syros GeoPark shall learn what dramatic history is hidden in the Cyclades. For Syros locals, becoming aware of how their island evolved is part of their cultural identification, their local root system and pride. As a result, ecological sensitivity will spread as well.

Beyond such educational goals, the Syros GeoPark Project aims to form a basis for sustainable economic development by promoting geo-tourism. Opportunities for soft tourism shall be offered in a balanced program combining geological, archaeological, historical and ecological topics. Tourism groups are increasingly keen on discovery programs with an environmental and popular science touch, or on combining physical fitness with family fun. Most hikers prefer moderate weather conditions, they favour spring and fall months over the hot summer. Geo-tourism promises calmer, substantially extended seasons, beyond the brief tourist hype.

Ambitions and Challenges

Over the past 50 years, intense research worldwide has been focusing on subduction-related processes. Studies conducted in the Cyclades have substantially contributed to our current understanding in this field. On Syros in particular, numerous structural, petrological and geochemical investigations have elucidated the evolution in great detail. Hence a vast body of knowledge now exists on the tectonic history of the Aegean-Cycladic archipelago. It is difficult, even for specialists, to integrate so many relevant research results, and bridging the gap to the general public amounts to an enormous challenge. In view of these considerations, the Syros GeoPark Project has developed two complementary elements : a **GeoCenter** with museum-style displays and activities, and a series of **GeoPaths** offering (self-)guided excursions for hiking-tourists. The goal of both elements is to motivate visitors to enter an enjoyable learning process. The challenge is to stimulate their curiosity, irrespective of prior knowledge and initial interest, so as to guide them to appreciate aspects of Syros beyond sun and fun at the beach…

The ambition of the **GeoPaths** is to provide incentive and information that will motivate locals and tourists to explore *Apano Meria*, the splendid northern part of Syros. An existing network of hiking trails exists, and along these visitors are guided to observe the magnificent landscape, to stop at points of interest (POIs), where they are introduced to specific phenomena, outcrops or (geo)morphological features. A GIS-based app has been specially developed (*Syros GeoPaths App,* Koutsabasis *et al*., 2023) to make necessary information available to visitors, to assist them in planning their hikes and to offer real-time guidance and explanations along each of the GeoPaths. This app will freely be available to download on smartphones or tablets.

The **GeoCenter** will establish the main focus of the Syros GeoPark in a historic building in Ermoupolis. The aim is to immerse visitors in a wide spectrum of geology-related topics relevant to Syros. Fundamental aspects, such as the vast time-scales in Earth science, are introduced, with links from history to archaeology, and from geology to cosmology. The origin of our solar system, its planets and our moon are explained, as are meteorites. From the fundamental structure of planets, displays move on to Earth dynamics, global plate tectonics, and subduction-related processes in particular. The complex history of the Mediterranean is reviewed. Emphasis is placed on showing visitors how researchers combine various disciplines, how progress in Earth science results from working together at many scales. The splendid minerals

and rocks found in Syros are displayed not only for their beauty, but to convey how such samples, metamorphosed at high pressure, provide insight into processes deep inside the Earth, at tectonic plate boundaries. Interactive models, both digital and analog, are used to make many of the concepts understandable, and visitors will also enjoy playing the field assistant to a geologist in a VR game.
Above all, the GeoCenter aims to motivate visitors to explore more of what they learnt by hiking along the GeoPaths. Conversely, observing phenomena in Apano Meria while hiking may well bring up questions that may steer people to visit the GeoCenter.

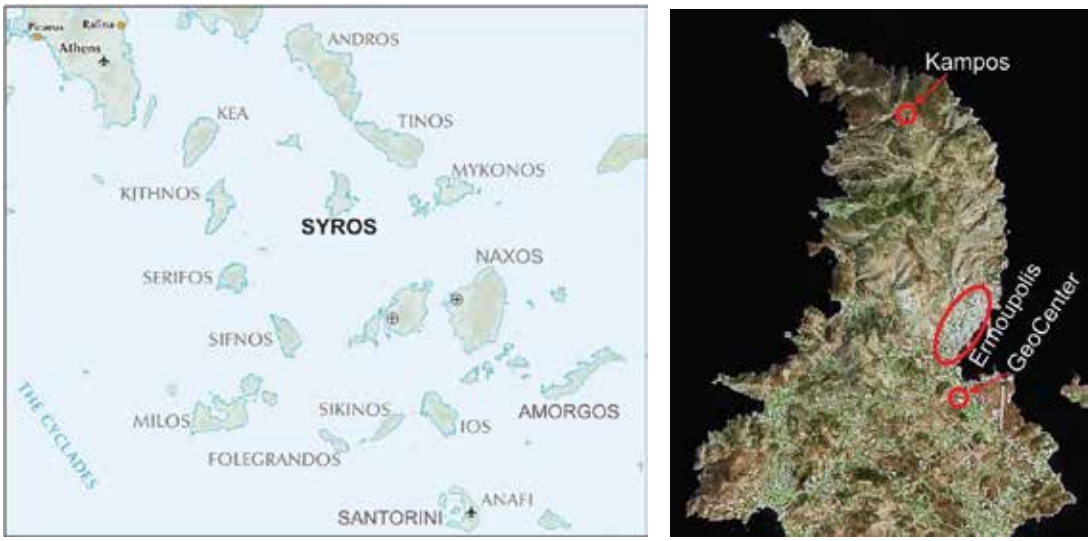

Figure 1. Overview map of the Cyclades (left), with locations relevant for the Syros GeoPark (right).

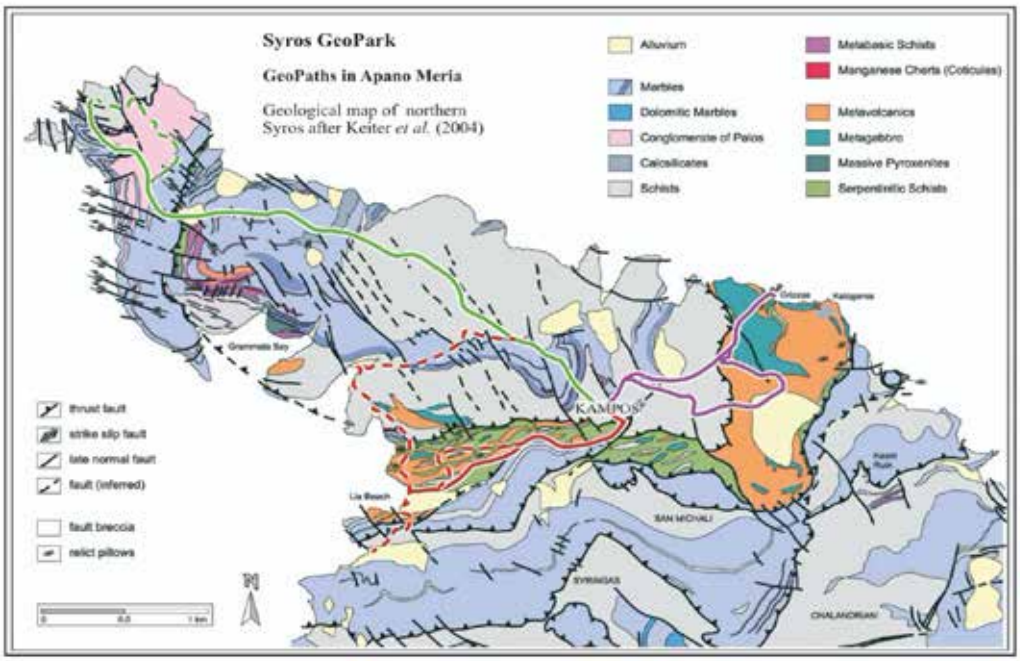

Figure 2. Geological base map of northern Syros (Keiter et al. 2004). GeoPaths from Kampos indicated by colored traces.

The Syros GeoPaths

The network of the GeoPaths is centered at Kampos, a tiny hamlet some 8 km north of Ermoupolis, where the road ends. All hikes start and finish all start at Kampos, they take between 3 and 6 hours round-trip (plus time for swimming etc.). Each GeoPath focuses on one or more geological themes (Table 1), so there is plenty to discover and enjoy.

Table 1. Characteristics of the GeoPaths in the Syros GeoPArk.

Path	Main topics of interest	Distances[1]	POIs, specials
Kampos – Lia	High-pressure shear-zone, tectonic contacts, brittle and ductile deformation, hydration phenomena, metasomatism, eclogite and glaucophane schists, marbles and metavolcanic rocks	H: 3.3 km V: 180 m	10 POIs Pretty beach “Aerolithos”
Kampos – Marmàri – Lia	Marble quarry, lawsonite pseudomorphs, cross section through shear zone, metasomatism, valley formation, mass flow	H: 4.5 km V: 310 m	11 POIs Nice beaches (3!)
Kampos – Diapori – Ryakas	Primary and tectonic contacts, fluid activity, erosional processes and features, soil formation, geomorphology, metaconglomerate, sedimentary *versus* tectonic origin	H: 8.4 km V: 410 m	13 POIs Fabulous views on clear days
Kampos – Grizzas	Intact (primary?) sequence of sedimentary and volcanic origin, metamorphic mineral growth, historic remnants, deformation in metagabbro, magmatic relics, chaotic breccia deposits, erosional morphology	H: 6.2 km V: 420 m	11 POIs Pebble beach “Cyclopic hand”
Kampos - Trochós	Metasediments and metavolcanics, karst formation in marble, eclogite lens, great views to Bronze-age Kastri fortress, historic Trochòs settlement and remnants, magmatic “factory”, veining	H: 2.8 km V: 110 m	5 POI Best view of Kastri

1: Approximate hiking distances. Horizontal (H) in kilometers for round trip. Vertical (V) in meters, necessarily up and down!

Popular destinations include the valley from Kampos to Lia beach, arguably the best researched transect in Syros. It displays an exceptionally well preserved high-pressure shear zone, that is interpreted as an exhumed part of a subduction channel. It presents a tectonic mélange containing massive eclogite fragments, elongate trails of metavolcanics and marble, all immersed in a highly tectonized serpentinite matrix, now composed mainly of talc-chlorite schist. The eclogite lenses display thin metasomatic rims and spectacular glaucophane veins, attesting to hydration of eclogite during exhumation. Most of the giant eclogite lenses are fragmented, but one boulder, known as “Aerolithos”, still stands over to 20 meters high. Its characteristic outline gave the Syros GeoPark its emblem (Fig. 3).

Figure 3. The “Aerolithos”, a giant eclogite fragment overlooking the bay of Lia

The Syros GeoCenter

The GeoCenter utilizes part of a 19th century industrial building, formerly one of the important tanneries in Syros. The impressive architecture of the Kornilaki building (Fig. 4) and its location slightly outside the busiest parts of central Ermoupolis offer a very suitable space for a museum-type installation.

Two floors of very distinct character lend themselves for displays. In preparation, some basic constructions were required to adapt the internal structure, notably to separate the display halls on the top floor from the building’s central

court. In total, the plans (Fig. 5) now encompass an entry and two display spaces at ground level, plus five exhibition halls upstairs.

Figure 4. The Kornilaki building in Ermoupolis, housing the GeoCenter and the library of the University of the Aegean

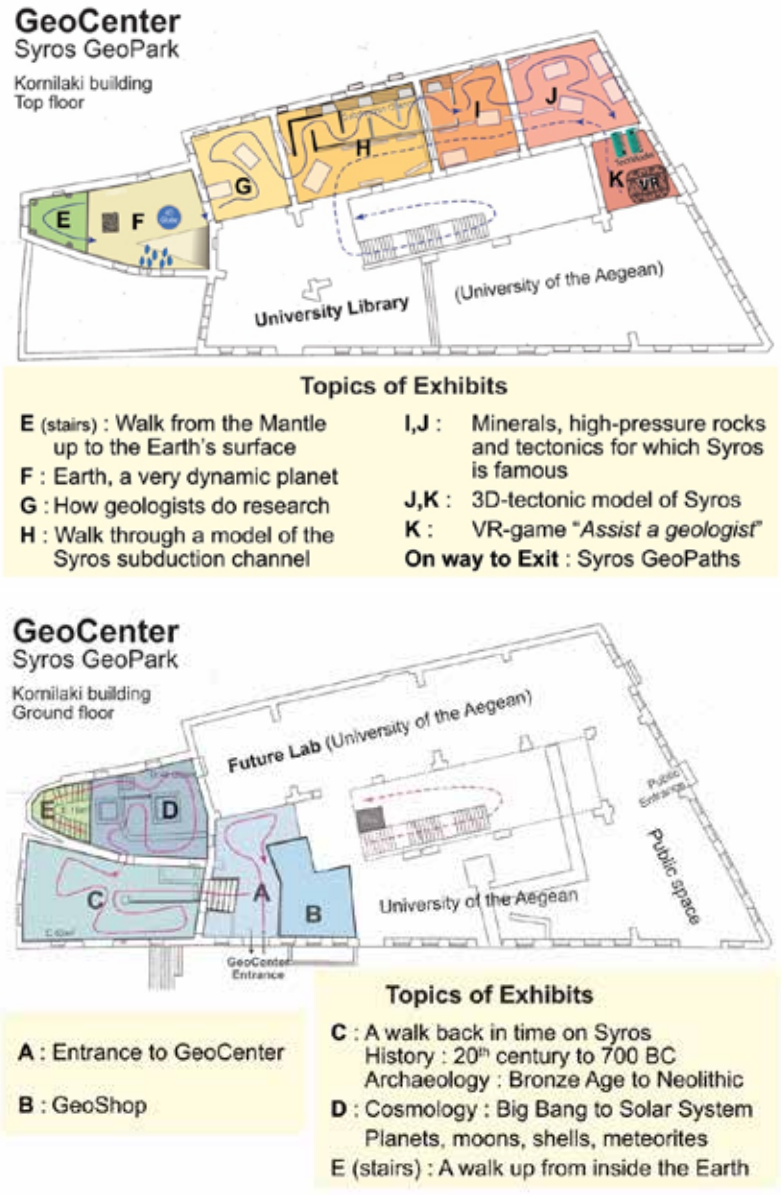

Figure 5. Floor plans at the GeoCenter, space distribution and topics of planned exhibits

Figure 6. Peeking into one of the exhibition halls of the GeoCenter

Project Organisation, Timeline, and Outlook

The Syros GeoPark was conceived as a project in 2017 by M. Engi and A. Gialoglou. In 2018 it received major funding through the SPECIAL PURPOSE DEVELOPMENT PROGRAMME for the SOUTH AEGEAN. In 2023 an extension with additional funds was granted. The project runs under the auspices of the Municipality of Syros, which has provided substantial support as well. A strong partnership with the University of the Aegean was established with P. Koutsabasis in 2018, and several international universities have been actively collaborating.

Regrettably, the initial time plan has been repeatedly disrupted due to the pandemic, an inefficient public administration, and a couple of individuals seeking to harm the project. Serious difficulties still remain due to urgently needed roof repairs on the Kornilaki building, as well as complicated negotiations with some of the land owners. Nevertheless, an optimistic time-plan presently counts on rapid progress over the next months, such that the Syros GeoPark should officially open in October 2025.

All along eight long years of preparation, the prospect of the GeoPark has generated growing enthusiasm in Syros, not only in the tourism sector, but equally among people with ecological, historical and archaeological interests. Strong connections have been established between the GeoCenter and sections of the University of the Aegean, some of which share the Kornilaki building. Beyond Greece, the many partners involved in the project have been spreading news about the project in international geological circles.

The idea of integrating the Syros GeoPark into a larger framework by associating it the with interested neighboring islands, so as to establish a topically broad Cycladic GeoPark has been discussed. No concrete plans exist so far, but at that scale an integration into the global network of UNESCO geoparks would appear both attractive and realistic.

Acknowledgements

Substantial funding for the Syros GeoPark Project by the Greek Public Investment Program is gratefully acknowledged. We thank the Municipality of Syros for all the support provided. Countless friends have collaborated with us – too many to name you all, but we do sincerely thank you, as this project could not be realized without you!

EXTENDED ABSTRACT 070

The 2024–2025 Seismic Sequence in the Santorini-Amorgos Region: High-Resolution Seismological Insights into a Volcano-Tectonic Crisis

Evangelidis C.P.[1] and Fountoulakis I. [1]
(1) National Observatory of Athens, Institute of Geodynamics, cevan@noa.gr

Introduction

The Santorini-Amorgos (SA) region lies within one of the most active segments of the South Aegean Volcanic Arc (SAVA), where complex interactions between tectonic structures and volcanic systems are driven by the ongoing subduction of the African plate beneath Eurasia (Fig. 1a). This region is characterized by extensional deformation along NE–SW-trending faults and includes prominent volcanic centers such as Santorini and Kolumbo. In mid-2024, low-level seismicity began beneath Santorini, gradually intensifying and migrating northeastward by early 2025. This development raised significant concern due to its location along known fault systems and in proximity to active volcanic centers. Historically, the area has shown evidence of tectono-magmatic activity, and the emerging sequence prompted the need for detailed monitoring and analysis. The primary objective of this study is to investigate the evolution and underlying processes of the 2024–2025 seismic sequence using high-resolution seismic monitoring. Specifically, we aim to enhance the existing seismic catalog through machine-learning-driven workflows, resolve spatial and temporal patterns of earthquake occurrence, and assess the physical nature of the events—particularly whether they result from tectonic faulting, magmatic intrusion, or a combination of both. A secondary goal is to develop and implement a near-real-time operational framework to support crisis response and long-term scientific research.

Methods

Seismic data were acquired from 23 broadband, short-period, and strong-motion stations, with coverage significantly improved by the installation of station HT.ANYD on Anydros Island in early February 2025. The analysis focused on the period between June 2024 and March 2025. Using continuous waveform data, seismic phases were automatically picked with EQTransformer (Mousavi et al., 2020), a deep-learning tool optimized for volcanic environments, and associated with the PyOcto phase associator (Münchmeyer, 2024). Initial event locations were determined with NonLinLoc and refined using a source-specific station term (SSST) relocation (Lomax et al., 2014; Lomax and Savvaidis, 2022), and the GrowClust algorithm (Trugman and Shearer, 2017) based on waveform cross-correlation. This workflow produced a final catalog of nearly 14,000 high-precision events. For larger earthquakes (ML ≥ 3.5), full moment tensor (MT) solutions were computed using Gisola (Triantafyllis et al., 2021), a high-performance implementation of the ISOLA method. The seismic signals were further analyzed using the Frequency Index (FI) metric, which estimates relative spectral content and provides insight into source complexity and potential magmatic influence.

Results

The relocated seismicity revealed a clear evolution of the sequence, beginning with shallow clusters beneath the Santorini caldera and shifting northeastward to greater depths beneath Kolumbo volcano (~20 km) (Fig.1b, 1a-b). The seismicity then migrated toward Anydros, forming a broad, diffuse seismogenic zone between 10–15 km depth, extending ~20 km in length and aligning with NE–SW-trending tectonic structures. Cross-sections indicate both steeply dipping and antithetic faults, consistent with transtensional deformation (Fig.1a-b, g-h, i-j). Moment tensor solutions display a dominant normal-faulting regime with significant non-double-couple components, especially positive isotropic and CLVD terms, suggesting crack-opening processes linked to magmatic fluid movement. The FI metric further supports this interpretation, revealing spatial variation in frequency content, with higher-FI events concentrated northeast of Anydros, where the activity appears more tectonic in nature, and lower-FI events toward the southwest, potentially indicating stronger magmatic involvement. Seismic migration patterns also exhibit rapid back-and-forth behavior with velocities up to 2.8 km/h.

Conclusions

The 2024–2025 SA sequence presents a compelling case of tectono-magmatic interaction, with seismicity progressing from deep initiation beneath Kolumbo to shallower zones aligned with known tectonic features. The combination of moment tensor inversion and frequency content analysis suggests that the sequence was not purely tectonic but involved magmatic processes such as dike injection or fluid migration. The study demonstrates the effectiveness of machine-learning-based workflows for real-time seismic monitoring during volcanic crises. The resulting high-

resolution catalog provides valuable insights into the geodynamic behavior of the region and is now openly available for future studies. This work establishes an operational framework that may serve as a model for future seismic and volcanic crises in similar geodynamic environments.

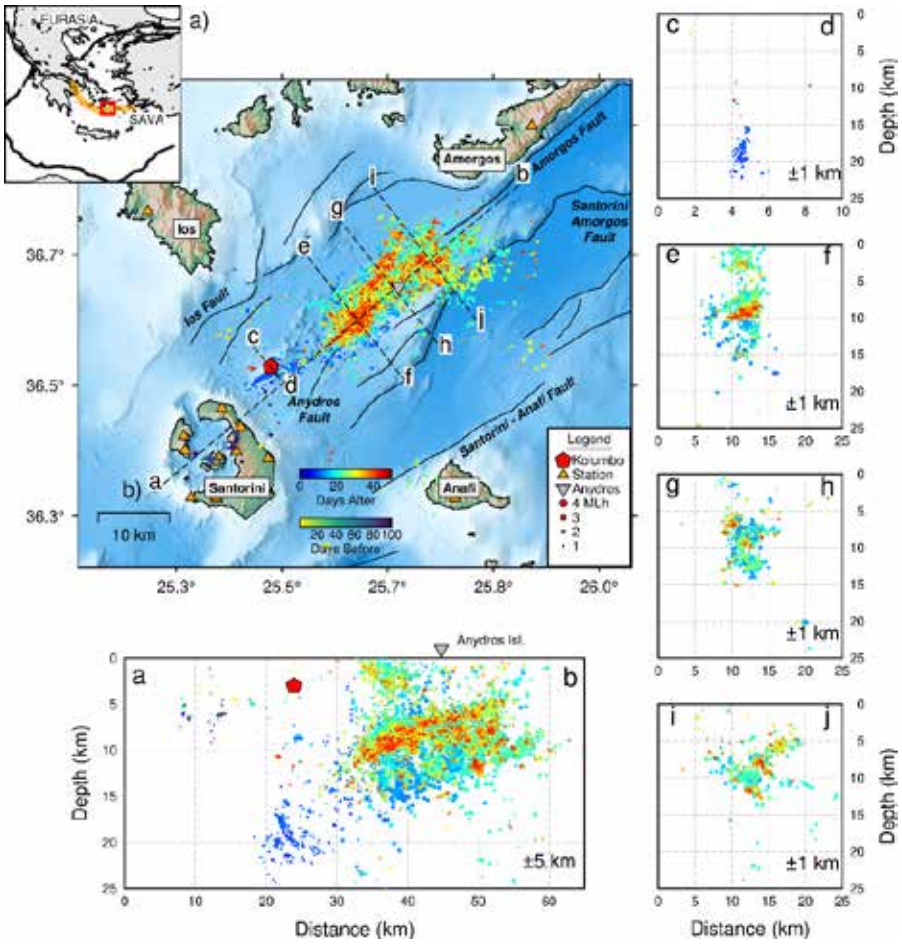

Figure 1. (a) General illustration of the broader Hellenic arc region, showing the main plate boundaries. The SAVA is highlighted in orange, with the study area shown in b) marked by a red rectangle. (b) Relocated seismic events, color-coded based on their occurrence date relative to 20/01/2025 (DD:MM:YYYY) and scaled according to their local magnitude (ML). Black lines represent the main fault traces in the area (Nomikou et al., 2018), while the red polygon defines the Kolumbo volcano chamber (2-4 km depth based on Chrapkiewicz et al. (2022)). The inverted triangle marks the location of Anydros Island, and triangles indicate the seismic stations used in this study. Vertical cross-sections (a-b to i-j) are also shown.

Acknowledgements

Figures and maps were created using the Pythonic interface of the Generic Mapping Tools (PyGMT) software (Tian et al., 2025) and the Matplotlib library (Hunter, 2007). Additionally, parts of the analysis were conducted using ObsPy (Beyreuther et al., 2010). We are thankful to all those scientists and personnel who maintain and operate their networks at the National Observatory of Athens-Institute of Geodynamics, Aristotle University of Thessaloniki-Seismological Station and National Kapodistrian University of Athens-Seismological Laboratory.

EXTENDED ABSTRACT 071

Tooth enamel meso- and microstructure of fossilized Hipparionine horses of Pikermi (Attica, Greece)

Fasoli D.[1], Stathopoulou E.[1]

(1) National and Kapodistrian University of Athens, Department of Geology and Geoenvironment, Panepistimiopolis, 15784 Zografou, Greece, dionfasoli@gmail.com , estathop@geol.uoa.gr

Research Highlights

There are no major differences in the microstructure of enamel between the two main subgenera of Pikermi. However, slight distinctions are present, in enamel thickness and Type III enamel presence.

Introduction / Background

Equidae teeth have a highly complex structure, consisting of heavily plicated enamel. Hypsodonty, along with enamel microstructure alterations, helped them adapt to changes in dietary conditions (Pfretzschner, 1993). Due to its unique diversity, enamel often allows for the identification and classification of mammals, shedding light also on their phylogenetic relations. Tooth enamel microstructure is known to be an indicator of dietary adaptations and biomechanical stress due to its unalterable nature (Koenigswald and Pfretzschner, 1991).

The objective of this study was to describe and compare the traits of Hipparionine dental enamel from the famous fossiliferous site of Pikermi (Attica, Greece). Any unique characteristics could offer crucial phylogenetic information and could even be used for the identification of the different species that have been recorded at the site, but till now they were only identified based on macroscopic features. This information was also correlated to the mesoscopic characteristics of tooth enamel, which in the case of these specific animals is extremely complicated, as well as fascinating. Intense plications and variations of the enamel thickness within a single tooth are extraordinary. This is the first attempt to discriminate different hipparionine species at the site based on enamel microstructure.

Materials and Methods

Twenty-four dental samples (upper cheek teeth) from the fossiliferous locality of Pikermi (Attica, Greece) were acquired, to test for distinctions between two subgenera belonging to the Pikermi fauna, in meso- and micro-scale. The physical characteristics and size of Pikermi hipparions allow us to discriminate between at least two species, *Hippotherium brachypus and Cremohipparion meditteraneum* (Böhme *et al.,* 2018) (*H. brachypus* and *H. mediterraneum* in Koufos, 1987, Koufos *et al.,* 2022). These subgenera descended from different lineages and show different cranial and limb bone characters (Koufos, 1987).

The rich terrestrial vertebrate fauna has been extracted from the Pikermi Formation, an up to 30-meter-thick series of mostly reddish silts with subordinate clastic channels of conglomerates and sandstones (Roussiakis *et al.,* 2019), with its deposition starting in the Early Tortonian (Vallesian) (Böhme *et al.,* 2017). The material at the site has been dated back to the Tortonian – Messinian boundary (middle Turolian) (circa. 7,25 Ma B.P.) (Koufos, 2013; Böhme *et al.,* 2017).

The material was grouped based on macroscopic and mesoscopic characters and measurements (height from the root, occlusal length, occlusal width, protocone length, number of enamel plications pointing at the protocone – plis caballins, number of rest of plications, shape of protocone) (Figures. 1,2), according to Eisenmann *et al.,* 1988.

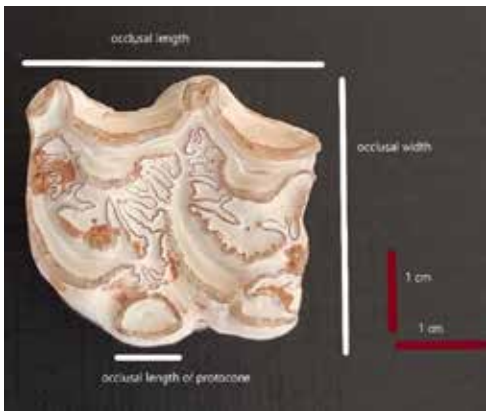

Figure 1. Macroscopic and mesoscopic measurements on the dental occlusal surface of sample Π89/39, according to Eisenmann *et al.,* 1988.

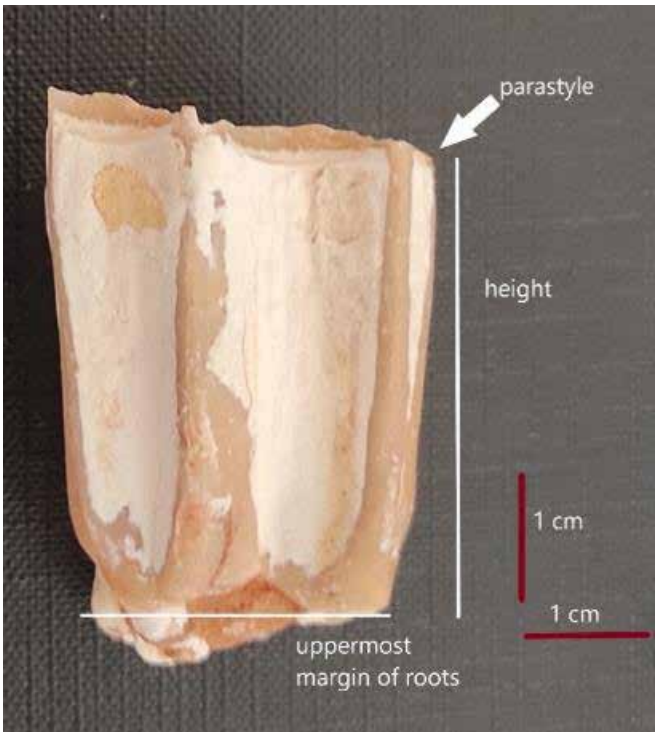

Figure 2. Macroscopic measurements on dental sample Π89/39 (vestibular view), according to Eisenmann et al., 1988.

Samples of each group were examined via stereoscope and Scanning Electron Microscope (SEM), regarding changes in the number of enamel plications while moving closer to the root (cut at 3, 2, and 1 cm from the root), enamel thickness, and enamel types and distribution. To study the enamel microstructure of the selected teeth, they were embedded in resin and cut at 1, 2 and 3 cm above the root of the samples. The embedded samples were prepared according to a specific procedure which includes etching with HCl, to enhance the enamel's characteristic features (Koeningswald and Rose, 2005), and after being coated with Au-Pd they were observed with a Jeol JSM 6390 Scanning Electron Microscope. SEM is considered essential for the observation of specimen histology.

Results – Discussion

No increase/decrease pattern was detected in the number of plications while moving closer to the root, although all samples, at 1 cm from the root, showed a simpler structure. There was the exception of one sample whose plis caballins (8) exceeded the range given by Koufos, 1987 (1-5).

Enamel maximum thickness ranged between 1000 – 1400 μm in peripheral enamel, 800 – 1400 μm in protocones, and 1000 – 1300 in the fossettes. The group with 1 pli caballin showed average maximum thickness of 1,3 mm in peripheral enamel, 1,17 mm in protocone, and 1,21 mm in the fossettes, while the group with >3 plis caballins showed average maximum thickness of 1,16 mm in peripheral enamel, 1,02 mm in protocone, and 1,16 mm in the fossettes.

Three main enamel types are seen in Equidae with hypsodonty. Modified enamel (or Type I enamel) closer to the EDJ (enamel – dentine junction) consisting of radial rows of prisms separated by relatively thick rows of IPM (inter – prismatic matrix), radial enamel (or Type II) closer to the ECJ (enamel – cementum junction) which consists of prisms of various sizes and shapes (horseshoe, keyhole, oval) with noticeably thinner – to – non-existent IPM, and a honeycomb – like structure (or Type III enamel) making small appearances in either the EDJ or the ECJ or both, composed of round- shaped prisms separated by thick IPM (Kilic *et al.,* 1997; Pfretzschner, 1992; Demeshkant *et al.,* 2023).

All samples showed all the aforementioned enamel types (Figures 3 – 5). The samples with 1 pli caballin had more Type III enamel than the ones with >3 plis caballins, in various areas, and even far from the junctions. Most plications showed irregularities regarding the enamel prisms and IPM orientations at the invaginations, with no distinct pattern (irregular enamel type) (Figure 6), while elsewhere the enamel prisms and IPM followed a relatively radial path between the boundaries, and in others HSBs (Hunter – Schreger bands) appeared. The plications of all the samples had triangular - like or rounded shapes and were either deep or shallow.

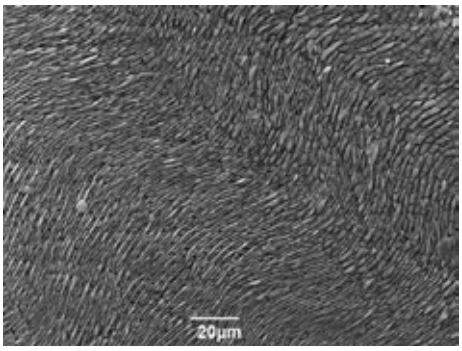

Figure 3. Type I enamel (modified) in sample Π89/9 (2cm distance from the root).

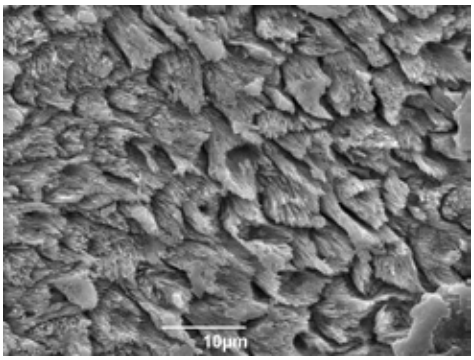

Figure 4. Prisms of Type II enamel (radial) in sample Π89/12 (2cm distance from the root).

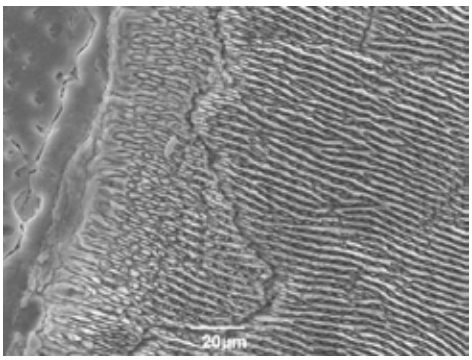

Figure 5. Type III enamel (honeycomb – like) (left) and Type I enamel (modified) (right) in sample Π89/9 (2cm distance from the root).

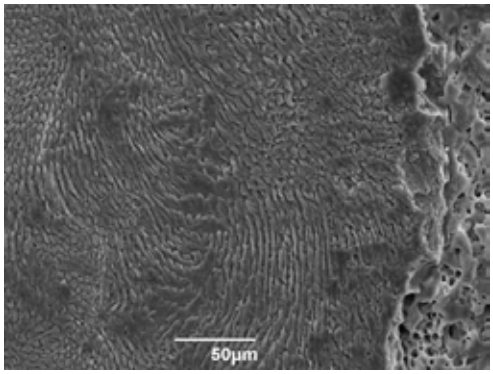

Figure 6. Irregularities appearing in one of the plis caballins of sample Π89/12_2

The presence of modified enamel (Type I) shows the evolutionary track of hipparionine horses, as the diet of Equidae altered from browsing to grazing (Pfretzschner, 1993). As the enamel microstructure in this genus (and in Equidae in general) is very complicated, a clear distinction between the two subgenera was not possible, as all samples exhibited the same features under SEM, similar distribution of enamel types, fragmented protocones, and similar plication forms, with the differences being the number of plications, the enamel thickness, and the more distinct presence of Type III enamel in samples with 1 pli caballin. Ongoing research will allow for further investigation of this hypothesis.

EXTENDED ABSTRACT 072

Local driven protection of a tectonic geosite, in Crete, Greece: The Paligremnos Protected Landscape

Fassoulas C.[1], Staridas S.[2], Nikolakakis E.[3]
(1) Natural History Museum of Crete- University of Crete, Heraklion, Greece, fasoulas@nhmc.uoc.gr (2) Staridas Geography, Heraklion, Greece, (3) University of Crete, Heraklion, Greece

Introduction

Protection of geodiversity is an urgent need of modern societies as it represents the crucial link between abiotic and biotic nature. Although in nowadays protection of biodiversity is one of the highest priorities of our societies, the same does not apply for geodiversity, which is under additional pressures related with row materials and development of big infrastructures that are so necessary for our technology. The oldest efforts for conservation of geoheritage are dated back to the 18th century in several European countries, followed by the establishment of the first National Parks in USA (Grand Canyon, Yellowstone etc.) with core geological features (Gray 2004).

In Greece, the first efforts to protect elements of our geoheritage can be found in the establishment of the two National Parks of Olympus (1938) and Samaria (1962), however without any concern or the direct protection of their geological values (Zouros & Fassoulas 2006). Yet, national legislation is very weak in respect to geoconservation and has changed several times overturing former positive initiatives. The first law with a clear provision for the protection of abiotic nature was the 1650/1986 which was foreseen that some aspects of geodiversity, like caves, gorges, plateau and fossil sites could be preserved as Natural Monuments. Application of this legislation was though incredibly difficult as it was requesting the elaboration of Special Environmental Studies of high cost and time consumption that were approved by the Ministry of Environment. As a consequence, no geological monument was protected under this law. In 1985 Lesvos Petrified Forest was declared by the Ministry of Culture as a Protected Monument of Nature, and in 1988 Meteora were nominated as a World Heritage Site mainly for its cultural value. A big step forward was achieved with the Law 3937/2011 which for the first time defined what a geosite is and foresaw the establishment of geoparks in the form of National or Regional Nature Parks, with much simpler studies checked by Regional Authorities. Implementation of this legislation was relative flexible permitting the protection of two geological monuments as Protected Landscapes, the Almyri Panagia in Lesvos and Limnos Petrified Forest. In 2020 legislation changed again with the Law 4685/2020 which abrogated the Nature Parks and thus geoparks and transferred the decision-making process back to the Ministry of Environment, Energy and Climate Change.

A milestone for the geoconservation in Greece was the establishment in 2015 of the UNESCO Global Geoparks by UNESCO, that recognized five territories in Greece under this program, namely the Lesvos Petrified Forest, Psiloritis, Chelmos-Vouraikos, Vikos-Aoos and Sitia. Still the nine existing UGGps in Greece lack of authorization and recognition by law. Concluding, the geological elements that are under protection in Greece are quit few, despite the extraordinary value of Greek Geological Heritage.

In 2022 an important geosite of Crete, the Paligremnos fault scarp (Fig. 1) was placed under serious threat by the initiation of excavations at the top of its scarp by a private company for the construction of touristic apartments. Being a local landmark, a postcard of Crete since the 1970's, an aesthetic landscape, an international climbing field, a well-studied fault (Angelier 1979) and a mapped geosite for Crete with at least regional value (Fassoulas et al. 2007), Paligremnos received an immense and unexpected support by locals, foreign residents, visitors and the climbing community of Greece. Just a week after the excavations, more than 1500 people gathered at Paligremnos protesting against its destruction and the construction of the apartments, requesting by the regional and local authorities its protection under the moto "We become a rock for the protection of our rock". In July 2022 the Municipality of Agios Vassilios in Rethimno assigned Natural History Museum of Crete the elaboration of a special study for the nomination and protection of Paligremnos as a Protected Landscape, whereas together with the protesting society, undertook legal actions to cancel the building license of the construction. Both actions were successful and finally the Paligremnos was declared in 2023 as a Protected Landscape and Protected Natural Formation due to its geological importance, with the Ministry Decision GGG 535/23-62023. This article presents the main geological features, their assessment and the documentation of the broader area of Paligremnos as a Protected Landscape due to the national value of its geological heritage.

Figure 1. The Paligremnos fault scarp in Plakias bay

Methodology

The Natural History Museum of Crete established a study group including various specialists such as a geologist, geographer, a biologist and an IT specialist with the aim to (1) Identify the area of interest, (2) identify, map, study and document the main geological and biological values of the area (3) Qualitatively and quantitatively assess the geological values of the area (4) identify the potential human and natural risks (5) document the reasons for monument's protection and preparation of a Ministry Decision under the 4685/2020 Law.

In Automn 2022 both geological and biological missions and inventories were contacted at the area, a detailed geological and tectonic mapping at a scale 1:5000 was applied, satellite images were analyzed, an UAV-based photogrammetric survey was conducted and a digital relief model was created for detailed measurements of the scarp, while existing literature was analyzed. Finally, we applied the quantitative geotope assessment method of Fassoulas et al. (2012) to demonstrate the touristic and educational potential of the monument and its vulnerability.

All collected data resulted in the compilation of the Special Geological Study foreseen by the L.3937/2011, which was quite similar to the well-known Special Environmental Studies of the L1650/1986, that was submitted to the regional and national authorities for the characterization of the broader Paligremnos area as Protected Landscape.

Results

The broader area of Paligremnos is characterized by the presence of Jurassic and Eocene limestones of the Tripolitsa nappe and small outcrops of the Eocene flysch, that cover a small peninsula named Psarela, opposite to the well-known tourist destination of Plakias in Rethimnon (Fig. 2). An east-west trending basin exists between the cape Psarela and the Asiderotas mts at the north, covered by late Miocene sediments in which an important amphibian and terrestrial fauna was discovered (Georgalis et al. 2016), while small sand dunes are formed at the southern part of the beach. The monument is located over the north facing steep cliff of the peninsula on which three parallel fault scarps were mapped along the east-west direction (Fig. 2). The first scarp (F1) is the Paligremnos, an almost vertical fault surface with two generations of striations present, as well as large corrugations and kinematic indicators pointing to a normal sense of shear. The second scarp (F2) located uphill is quite long dipping into the sea westwards. This scarp has a moderated dip towards north, and although more weathered it presents also several corrugations, while two coastal caves exist at its surface. A small tunnel was opened during the WWII reaching the caves, to transfer coal excavated inland at the far-most cave where ships could deliver it. The tunnel was supported by fortification establishments too. The higher scarp (F3) has smaller extent, moderate dip with polished surfaces at places, where one set (the oldest) of slickensides can be seen. The analyses of the photogrametric data and the digital relief model (Fig. 3) revealed that the Paligremnos scarp is 132 m long and 42 m high, with a total surface of 5274,1 m^2. Field and other historical data proved that the scarp was naturally exposed. Finally, another older normal fault (F4) oriented northwest-southeast has been mapped on top of the hill forming together the F3 a high escarpment at the Tripolitsa limestone.

Along the coastal cliffs and in several cases on the F2 fault scarp, a sea notch at 1.4m above m.s.l. indicates the tectonic uplift of the whole territory related with the 365 A.D earthquake. Geomorphotectonic mapping and study revealed five distinct marine terraces on the peninsula (Fig.4), the lowest at about 15m height, and the highest at about 120m. showing the gradual rock uplift recorded at the southern coastal zone of Crete during the upper Pleistocene (Ott et al. 2019).

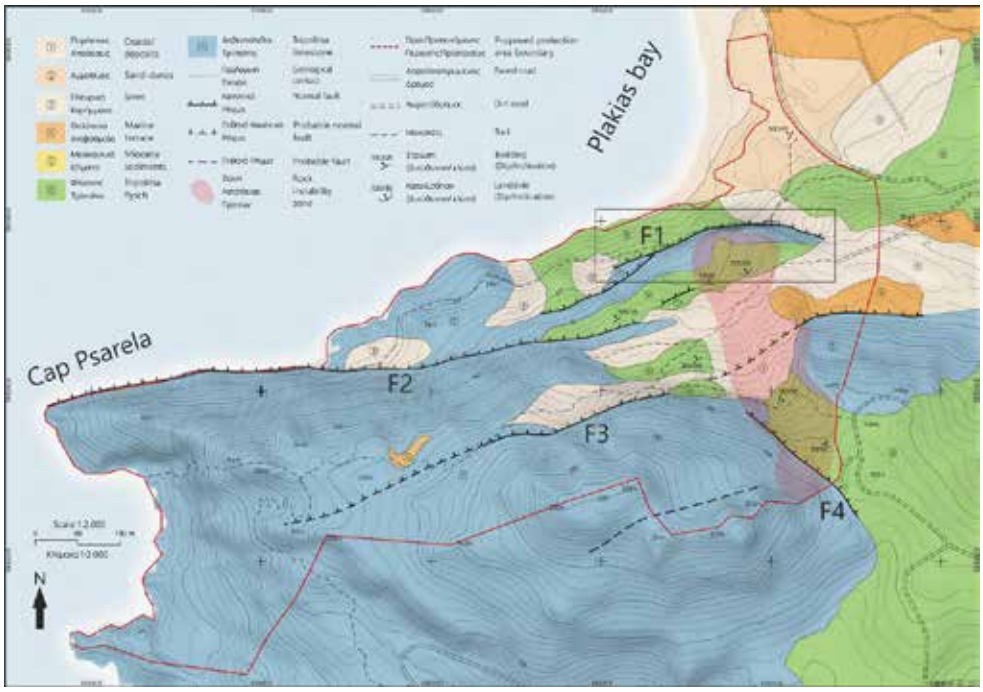

Figure 2. Geological map of study area. F1,..,4 refer to faults in text, square shows Paligremnos scarp

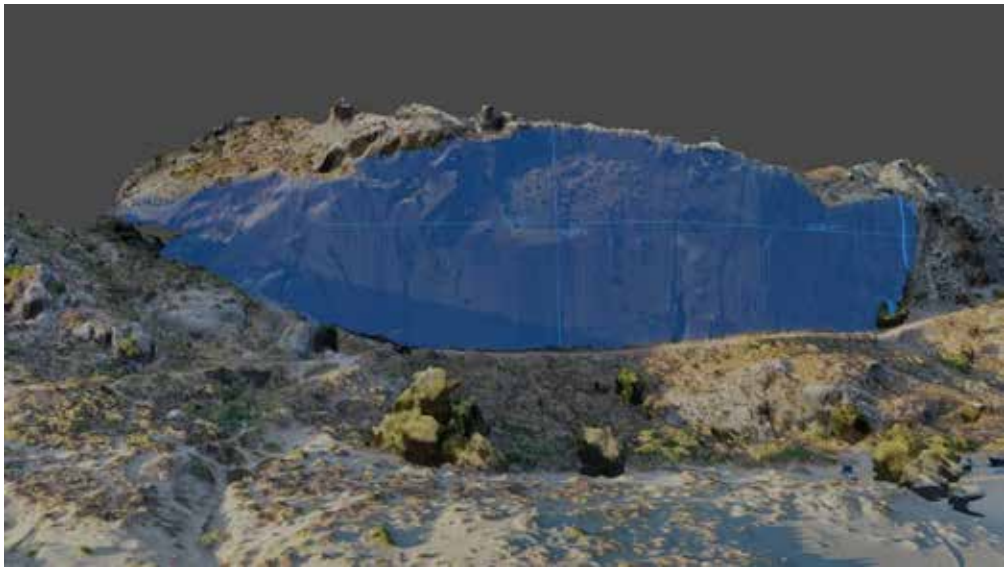

Figure 3. The 3-d relief model of Paligremnos scarp developed for the accurate measurements of its surface

Fault kinematic analyses, using Stereonet software, revealed for the older set of striations a stress field with the maximum extensional axis gently dipping towards the NNW direction and an almost vertical maximum compressional axis, pointing out, together with the kinematic indicators, to a normal sense of shear (Fig 5a). The younger set of lineations indicated a normal sense of shear with considerable lateral component, and the maximum extensional axis almost horizontal dipping towards NNE direction (Fig 5b). This latest stress field is the same with the stress field recognized by Mouslopoulou et al. (2014) for the nearby active Spili fault. In addition, the Paligremnos faults appear to act as antithetic to the main fault zone of Sellia- Assomatos, located north of Plakias basin. Sellia-Assomatos fault zone appears to be the eastwards continuation of the Sfakia fault zone, which is considered as the most important active zone of the southwestern cost of Crete (Nicol et. all, 2020; Ott et al. 2019). The vertical inclination of the Paligremnos scarp was thus interpreted as a rotated surface due to the main activation of the Sellia-Assomatos fault, indicating that the fault zone should be considered as active too.

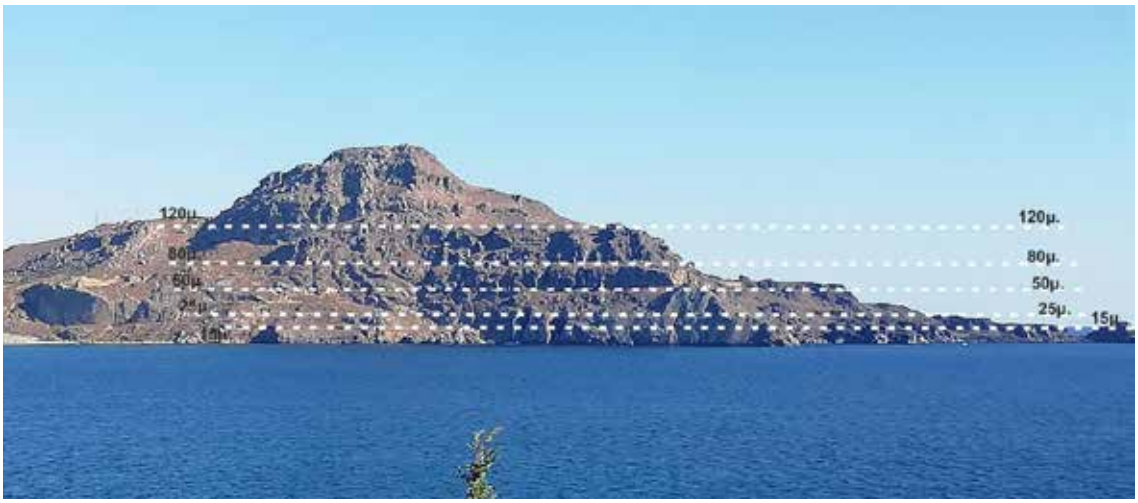

Figure 4. The five marine terraces recognized on the Psarela cape

In respect to other geomorphological features, geological mapping identified a rock instability zone just over the Paligremnos fault scarp initiated at the crosscutting of the F3 and F4 faults on top of the hill. Scattered boulders and large rock blocks seem that have been fallen from the escarpment and then slid on the clay flysch of Tripolitsa reaching finally the edge of the Paligremnos fault scarp. This instability zone covers the area of the touristic constructions imposing a high risk on it.

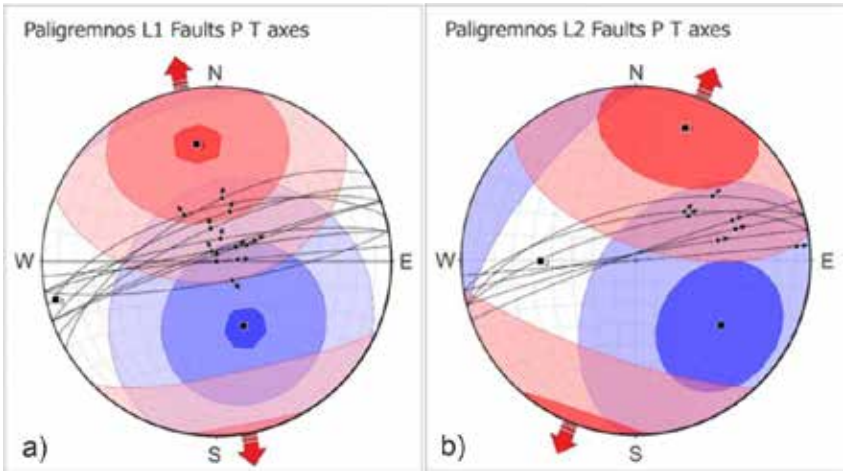

Figure 5. Paleostress analyses of the two striae generations the older a) and newer b)

In what regards the biological value of the area, apart from the sand dunes at the beach that host some very important local flora and are very sensitive ecosystems, the study identified another important area at the western part of the peninsula where, over one of the intermediate marine terraces, a seasonal pond is developed that is crucial for bird fauna. Based on all the above data the suggested area for the protection of the monument was drawn, including all the important geological (fault scarps, notches, marine terraces), biological (part of the dunes and the seasonal pond) and the cultural elements (the tunnel and the remains of the WWII railway and the fortifications) of the monument (Fig. 2).

The qualitative and quantitative assessment that followed documented the value of the area and the reasons to be nominated as a Protected Landscape. The fault scarp is the largest naturally exposed fault scarp in Greece, with the second larger in dimensions but artificially exposed, being the Arkitsa fault (Kokkalas et al. 2007). The Paligremnos fault zone is an active fault zone forming together with the Sellia-Assomatos fault the Plakias graben since the Miocene times. Together with the five marine terraces and the 365 AD notch demonstrate impressively and didactically the Pleistocene rock uplift of the southern coasts of Crete. The Paligremnos fault scarp tucked into the embrace of Plakias bay constitutes a unique and outstanding landscape that forms one of the most attractive landmarks of Crete, listed in geological text books and Atlases (Papanikolaou & Sideris 2013; Mountrakis et al. 2002). Quantitative analyses of the geosite indicated in addition, that the area has of the highest scientific and aesthetic values among the geosites studied with that method in

Greece, and of the highest potential for touristic and educational development. In addition, the vulnerability of the geosite is higher than the normal mean values, mainly due to the thread that touristic constructions may impose.

Conclusions

Based on the processing of bibliographic data, the geological mapping, the analyses of the data collected during the fieldwork and the data provided by residents and visitors of the area, it is demonstrated that the "Paligremnos - Akrotiri Psarela" area of Plakias, Municipality of Agios Vasilios, Rethimno has special and remarkable characteristics of the geological and geomorphological environment, hosts endemic forms of flora and fauna of Crete and gathers some rare and unique for Crete cultural elements related to mining and quarrying activities of the past. It is obvious that the dominant and special characteristics, worthy of protection, are the geomorphological and geological formations that crop out in almost the entire area under consideration, but specifically at the Paligremnos fault scarp that appears to be the largest, naturally exposed fault scarp in Greece. Due to all these values the area finally was declared as a Protected Landscape and Protected Natural Formation under the Greek legislation in 2023, crowning the efforts of local communities to protect their nature.

As an outcome of this study and in order to further promote the values of this area we have developed a virtual tour based on UAV shots and 360° panoramas that virtually guides visitors, step by step, along the main features of the Paligremnos and cape Psarela area. In addition, the tour offers panoramic view of the whole Plakias bay and graben. The tour can be visited thought the following link https://tours.panotours.gr/plakias/.

Acknowledgements

This study is based on the Special Study for the Nomination of the area as Protected Landscape and Protected Natural Formation, assigned to the Natural History Museum of University of Crete by the Municiaplity of Agios Vassilios in Rethimnon. We would like to thank Agios Vassilios Municipality for all the support that has provided during and after the implementation of the Study. We owe special thanks though, to the inhabitants, locals and foreigners, the Climbing and Speleological community of Crete and other specialists who have provided valuable information and data for the development of the Study and the strong motivation and support they offered for the nomination and protection of the area. The final result is dedicated to all of them.

Introduction

It is well documented that only preparedness and prevention can support modern communities in respect to the earthquake risk. Being one of the most seismic prone areas in the world, Greece has invested a lot in the prevention of the impacts of future earthquakes and in the increase of preparedness of the structured and non-structured elements of our societies. Prevention is achieved through interventions and actions aiming at the identification of hazard zones, minimizing the exposures on the build environment and developing plans and regulations to manage crises. In most cases preparedness is achieved by strengthening and improving the behavior of material elements and infrastructures, the increase of knowledge regarding the hazard and its impact, as well as the improvement of the self-protection of citizens. In the past years, repeated Earthquake crises revealed that further improvements both on prevention and preparedness are necessary which can be made only if assessment of past crises' management is performed.

The earthquake of Arkalochori in central Crete is of one the most recent and most peculiar crises in Greece. The foreshock sequence started on the beginning of June 2021, just at the end of the COVID 19 crisis, and lasted almost three months having one strong earthquake of 4,8 R on July 24. The long foreshock period enabled the establishment of many seismic instruments in the broader area to monitor the phenomenon. The main shock took place early in the morning on September 21st, 2021 with a magnitude of 6 R scale and focal point 10 kms below the town of Arkalochori (Ganas et al. 2021). The earthquake took place along a well-known active fault in the area, the Kasteli fault (Fassoulas 2001) that has produced a swam of small eq in 1995 too (Delibasis et al. 1999). The town, that is one of the largest of rural Crete with a population of about 4000 inhabitants and many nearby villages were seriously affected with collapses and damages of old and more recent constructions, while even the city of Heraklion experienced moderate intensities with minor impacts. This was the first strong earthquake onshore Crete for more than a century (Papadopoulos 2011), and fortunately, there was only one human victim that was killed by a strong aftershock that happened few hours after the main event.

The most peculiar feature of this crisis was though the very long aftershock period that lasted almost a year with several events between 4 and 5 R scale. It was estimated that more than 4750 earthquakes took place on the broader area over a period of one year (Vallianatos et al. 2022) challenging the structural behavior of the buildings and the mental health of local population. The response of the Civil Protection mechanism was immediate with first responders and civil protection volunteers taking action soon after the main shock installing temporary camps at the Arkalochori and several other villages, and a more organized shelter at the Exhibition Center of Arkalochori few days after. The response of the local population was remarkable with hundreds of them arriving at Arkalochori from the first day to support the victims. This huge offer of volunteers created problems till a mechanism to manage them was set, but their contribution in compensating the burden of the local people and supporting their daily needs was invaluable even months after the earthquake.

The total toll of impacts counts more than 7000 houses heavily damaged by the main shock and its aftershocks with about 3900 of them to be demolished. Within these structures occur many local schools and churches. Apart from the first financial support that state provided soon after the earthquake to those affected by, the recovery process according to the locals failed totally to cover the needs of local societies (p.c. K. Gantatsios, president of "Elpis" the association of the victims of the earthquake 2024). Three years after the earthquake many families still live at preconstructed houses at the temporary shelter, from the 7000 applications for financial aid to repair houses that have been submitted only few tens have been elaborated by the relative services and the broader area presents images of abandonment and depopulation that was obvious at the recent census.

It is important to mention that the psychological burden of the local communities was not only increased by the long-lasting aftershocks but also from rumors and fake news that were circulated at social media but even the national

broadcasting channels. Rumors for stronger earthquakes were appearing after interviews or posts of “earthquake specialists” in national and international media. Fake news about the reasons of the long seismicity were repeatedly circulated connecting the earthquakes with the construction nearby of a new airport, the existence of a dam few kms away from the epicenters, but even the overfilling of a chapel under the runway of the new airport, that further increased the communication chaos.

The Arkalochori earthquake is a case study under RESILIAGE project funded by the Horizon Europe and coordinated by the Polytechnic of Torino, in which the University of Crete is among the 18 partners that aim to build sustainable resilient communities with local heritage drivers (https://resiliage.eu/). In general, recent crises and disasters have affected the European citizens’ lives, livelihoods, and environment in unforeseen and unprecedented ways. These disasters are exacerbated by social inequality, lack of adequate information and technology, as well as economic and political crises, that reduce the effective preparedness and response. The main objectives of the project are thus focused on understanding citizen reaction in case of crisis, on cocreating new knowledge encompassing the local heritage drivers that make communities stronger and new tools that provide more accurate information and make it accessible through easy-to-use tools and finally, lightweighting solutions to support first responders and empower citizens in crisis and disaster situations. The project has defined five Systemic Resilience Innovation (SyRI) frameworks focusing on Adaptive Governance, Health and Wellbeing, Active Memory, Social Interaction and Inclusiveness and Socio-economic Resilience that are examined in five European territories facing variable risks. The Region of Crete is one of them addressed to the Active Memory in respect to the earthquake risk.

Hereby we present the results of two workshops that have been developed in Crete under RESILIAGE in order to assess the management of Arkalochori EQ crisis, to identify the cultural factors that may influence local resilience, to build local networks through synergies and collaborative actions, and to identify the gaps in the management crisis operation in order to develop proposals for future improvement.

Figure 1. Implementation of focus groups discussions during the first workshop of RESILIAGE at Cretan CORE Lab on May 2024.

Methodology

The RESILIAGE project has foreseen the organization of five Community Resilience Laboratories (CORE Labs) in five European territories that have suffered in the past from various disasters. These include the City of Trondheim in Norway that faces the risk of landslides (slow clay) and focusses on Health and wellbeing, the Famenne-Ardenne UNESCO Global Geopark in Belgium which has been affected by serious floods several years ago and focuses on Socio-economic resilience, the Region of Crete focusing on the earthquakes and the Active Memory, the Naturtejo UNESCO Global Geopark in Portugal which repeatedly experiences wild fires and focusses on Social Interaction and Inclusiveness and the town of Karsiyaka in Turkey that is facing risks form heatwaves and focusses on the Adaptive Governance.

The relative partners in these counties were obliged to set the CORE Labs by inviting local stakeholders. In Crete the Natural History Museum of Crete invited various stakeholders that are engaged in crisis management, or represent certain local target groups, education and communication organizations and citizens. The CORE Lab was thus formed by representatives of First Responders (National Center of Immediate Aid, Fire Brigade, and Volunteer groups),

Local Municipalities and the Region of Crete, Local Development Companies, The Church of Crete, Local Museums, Educational Centers, Local Cultural Clubs and Associations, Sport Clubs and Citizens.
Two onsite workshops were organized in Crete using the focus group methodology (Wilkinson 1998) associated by structured interviews and web questionnaires. In each workshop we used boards, concept, interaction and territorial maps, discussion recordings and the assistance of facilitators to gather and analyse local data in a qualitative manner. The first WS took place on the 21st and 22nd of May 2024 at the premises of Natural History Museum with 30 participants (Figure 1). The aims of the WS were to understand how the local community define its territory in terms of main environmental, historical, and cultural characterizations, understand how local community interacts with the environment from a cultural and historical perspective, gather local narratives of disaster risk reduction, extract cascade effects related to the historical, cultural and environmental factors that intervene in crisis response, and identify lessons learned related to the historical, cultural and environmental factors that intervene in crisis response, having as case study the Arkalochori EQ crisis. During the WS field visit to Arkalochori and nearby areas was organized to discuss with the local stakeholders and inhabitants there (Figure 2).

Figure 2. Pupils performing local dances during the visit of RESILIAGE partners at the preconstructed classrooms hosting the primary school of Arkalochori on May 2024.

The second workshop took place on the 7th of February 2025 again at the Natural History Museum of Crete with the participation of 19 people (Figure 3). This WS was aiming on mapping certain heritage elements recorded at the collective memory that can be used to strengthen local resilience and improve preparedness planning. Activities were thus focused on the co-mapping of local cultural elements supportive to strengthen citizen's resilience, on the co-creation of synergies and collaborations to safeguard those heritage elements through the establishment of a local agreement to safeguard them, and on proposing actions for the inclusion of local communities and vulnerable groups in the crisis management plans through the improvement of communications, the raise of awareness and sensitization of citizens and improving adaptive governance. In this second workshop more advanced methodologies and means were used like serious game, stickers, card boards, thematic maps etc. (Figure 4).
The data collected through these onsite CORE Lab activities were further elaborated by the research partners to step on and develop soft solutions and digital tools that will be evaluated by CORE Lab in a second phase of the project implementation.

Results

The main priority of Civil Protection is always the proper management of a crisis putting more efforts and means though on the response phase. Preparedness and prevention are less developed, whereas the recovery phase is the one that is less considered. RESILIAGE invests in the improvement of preparedness of local communities using their cultural assets and local heritage as potential drivers for establishing strong community resilience that can contribute in a more effective recovery phase. The inventory of these drivers and the assessment of crisis management is the main tool to identify the local needs, capacities and strengths, on which new tools and actions are being developed. The main results under the scopes of RESILIAGE project from the CORE Lab activities in Crete may be summarized as follows.

Figure 3. Co-mapping of cultural and natural heritage elements during the second workshop of RESILIAGE in February 2025.

Cultural bonds remain very strong in the island of Crete based on traditions and ethics dated back in time. Dances, songs, “mantinades” (local rhymes) and common celebrations under various occasions tightened relationships between communities and helped a lot the citizens to cope with the Arkalochori EQ consequences and long-standing impacts (Figure 2). The oral traditions and transfer of myths and stories between generations appears to be a key channel for the preservation of values and collective memory, connecting generations through shared narratives. The workshops also highlighted issues related to social ethics and values as well as the strong blood bond that highlights the importance of family ties that can influence social interactions and contribute to shaping the resilience of the community. At the same time, the workshops underscore that in each settlement there are dozens of reference points and monuments that connect residents to the place and history and offer relief and a source of encouragement in times of crisis, that must be preserved. The existence of social interaction spaces where people can meet and promote social interactions is an important foundation in the event of crises that must be maintained during the operation of temporary shelters.

In places where social interaction was intense, like in Arkalochori where a local sport club and the community were organizing various annual events, this played a crucial role in managing the crisis and offering immediate support to the victims. Their role was remarkable in providing food, immediate aim, managing and organizing the many volunteers and retaining community alive for long period. The engagement of young people in such social and community activities enforces the local cohesion and reduces the vulnerability of the communities. The local Church is also a very important actor in the post crisis phase because it has the organization and means to support immediately the victims especially at the rural areas, with material and immaterial aid. The existence of local volunteer groups is also a very important factor to manage a crisis as they can offer assistance to CP mechanism, support the victims and palliate the psychological burden.

The need for reliable information and proper communication, before but especially during the crisis, emerged as the top problem in the case of the Arkalochori earthquakes. The absence of reliable and timely information, as well as of corresponding official state communication channels, contributed to the increase in the spreading of fake news and rumors that increased further the stress of those affected. The battle with fake news and incorrect information was lost very early on as there was no way to deal with this on social networks. Throughout the long post-earthquake sequence, residents felt the lack of communication and information from the official authorities, a problem that was much more intense in elder people. In these cases, the Church could play an important role, if proper cooperation has been developed between the Church, the relevant scientific bodies and the State. To enhance disaster preparedness and response, it is crucial to adopt a more proactive and comprehensive approach to communication. This should include regular awareness campaigns before a disaster, accessible guidance for individual groups after a disaster and ensure that all relevant information sources are easily identifiable and accessible.

Figure 4. The concept board for the assessing of Crisis Management plan after the implementation of the second workshop of RESILIAGE in February 2025.

Regarding the crisis management it was obvious that the CP mechanism responded immediately after the main shock establishing shelters and providing support to the affected societies, following a well operational management plan. However, it is apparent that despite the comprehensive national policies and documentation, shortcomings exist in resources evaluation and cooperation mechanisms at the local level, which hinder effective disaster response. The strong building codes and regulations didn't prevent the numerous damages and destructions, mainly because of the weakness of the relative authorities to monitor and ensure their implementation. The case of Arkalochori EQs underpin the fact that in rural areas older infrastructure remains vulnerable, highlighting a need for reinforcement and modernization. In addition, and under the threat of Climate Change it was highlighted that disaster risk management plans are not integrated with climate adaptation strategies, causing missed opportunities to leverage ecosystems in disaster management.

Under this scope it was also stressed that detailed risk assessments are outdated and require revisions. The risk and vulnerability assessments identify key vulnerabilities within the adaptation plan, such as: socio-demographic factors (population distribution and vulnerable groups), impacts on buildings and infrastructure, and cultural heritage considerations. The assessment should thus consider agriculture, forestry, biodiversity, and fisheries, as well as references to vulnerable groups such as the elderly and disabled at the national or regional level.

The crisis management was further exacerbated by the fact that the financial legislation lacks detailed information regarding funding mechanisms available for disaster management. Alternative financing mechanisms for risk reduction are scarce, while state financial resources for risk reduction are insufficient, limiting the implementation of disaster resilience measures. The total failure of the CP mechanism in the recovery phase is indicated by the fact that three years after the crisis from the thousands of applications seeking state support to reconstruct the damaged properties, only few tens have been elaborated so far. This situation is not only socially inappropriate, but ethically and morally too as a large number of the Arkalochori victims were elder.

Introduction / Background

The Gulf of Corinth (GoC), which is a semi-isolated marine basin derived from a geologically young active rift (McNeill *et al.,* 2019b), offers a unique opportunity to study changes in environmental conditions during the Quaternary period in a region where long sequences are few. The GoC is linked to the global ocean via the Gulf of Patras in the Ionian Sea. This connection is facilitated by the Rion Strait to the west and the Corinth Isthmus to the east. The Rion Strait forms a narrow and deep marine embayment, resembling a fjord, with fully marine conditions (Poulos *et al.,* 1996). The recent IODP expedition (IODP381) has retrieved three long sequences (M0078A, M0079 and M0080) recovering most of the Quaternary period and providing the first comprehensive insight on the evolution of a young active rift (McNeill *et al.,* 2019b). The sedimentary sequence drilled 610.43 mbsf that were divided into two main Lithostratigraphic Units (LU). Deposition during the upper one, LU1 (0–385.14 mbsf), is primarily controlled by eustatic sea level and dominated by detrital clay- and silt-grade carbonate, this interval has been divided into 16 subunits (LU1.1-1.16) with respect to the alternation of marine and isolated/semi-isolated intervals, while below 385.14 mbsf, LU2 is composed almost entirely of weakly laminated to homogeneous highly bioturbated mud (McNeill *et al.,* 2019a).

Preliminary observations of conventional biological proxies used for determining past palaeoceanographic conditions during the onshore party of IODP 381 expedition (*McNeill et al., 2019b*) have highlighted an unexpected richness in dinoflagellate cyst taxa, notably species that were only known from the Marmara-Black Sea corridor (e.g., Marret *et al.,* 2004; Mudie *et al.,* 2004; 2017). Due to periods of isolation during Quaternary lowstands, the water conditions were not favorable for the occurrence of conventional palaeoceanographical proxies such as planktonic foraminifera. Fatourou *et al.* (2023) presented an initial study of organic-walled dinoflagellate cyst assemblages from site M0078A, covering the upper 384m (~Marine Isotopic Stage 18), highlighting distinct shifts related to fluctuations in sea-surface temperature and salinity in response to global sea-level changes.

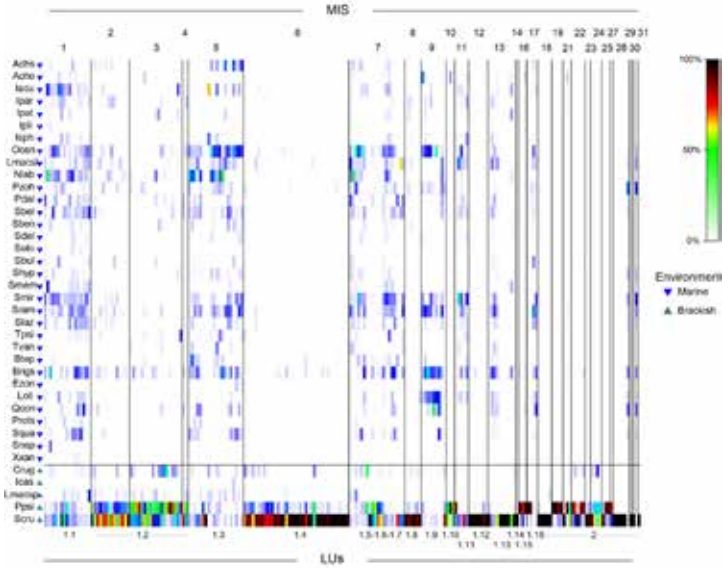

Table 1: List of identified dinoflagellate cyst taxa, with micropalaeontological (cyst) name and associated biological name, trophic level (P: Phototrophic; H: Heterotrophic), and environmental conditions (B: brackish; M: marine) of the Gulf of Corinth.

We present here a continuous record of dinoflagellate cyst assemblages of the last 1.1 Ma aiming to examine the shifts between marine and isolated/semi-isolated depositional environments in response to eustatic sea level changes in the GoC. The dinocyst assemblages encountered within the intervals described below consist of the low salinity indicators *S. cruciformis*, *P. psilata*, *Caspidinium rugosum, Impagidinium caspienense* and *Lingulodinium machaerophorum* s.p.. *Spiniferites cruciformis* and *P. psilata* are the most dominant species during those intervals, however, a distinct variability in those assemblages is recorded. The dinocyst assemblages recovered within the marine intervals of M0078A record are characterised by a high diversity (30 different species) and with mean concentrations of 24,632 cysts/g. In addition, results from other proxies (aquatic palynomorphs, foraminifera and diatoms) offer an integrated perspective on the evolution of the basin and its surroundings. The freshwater and brackish diatoms, as well as the euryhaline foraminifera identified during the onshore phase of the IODP 381 expedition (McNeill *et al.,* 2019) seem to correlate well with the isolated LUs and the brackish dinocyst assemblages. During the Holocene, the presence of several dinoflagellate cysts, alongside with the decreased TOC and TOC/N at the upper part of LU1.1 (Holocene) confirm the occurrence of well-oxygenated bottom waters in the basin.

Figure 1: Shade plot: visual representation of the species encountered in the different LUs (LU1.1 to LU1.16) and Marine Isotope Stages (MIS). Samples were arranged based on core depth. White colour indicates absence, black the highest abundance in the dataset, while all the different colours suggest low (blue colour), medium (green colour) and high presence (orange and red) (Fatourou, 2024).

This record aims to fill a gap in palaeoceanographic studies in Eastern Mediterranean region and to provide a better understanding of how shallow-sill connected basins respond to global climate changes. Dinocysts and other palynomorphs (NPPs) suggest that the GoC was repeatedly isolated and reconnected to the Mediterranean Sea during global sea-level lowstands associated with glacials. These proxies combined suggest that marine water flowed into the GoC during the eustatic highstands associated with interglacials. The dinocyst assemblages show a close affinity to modern assemblages from the Black, Caspian, and Marmara Seas (e.g., Marret *et al.,* 2004; Mudie *et al.,* 2004; 2017).

EXTENDED ABSTRACT 075

Underground rivers in Greece

Fellachidou K.[1], Lazaridis G.[1]
(1) Aristotle University of Thessaloniki, School of Geology, Department of Structural, Historical and Applied Geology, Laboratory of Geology and Paleontology, Thessaloniki, Greece, fellachid@gmail.com

Research highlights

This study presents the first national-scale mapping of underground rivers in Greece, documenting a total of 60 systems. It also offers the first systematic classification of the underground rivers, emphasizing their spatial distribution and characteristics in relation to tectonostratigraphic units. Spatial analysis reveals the dominance of the External Hellenides in speleogenesis, as they host 67% of the documented underground rivers. Limestone hosts 21 underground rivers, highlighting its critical role in speleogenesis. High-relief regions (>900m) host the majority of these systems, influenced probably by climatic and hydrological conditions. Conversely, the Internal Hellenides display fewer and more isolated underground rivers due to their complex geological history and diverse lithologies. Overall, the findings enhance the theoretical understanding of underground river systems while providing practical applications for water resource management, environmental protection, and geological risk assessment.

Introduction

Underground rivers represent a unique and significant geological feature, particularly in regions such as Greece, where complex geological formations and hydrological conditions prevail. Their formation is attributed to processes of epigene speleogenesis. These processes occur when meteoric water infiltrates from the surface, utilizing its dissolving capacity derived from surface environmental conditions. Specifically, the water acquires its ability to dissolve carbonate rocks by absorbing carbon dioxide from the atmosphere, particularly within the soil. As the water percolates through limestone or other soluble lithologies, its flow transitions from diffuse pathways to more convergent routes, eventually emerging at discrete springs in adjacent valleys (Audra & Palmer, 2011).

These caves form under specific geological and environmental conditions, influenced by factors such as lithology, tectonics, the type of recharge and base-level changes. In most cases, the passages of epigene caves develop along discontinuities, such as bedding planes, fractures and faults (Gunn, 2004), forming cave patterns that include isolated passages or branchworks, with angular configurations (Audra & Palmer, 2011).

According to Ford (2007), as the frequency of permeable discontinuities increases significantly, resistance to water flow is drastically reduced. This allows water to follow the pathway closest to the water table, which is also the shortest route to spring. This process results in the formation of “ideal” water table caves. As the fluvial base level drops, new phreatic passages form at successively lower levels, while pauses in base-level lowering result in the creation of cave levels that correlate with river terraces (Audra & Palmer, 2011). Vadose shafts and canyons extend downward to the new water table, while older conduits become abandoned, often filled with sediments and intersected by newer passages. This dynamic process leads to the integration of multiple cave levels, preserving a record of successive stages of base-level lowering. A notable example is the Stefanina Cave in northern Greece, where tectonic discontinuities, including joints and bedding planes, have played a key role in guiding water flow and shaping the underground river’s morphology (Lazaridis et al., 2021). Additionally, scallops, small-scale dissolution features typically formed in shallow phreatic environments, found within the cave have enabled the estimation of past flow velocities and discharge rates.

The geotectonic setting of Greece consists of the Hellenides showing an arcuate orogenic belt, subdivided into two distinct tectonostratigraphic domains, the External and Internal Hellenides zones. The Internal Hellenides comprise Paleozoic basement overlain by Mesozoic carbonate platform sediments, obducted by Neo-Tethyan ophiolites during the Mid-Late Jurassic, exhibiting a multiphase tectonic history and significant metamorphism during the Alpine orogeny. During the Eocene-Oligocene, the Internal Hellenides overthrusted the External Hellenides which are primarily composed of Mesozoic and Cenozoic sediments from deep-sea and shallow-water environments, characterized by continuous sedimentation that took place during the Paleocene to Miocene period, forming a complex thrust and fold belt with no significant metamorphism (Kilias, 2024).

Methodological approach

This study employs a systematic approach that combines bibliographic review, data collection, processing and analysis. The methodology follows a structured framework that integrates both primary and secondary data sources, tools and comparative evaluations. The first step involved an extensive bibliographic review to gather relevant scientific

information. Searching was conducted in databases such as Scopus, ScienceDirect, ResearchGate, Google Scholar, Academia and Theophrastos digital library of Aristotle University of Thessaloniki. Additional information was gathered from online resources, archives of speleological associations in Greece and the Bulletin of the Hellenic Speleological Society to address gaps in the existing literature. Each source was critically analyzed for quality and reliability and the literature was categorized based on themes and regions.

Next, the study proceeded with the collection and recording of data, which included both primary and secondary sources. Primary data were derived from spatial analyses, while secondary data were extracted from bibliographic sources and existing studies. Data were systematically stored and classified based on criteria such as geographical region, tectonostratigraphic unit and morphological characteristics of the underground rivers, forming the basis for a detailed catalog of Greece's underground rivers (Fellachidou, 2024 and references therein).

The data processing phase involved both statistical and spatial analyses. Quantitative data were analyzed using tools such as Excel, allowing for the identification of trends and patterns across variables. Spatial analysis was performed using the QGIS tool enabling detailed mapping of underground river distribution and their relationship with geological and tectonic features. Data visualization, including the creation of charts, graphs and maps, further supported the interpretation and presentation of results.

Results and discussion

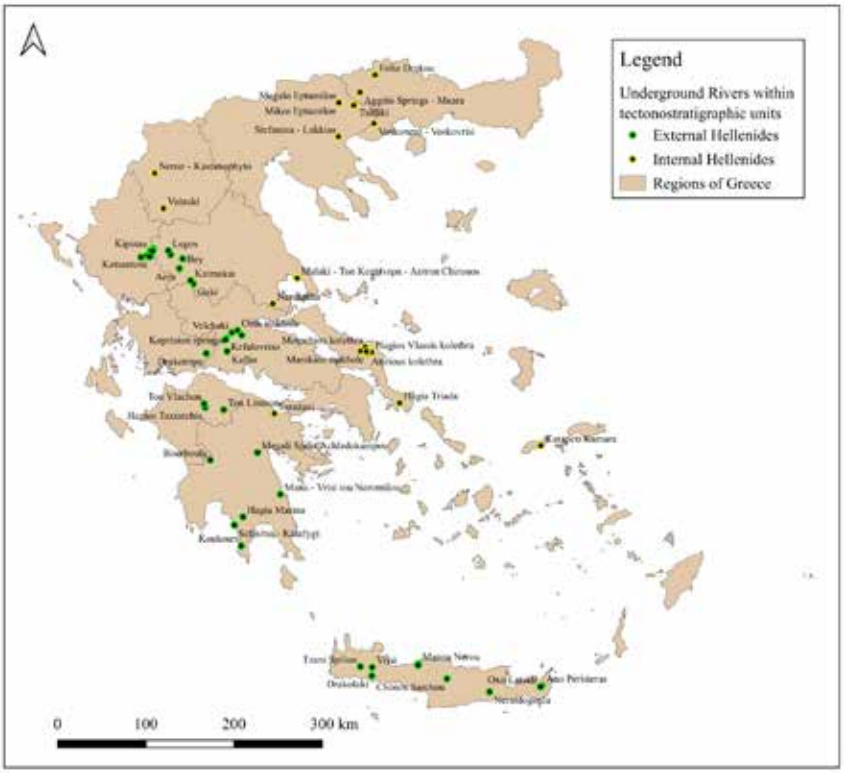

Figure 1. Geographical distribution of underground rivers across 13 Greece's regions, categorized by tectonostratigraphic units. Locations marked green represent underground rivers within the External Hellenides (40 in number), while those in yellow correspond to the Internal Hellenides (20 in number). (Regions of Greece retrieved from https://geodata.gov.gr/en/)

The analysis revealed significant insights into the distribution, geological characteristics and morphology of Greece's underground rivers. The compiled catalog of underground rivers served as the basis for constructing a map depicting their spatial distribution. The map (Fig. 1) presents a detailed spatial representation of underground river systems in Greece, categorized into two primary tectonostratigraphic units: the Internal Hellenides and External Hellenides. It reveals a total of 60 documented underground rivers, with 40 concentrated within the External Hellenides mainly along the Pindos mountain chain. Conversely, only 20 underground rivers are documented within the Internal Hellenides, where they are more sporadically distributed, with notable examples including Karapeti Kamara in the South Aegean and Neron-Kastanophyto in Western Macedonia. Furthermore, Aggitis River, the longest underground

cave of Greece is also located in the Internal Hellenides.
Notable clusters are observed in Epirus region (e.g., Anemotripa, Klifkis, Kipon, Katsantoni, Kipinas, Stafyla, Gouva Mare, Galazio Nero), in Sterea Ellada region (e.g., Koprision springs, Kefalovriso, Velchaki, Oitis sinkhole, Sklithraki) and the Euboea Island (e.g., Metochiou kolethra, Genitsari, Manikion sinkhole, Atsitous kolethra, Hagios Vlassis kolethra). Crete Island also emerges as a significant region, hosting nine underground rivers such as Tzani Spilios, Drakolaki and Chonos Sarochou, Manna Nerou, Ano Peristeras etc.) reflecting its dynamic karstic systems. The geographical distribution highlights regional variability, with certain areas, such as the South Aegean, Ionian Islands and Attica, lacking any recorded underground rivers.
Overall, the External Hellenides account for 67% of the recorded underground rivers in Greece (Fig. 2A), emphasizing their dominant role in karst system development. In contrast, the Internal Hellenides, shaped by a complex geological history involving metamorphic processes, host fewer and more isolated underground rivers.

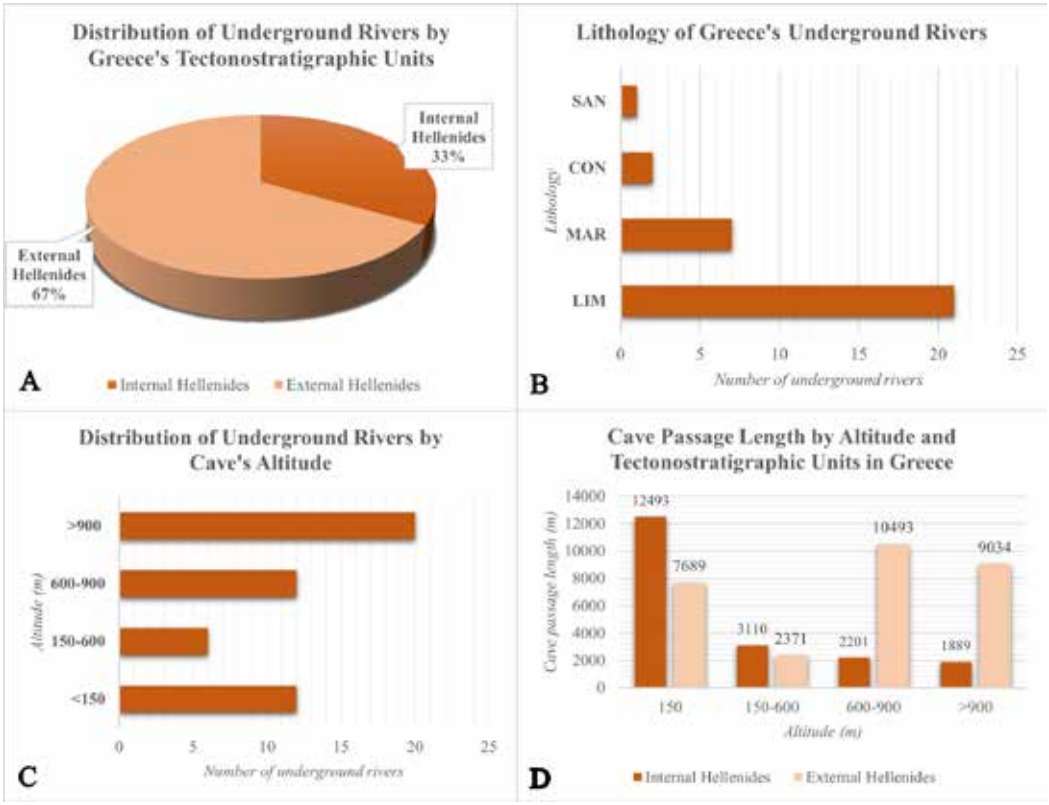

Figure 2. A: Proportion of underground rivers distributed between the two tectonostratigraphic units in Greece, the Internal Hellenides and the External Hellenides. B: Number of underground rivers associated with different lithologies in Greece. SAN: Sandstones, CON: Conglomerates, MAR: Marbles, LIM: Limestones. C: Number of underground rivers found at different elevation ranges in Greece according to Dikau (1989) classification system (>900: mountainous areas, 600-900: semi-mountainous areas, 150-600: hilly areas, <150: lowland areas). D: Total length of underground river cave passages (speleogenesis in meters) within the Internal and External Hellenides across different altitude ranges in Greece.

Figure 2B delves into the influence of lithology on speleogenesis, highlighting the critical role of carbonate rocks. Limestone, due to its high solubility, hosts the majority of underground rivers (21), underscoring its dominance in karst development. Marble, while also capable of supporting karst systems, accommodates fewer rivers (7). Conglomerates and sandstones, which account for just 2 and 1 rivers respectively, further emphasize that lithology is a key determinant in the formation and distribution of underground river systems.
Elevation plays a critical role in the distribution of underground rivers (Fig. 2C). Mountainous areas (>900m) host the highest number of underground rivers (20), followed by semi-mountainous (600-900m) and lowland areas (<150m), each with 12 rivers, while hilly areas (150-600m) contain only 6. This high concentration of underground rivers in high-relief regions can be attributed to the unique climatic and hydrological conditions of these areas. In mountainous regions, colder infiltrating water retains higher levels of carbon dioxide, enhancing its aggressivity and promoting

extended speleogenetic processes. Additionally, seasonal climatic variations, including snow accumulation in winter, rapid snowmelt in spring and intense summer thunderstorms, lead to periods of extreme discharge and flooding, which significantly influence cave development and morphology through the interplay of climatic factors and speleogenesis (White & Culver, 2012).

Finally, the relationship between altitude and tectonostratigraphic units is further elaborated (Fig. 2D). At lower altitudes (<150m), the Internal Hellenides exhibit longer cave passages, reflecting prolonged water flow and underground karst development. In contrast, at higher altitudes (600-900m and >900m), the External Hellenides dominate in terms of cave passage length, highlighting their structural and geological suitability for high-altitude underground river development. These observations reinforce the role of both altitude and tectonostratigraphic context in shaping speleogenetic processes.

Concluding Remarks

In summary, the distribution, lithological dependence, geomorphological and tectonostratigraphic influences collectively reveal the complexity of underground river formation in Greece. Detailed examination of the general geographical distribution to specific geological factors, provides a clear narrative of how various processes interact to shape these unique systems. This multi-layered analysis highlights the intricate interplay between geology, hydrogeology, tectonics and topography in determining the characteristics of underground rivers in Greece.

- This study provides a comprehensive insight into the underground rivers of Greece, representing the first national-scale mapping effort.
- The distribution, lithological dependence, geomorphological and tectonostratigraphic influences collectively reveal the complexity of underground river formation in Greece.
- Significant insights are provided into the spatial and geological dynamics that shape these systems, demonstrating the dominant role of the External Hellenides and carbonate lithologies in underground karst system development.
- Areas within the Internal Hellenides, where geological complexity and mixed lithologies prevail, display fewer and more sporadically distributed underground rivers.
- Low altitude concentration of underground rivers occurs in Internal Hellenides, in contrast to the External Hellenides, where these caves are developed mainly in higher altitudes.
- The results contribute to theoretical knowledge and may have practical implications for water resource management, environmental protection and geological risk assessment.
- Future studies can build upon this foundation to explore more localized patterns and predict potential changes in underground hydrological systems.

Introduction

A hydrograph is the discharge (Q) diagram of a spring or a watercourse as a function of time (t). From the study of hydrographs of karst spring areas, it is possible to (Lundberg & Worsfold, 1993; Ford & Williams, 2007; Zhou & Li, 2010; Ma & Zhang, 2016):

- Find a "transformation coefficient", that is, a relationship that connects the input of the karst system to the output, i.e., the spring.
- Make predictions of the spring discharge and calculate the reserves.
- Provide information about the organization and operation of the karst system.
- Characterize the hydrogeological system that feeds a spring based on the slope of the depletion line between two given discharges (Q_1) and (Q_2). The change in slope from one year to the next indicates either water withdrawals from the aquifer (increase in slope), or recharge of the aquifer during the dry period from irrigation returns (decrease in slope), or changes in the structure of the aquifer, such as due to seismic activity.
- Calculate the water reserves in the system, which are located higher than the outflow point (discharge point) and equal to (Qt_d) at any given time.

Large values of the depletion coefficient (a) (in the range of 10^{-1} to 10^{-2}) mean that the karst system has conduits and generally large diameter voids with adequate continuity. In contrast, small values of (a) (in the range of 10^{-3}) mean that the water flows through fractures and intra-stratigraphic voids. In the first case, we typically have massive limestones, while in the second case, stratified ones (Soulios, 1985).

The spring "Kefalari Agios Ioannis" is located at an elevation of approximately 871 m, about 1,650 m south-southeast of the picturesque village of Dimitsana (Peloponnesus, Greece) discharging a karst aquifer. Its water is used for drinking water supply and irrigation. The clarification of the hydraulic characteristics of the karst aquifer, through the "Kefalari Agios Ioannis" spring, is of immense importance for the sustainable management of water resources in the broader area of Dimitsana, which is continuously developing in terms of tourism.

Geological Setting

The area of Dimitsana is composed of geological formations belonging to the lower Tripolitza Unit (Blumenthal, 1933; Dercourt, 1964; Lekkas, 1978; Tsaila – Monopolis, 1977; Fleury, 1980; Thiebault, 1982) and the higher Pindos Unit (Aubouin, 1959; Dercourt, 1964; De Wever, 1975; Fleury, 1980). Post-alpine sediments have locally unconformably covered the alpine formations. The post-alpine formations comprise the following (Exindavelonis, 1988):

- Alluvial deposits (H.al) consisting of pebbles, gravels and clayey-sandy materials.
- Scree and talus cones (H.sc,cs) mainly consisting of carbonate fragments of local origin.

The Pindos Unit includes the following formations (Exindavelonis, 1988):

- Platy limestones (Ks-Pc.k) dated Upper Cretaceous to Paleocene of green-gray and locally reddish colour with nodules and thin chert intercalations. The upper parts of the formation correspond to the transitional beds towards the flysch and comprise alternations of thin-platy limestones, sandstones and breccia limestones.
- Red cherts, siltstones and "First Flysch" (Js-Ki.fl) dated Upper Jurassic to Lower Cretaceous consisting of alternations of cherts, siltstones, shales, sandstones and clastic limestones often containing chert angular pebbles.

The Tripolitza Unit comprises the following formations (Exindavelonis, 1988):

- Flysch (Ft) consisting of alternations of grey marls, sandstones with intercalations or lenses of breccia limestones and conglomerates.
- Limestones, dolomites and dolomitic limestones (Ks-Es.k,d) dated Upper Cretaceous to Upper Eocene consisting of grey to black, thick-bedded limestones and dolomitic limestones.

The formations of both the Pindos and Tripolitza Units are juxtaposed through thrust faults and high-angle normal faults. This deformation can be ascribed to a compressional tectonic episode that transpired during the Middle Eocene to the Lower Miocene followed by an extensional one since Middle Miocene.

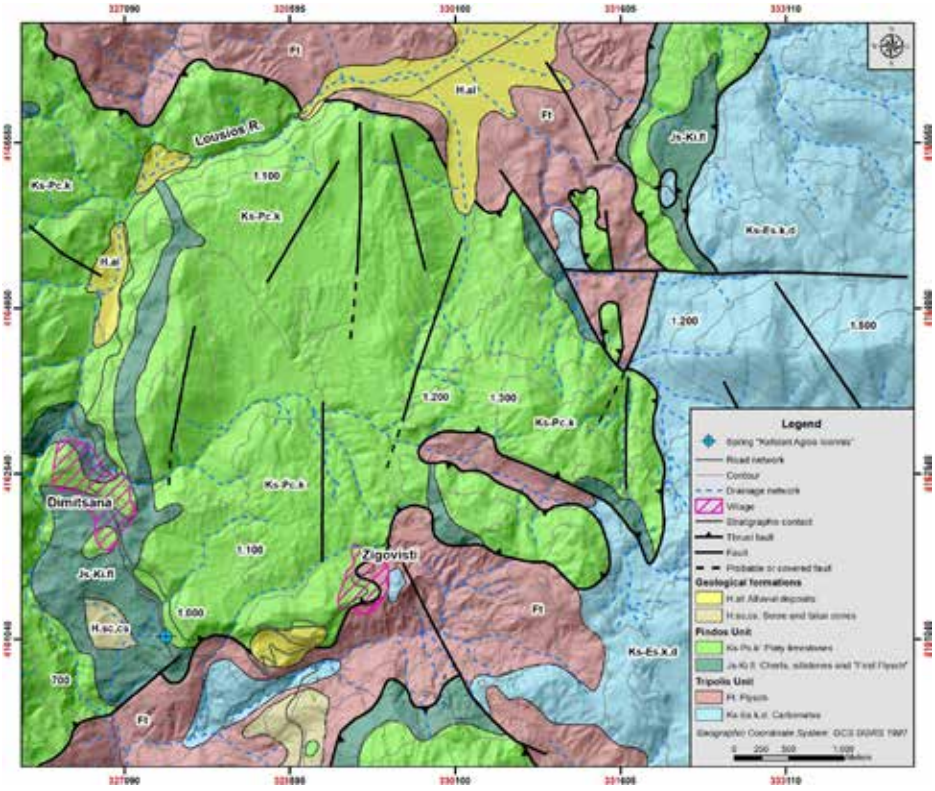

Figure 1. Geological map of the study area (modified from Exindavelonis, 1988).

Hydrogeological Conditions

The geological formations of the study area fall into the following categories, according to the standards of the International Association of Hydrogeologists (Struckmeier & Margat, 1995; Nikas et al., 2010):

- Alluvial deposits (H.al): They develop local and thin aquifers with high yield or extensive aquifers with moderate yield (Subclass 1b).
- Scree and talus cones (H.sc,cs): They develop local and thin aquifers with high yield or extensive aquifers with moderate yield (Subclass 1b).
- Platy limestones (Ks-Pc.k): This formation generates local and thin aquifers with high yield or extensive aquifers with moderate yield (Subclass 2b).
- Red cherts, siltstones and “First Flysch” (Js-Ki.fl): They develop aquifers of minor practical significance or non-aquifer formations (Subclass 3b).
- Flysch (Ft): This formation develops aquifers of minor practical significance or non-aquifer formations (Subclass 3b).
- Carbonates (Ks-Es.k,d): This formation generates extensive aquifers with high yield (Subclass 2a).

The carbonate formations of the Pindos Unit (Ks-Pc.k), characterized by their multifold and fractured structure, give rise to a karst aquifer of moderate capacity situated to the east of Dimitsana. The underlying impermeable substratum is comprised primarily of the flysch (Ft) of the Tripolitza Unit, predominantly located to the north, east, and south, as well as the red cherts and siltstones and “First Flysch” (Js-Ki.fl) of the Pindos Unit, mainly to the west.

Conversely, the carbonate formations of the Tripolitza Unit (Ks-Es.k,d) exhibit considerable fragmentation and fissuring, revealing two or more primary joint systems, accompanied by additional secondary systems that display distinctive karstification. These formations give rise to a deep karst aquifer of substantial capacity.

It is noteworthy that in certain regions, the carbonate formations of the Pindos Unit directly overly those of the Tripolitza Unit, facilitating the transfer of groundwater to greater depths through lateral hydraulic connectivity.

Recession coefficient of the “Kefalari Agios Ioannis” spring

The contact spring “Kefalari Agios Ioannis” (Figure 2) discharges the karst aquifer that develops in the platy limestones (Ks-Pc.k) of the Pindos Unit at their contact with the underlying and impermeable red cherts, siltstones and “First Flysch” (Js-Ki.fl) of the Pindos Unit, as shown in Figure 1.

Figure 2. View of the "Kefalari Agios Ioannis" spring on 26-11-2023. The turbidity of the water is due to the heavy rainfall of the previous days.

For the evaluation of the quantitative status of the "Kefalari Agios Ioannis" spring, flow measurements were conducted using an appropriate flow gauge within the rectangular cross-section of the concrete channel to which the water flows, leading to the Open-Air Water Power Museum of the Piraeus Cultural Foundation (Table 1, Figure 3 & Figure 4).

Table 1. The dates of the flow measurements, along with the quantitative data (discharge) and qualitative data (water temperature, pH, and electrical conductivity) of the "Kefalari Agios Ioannis" spring.

Seq. No.	Date	Discharge (m^3/h)	T °C Water	pH	Electric Conductivity (μS/cm)
1.	18-04-2024	711.1	12.9	7.7	320.0
2.	04-05-2024	468.9	12.7	7.6	320.0
3.	16-05-2024	312.3	12.6	7.7	300.0
4.	30-05-2024	245.2	12.9	7.6	300.0
5.	14-07-2024	101.7	14.4	7.4	310.0
6.	07-08-2024	98.2	13.5	7.4	280.0
7.	07-09-2024	84.7	13.7	7.6	290.0
8.	29-09-2024	70.3	13.7	7.6	260.0
9.	27-10-2024	69.4	13.8	7.6	270.0

Figure 3. Flow measurements taken with an appropriate flow gauge at the "Kefalari Agios Ioannis" spring on 04-05-2024.

Figure 4. Flow measurements taken with an appropriate flow gauge at the "Kefalari Agios Ioannis" spring on 30-05-2024 (up) and on 14-07-2024 (down).

Quantitative analysis of the “Kefalari Agios Ioannis” spring hydrograph is based on the equation proposed by Maillet (1905), who suggested that the discharge of a spring is a function of the volume of water held in storage and is described by an exponential equation.
The “Kefalari Agios Ioannis” spring hydrograph based on the flow measurements, which were conducted from 18-04-2024 to 27-10-2024 (Table 1) is presented in Figure 5. For the calculation of the recession coefficient of the “Kefalari Agios Ioannis” spring, flow measurements which were conducted from 14-07-2024 to 27-10-2024 were used (Table 1 & Figure 5) and if they get plotted to semi-logarithmic graph paper, the curve of Figure 5 is represented as a straight line (Figure 6).

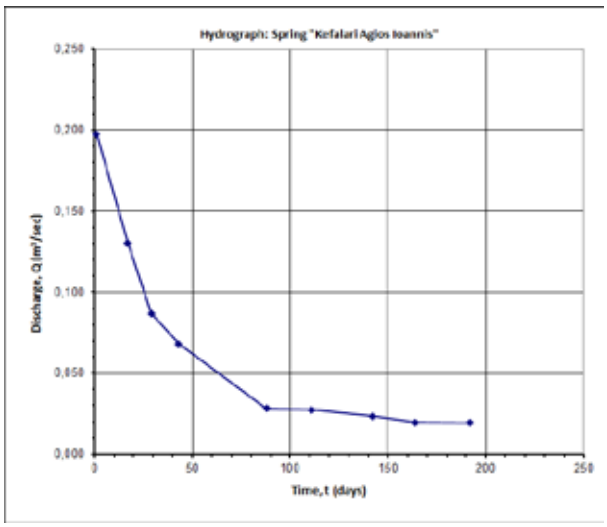

Figure 5. Hydrograph of the “Kefalari Agios Ioannis” spring based on the flow measurements, which were conducted from 18-04-2024 to 27-10-2024.

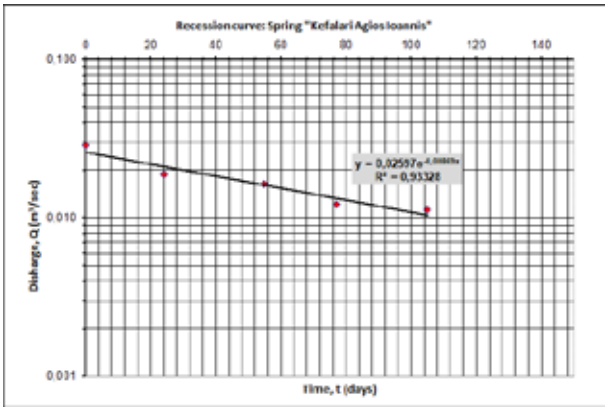

Figure 6. Semi-logarithmic graph paper of the “Kefalari Agios Ioannis” spring flow measurements, which were conducted from 14-07-2024 to 27-10-2024, used for the calculation of its recession coefficient.

The value of the recession coefficient derives from the hydrogeological characteristics of the aquifer, especially effective porosity and transmissivity (T). The recession coefficient of the “Kefalari Agios Ioannis” spring calculated from the flow measurements, which were conducted from 14-07-2024 to 27-10-2024 is 8.69×10^{-3} $days^{-1}$ (Figure 6), which means that the water flows through the fractures and the intra-stratigraphic voids of the platy limestones (Ks-Pc.k) of the Pindos Unit (Soulios, 1985).

Discussion - Conclusions

The contact spring “Kefalari Agios Ioannis” discharges the karst aquifer that develops in the platy limestones (Ks-Pc.k) of the Pindos Unit at their contact with the underlying and impermeable red cherts, siltstones and “First Flysch” (Js-Ki.

fl) of the Pindos Unit.

The clarification of the hydraulic characteristics of the karst aquifer, through the “Kefalari Agios Ioannis” spring, is of immense importance for the sustainable management of water resources in the broader area of Dimitsana, which is continuously developing in terms of tourism. Additionally, the operation of the Open-Air Water Power Museum of the Piraeus Cultural Foundation, which is located immediately downstream of the spring, is inextricably linked to the functioning of the “Kefalari Agios Ioannis” spring.

The recession coefficient of the “Kefalari Agios Ioannis” spring calculated from the flow measurements which were conducted from 14-07-2024 to 27-10-2024 is 8.69×10^{-3} $days^{-1}$, which means that the water flows through the fractures and the intra-stratigraphic voids of the platy limestones (Ks-Pc.k) of the Pindos Unit. The aforementioned calculated value is consistent with the literature data for the recession coefficient of karst aquifers developed in the Pindos Unit and in equivalent units, which is on the order of 10^{-3} $days^{-1}$ (Soulios, 1985; Giannatos, 1999; Karalemas, 2010).

It is noted that the hydrological year 2023-2024 was particularly dry, and the calculation of the «Kefalari Agios Ioannis” spring’s recession coefficient should be considered with special caution, as it has been derived from flow measurements, which are the result of prolonged drought and water scarcity. This might has caused different conditions of groundwater circulation, which are not uniform across the entire hydrogeological basin and becomes apparent under extreme hydrological conditions, either surplus (wet hydrological years) or deficiency (dry hydrological years), during which different sections and levels of the recharge area are activated or operate differently. It is noteworthy that the recession period lasted at least 105 days, from 14-07-2024 to 27-10-2024.

Therefore, the recalculation of the spring’s recession coefficient is considered necessary for the hydrological year 2024-2025 as well, which so far appears to be more representative compared to the previous one.

Acknowledgements

The research team extends its most heartfelt gratitude to the director and the staff of the Open-Air Water Power Museum of the Piraeus Cultural Foundation, for the time they dedicated and their invaluable assistance during the fieldwork. Additionally, we express our appreciation to Mayor of Gortynia Mr. Efstathios Koulis for his collaboration.

Background

The Santorini volcano is associated with one of the most destructive volcanic eruptions in human history, yet it remains insufficiently monitored. This is partly due to its behavioral pattern, characterized by long periods of rest interrupted by short and rapid episodes of unrest (Hooper, 2012). Indeed, the last well-documented unrest episode in 2011–2012 (Newman *et al.*, 2012; Parks *et al.*, 2012; Papageorgiou *et al.*, 2012), characterized by comprehensive instrumentation and quantitative measurements, occurred after approximately 60 years of quiescence since the 1950 volcano activity.

Despite the significance of the 2011–2012 unrest, post-crisis monitoring efforts were limited, sustained mainly by the Institute for the Study and Monitoring of Santorini Volcano (ISMOSAV; www.ismosav.gr), and without any coordinated activity at a national level. ISMOSAV is a non-profit organization established in the summer of 1995, with the primary objective of operating volcano monitoring networks and providing informed assessments regarding the state of the volcano. The monitoring efforts over the past 12 years were substantial enough to enable early detection and timely notification to relevant authorities, contributing to the governmental response when a new unrest phase began in mid-summer 2024.

The role of Earth Observation (EO) and geodetic imaging, specifically Interferometric Synthetic Aperture Radar (InSAR), is crucial for the systematic long-term monitoring of Santorini. Several studies utilized archive SAR missions from the European Space Agency (ESA), namely ERS and ENVISAT satellites, to characterize displacement fields from 1992 to 2010 (Papageorgiou *et al.*, 2012; Parks *et al.*, 2015), as well as during the 2011–2012 unrest phase (Foumelis *et al.*, 2013). Since October 2014, Copernicus Sentinel-1 mission has enabled actual continuous monitoring. While the ERS and ENVISAT era allowed accurate annual displacement measurements, the limited temporal sampling (i.e., long satellite repeat-cycles) prevented the detection of short-term behavioral changes of the volcano. On the contrary, systematic acquisitions from Sentinel-1 have proven adequate for capturing early indicators of deviations from background behavior.

EO-based Monitoring

This EO-based monitoring capability was made possible through the deployment of an operational solution using the SNAPPING service of the Geohazards Exploitation Platform (GEP) (Foumelis *et al.*, 2022). SNAPPING is a Persistent Scatterer Interferometry (PSI) chain integrated by AUTh on the GEP platform, facilitating access to Sentinel-1 surface motion measurements for users and EO practitioners. The SNAPPING service generates average Line-of-Sight (LoS) motion rate maps and displacement time series at both reduced spatial (at approx. 100 m) and full sensor resolutions (SNAPPING, 2022). A well-defined set of processing parameters optimized to the specific environment are defined and a dedicated application on GEP is designed to execute SNAPPING in a monitoring framework based on user defined temporal step.

During unrest events, near-real time PSI solutions were generated whenever a new Sentinel-1 acquisition was available, based on both online hosted SNAPPING service, as well as in-house GAMMA Multi-Temporal InSAR (MT-InSAR) processing. This dual-processing methodology serves as a verification mechanism for the detected displacement signals.

Surface Motion Measurements

In the period following the 2011–2012 unrest, the Santorini volcano experienced deflation centered on Nea

Kameni (Figure 1), extending as far as Thera Island, including Cape Skaros and the northern caldera walls. The observed motion rates of approximately -7.8 mm/yr remained elevated compared to pre-unrest levels of around -5 mm/yr, though slightly lower than the -9 mm/yr reported seven years after the 2011 event (Papageorgiou *et al.*, 2019). These observations suggest that the volcano was undergoing a prolonged deflation phase, gradually returning to its pre-unrest state before the onset of a new unrest in July 2024. Although the initial 2024 inflation signals were detected by InSAR and the local GNSS network of ISMOSAV, the confirmation of a new unrest phase was underlined by the onset of seismicity a few months later (AUTh Seismological Station, 2024). Since summer 2024, inflation of Santorini, the second episode of significant magnitude within the last 15 years, has continued through the end of the year. This local inflation was consistent in both displacement pattern and magma source location with the 2011–2012 unrest. However, it was also soon superimposed by a more significant event that occurred in the early part of February 2025 and originated from the broader Kolumbo–Anydros area. The Anydros event was shorter in duration but associated with deformation nearly two orders of magnitude greater than the prior Santorini caldera inflation. While the inner caldera magma source was deforming the volcanic complex at a rate of 10–12 cm per year over a six-month period, the Kolumbo–Anydros activity exhibited meter-level displacement rates within just two weeks, highlighting their distinct dynamics and potential implications. These differences are further reflected in the number and magnitude of the accompanying seismic events.

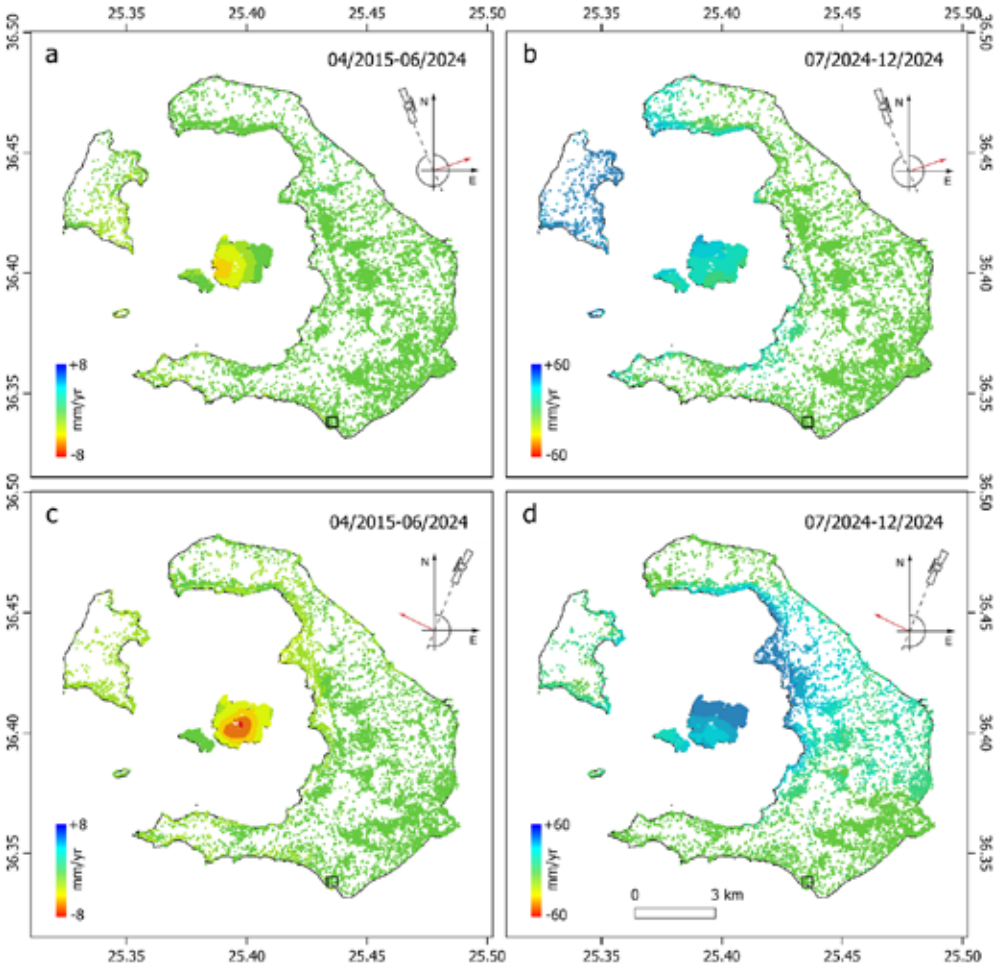

Figure 1. Sentinel-1 MT-InSAR LoS motion rates prior (a,c) and during (b,d) the 2024 unrest for the ascending 029 (a,b) and descending 109 (c,d) satellite tracks. Local reference point for InSAR processing is located in the southern part of the island (black square).

Discussion and Conclusions

The Earth Observation and Geospatial Applications Laboratory (EO.Lab) of AUTh has systematically monitored Santorini through InSAR, as part of the operational framework of ISMOSAV, using automatic solutions such as GEP SNAPPING, internal processing chains based on Copernicus SAR data, and collaborations with space agencies for complementary SAR monitoring. In this work, we present the evolution of surface displacements as measured by satellite InSAR techniques for the broader Santorini–Anydros region. We discuss the role of geodetic imaging techniques in volcano monitoring, their advantages, and complementarities with other geodetic and in-situ networks and finally, we emphasize the need to establish a local volcano observatory, involving scientists across multiple domains, integrating diverse techniques and equipment for real-time monitoring of this volcanic region and its surrounding areas.

Acknowledgements

The authors would like to thank the GEP platform providers for allocating resources to support the execution of services related to the monitoring of the Santorini volcano.

EXTENDED ABSTRACT 078

Seismotectonic Features of the 2023 Strong Earthquake Sequence in Southeast Türkiye.

Introduction / Background

Türkiye is one of the most seismically active countries in the world, and the East Anatolian fault is one of the largest and most active faults in the Eastern Mediterranean, as proven by the recent, destruvtive earthquake sequence in 2023. On February 6th, 2023, three earthquakes with magnitudes Mw > 6.5 struck within 11 hours, followed by another earthquake of Mw > 6 two weeks later. The aftermath of these events were thousands of casualties and an unprecedented infrastructure damage in Türkiye and Syria. Landslide phenomena and widespread liquefactions were a direct consequence of the earthquakes, further worsening the already immense destruction (Chadha, 2023). This study aims to better understand the sequence's behavior through an analysis of Coulomb static stress changes. More specifically, the four strongest earthquakes in the February 2023 sequence were attributed to four respective faults which have been modelled in order to be imported to the Coulomb 3.3 software (Toda et al., 2011). The Coulomb 3.3 software calculates the loading or unloading of stress on the modelled faults and in the surrounding area.
The Coulomb Failure Criterion determines the critical value of maximum shear stress without specifying the point where a rupture starts or how it will evolve. It is expressed by the relation $\Delta\sigma f = \Delta\tau_s + \mu' \Delta\sigma_n$, where $\Delta\sigma f$ is the difference in Coulomb stress failure. When $\Delta\sigma f > 0$, there is stress loading in the surrounding area, suggesting a higher likelihood of fault reactivation (triggering effect). On the contrary, when $\Delta\sigma f < 0$, there is stress release and a reactivation is potentially delayed. The fault or faults that are being triggered are referred to as source-faults, while the fault that receives the transferred stresses is referred as the receiver-fault. The stress change is strongly dependent by the receiver fault's geometric and kinematic attributes (Harris, 1998; Steacy et al., 2005; Toda et al., 2011).

Seismotectonics in East Türkiye

In East Türkiye the major tectonic structures are Caucasus Fault Zone which is a right-lateral strike-slip faults in the NW, Dead Sea Fault Zone (DSFZ) which is a 1000 km zone of left-lateral horizontal slip, Cyprus Arc which is a convergence boundary of the African and Anatolian plates, causing high seismicity begins from Cyprus to the Kahramanmaraş Triple Point, East of Karlıova Triple Junction where there is a compressional tectonic area of N-S and strike-slip faults (right-lateral & left-lateral) and the interconnected strike-slip zones of North Anatolian Fault Zone (NAFZ right-lateral) & East Anatolian Fault Zone (EAFZ left-lateral) (Taymaz et al., 2021; KOKUM & OZCELIK, 2020).

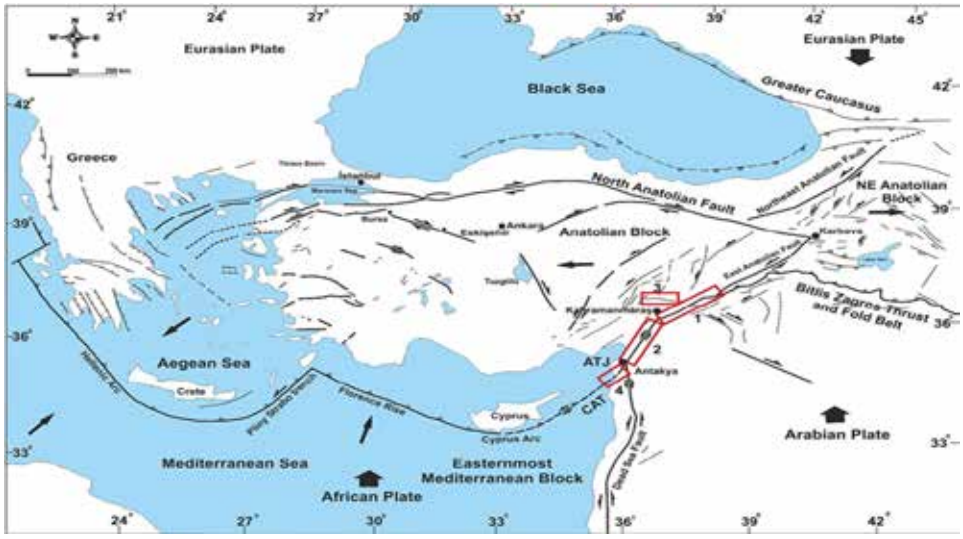

Figure 1: Tectonic map of East Mediterranean region (modified from Barka, 1992; Över et al., 2010).

More specifically, EAFZ facilitates the westward extrusion of the Anatolian plate, has a total length of 700 km. It consists of two branches: i) the Southern one, from Karlıova to Antakya, towards the DSFZ and the Cyprus Arc, and ii) the Northern one, from Celikhan to the Iskenderun Gulf, with a length of ~ 350 km. EAFZ constists of strike-slip faults with a normal component (h < 20 km) and is a zone of high seismic activity with magnitudes M > 6 during the past 300 years (Taymaz et al., 2021; KOKUM & OZCELIK, 2020).

The 2023 earthquake sequence

The study focuses on the four strongest earthquakes of the sequence, with M_w >6, all of which had shallow hypocentral depths. Their focal mechanisms indicate left-lateral strike-slip motion, a characteristic feature of the East Anatolian Fault Zone. The four strongest earthquakes appeal to a really rare phenomenon of multiplet earthquakes where magnitudes differ no more than ±0.4M_w and all shocks are considered to be mainshocks (Goldberg et al., 2023).

- February 6, 2023 (Mw 7.7): known as the earthquake of Nurdağı - Pazarcık - Kahramanmaras Earthquake, at 01:17 (local time) and a total duration of 80 seconds. The ground acceleration reached 1.5 g, with a rupture velocity of 3.2 km/s. It is a shallow earthquake of 8.6 km hypocentral depth with NE-SW stress orientation. Its epicentre is located at the Türkiye-Syria border, in the Kahramanmaraş (KMTJ) – Gaziantep region (32 km NNW). The rupture is considered to be dual, as it initiated on the Narli fault (20 km from the EAF), lasting for 20 seconds and then extended 50 km NE-SW (Karabulut et al., 2023; Wang et al., 2023; Melgar et al., 2023).
- February 6, 2023 (Mw 6.8): this earthquake is reffered as Nurdağı Earthquake and it struck just 11 minutes after the first shock (01:28 UTC), with epicentral depth 6.2 km. Its epicentre is located at the southern end of the EAFZ and its stresses oriented in a NE-SW direction (Karabulut et al., 2023; Wan et al., 2024).
- February 6, 2023 (Mw 7.5): this earthquake is known as Elbistan – Ekinözü Earthquake, it occurred just 9 hours after the first one, at 10:24 (UTC) with a total duration of 50sec. Its epicentral depth is 8.6 km, the maximum slip reached 7m and the length of the rupture was approximately 160 km (SOFTA et al., 2024; Chen et al., 2023; Over et al., 2023).
- February 20, 2023 (Mw 6.3): the earthquake of Uzunba – Antakya took place two weeks after the initial event. M_w 6.3, its epicentre was in the area where the EAF and Cyprus Arc meet, its hypocentral depth was deeper than the first three earthquakes, estimated approximately at 22 km. Despite its smaller magnitude, it caused significant damage, particularly in areas affected by the previous earthquakes. The fault responsible was blind and unmapped, its focal mechanism was a left-lateral strike-slip with a small horizontal component and the length of its rupture is estimated at 25 km (Barbot et al., 2023; Over et al., 2023; Karabulut et al., 2023; Gürboğa et al., 2023).

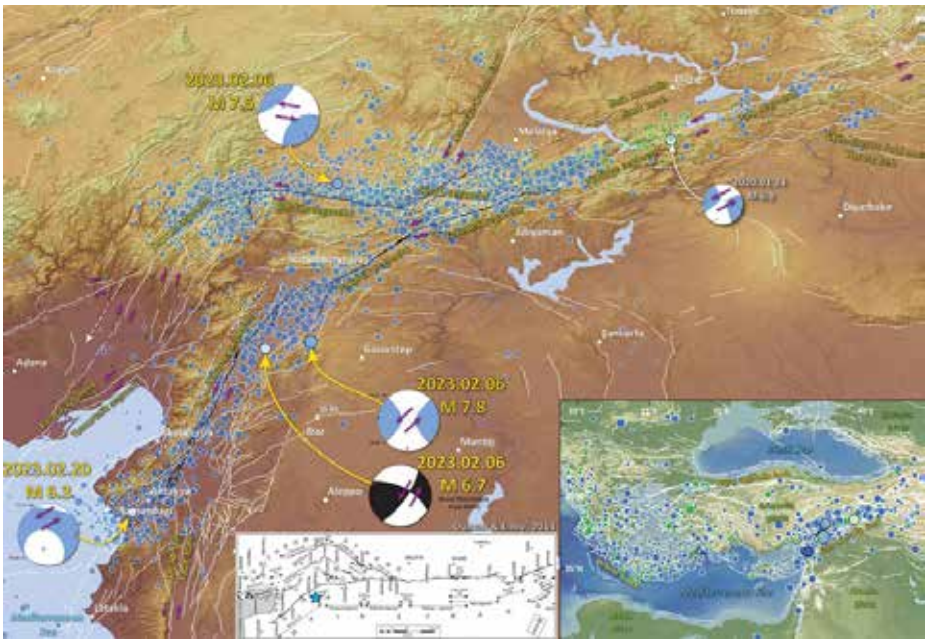

Figure 2: Epicentral map of the 2023 sequence (blue dots) with the four strongest earthquakes highlighted (USGS, 2023) (Duman & Emre, 2013).

Seismic Fault Modelling and static stress changes calculation

Firstly, we selected the nodal plane of the focal mechanisms that best fits: i) the fault direction and ii) the aftershock spatial distributions. The modelling was performed in the Coulomb 3.3 application in which we set the geometric and kinematic parameters (length and width are automatically calculated by the integrated scalar relationships of Wells & Coppersmith, 1994). After modelling the seismic sources, we applied the Coulomb Failure Criterion within the same application under the following scenario: we set in each fault rupture the ruptured fault(s) as the seismic source(s) and the faults that didn't yet rupture as receiver faults. Coulomb 3.3 software is based on the Coulomb Failure Criterion. Thus, we examined all the intermediate change of stress between the successive major ruptures of the earthquake sequence ('in-sequence' investigation).

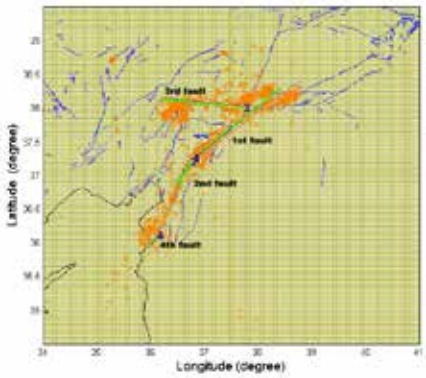

Figure 3: This figure shows the four modelled faults (1, 2, 3, 4) in Coulomb 3.3, along with the overlays of coastline (in black), regional faults (in blue) and seismic sequence of 2023 (in orange circles).

Results and conclusions

During the seismic sequence of the four strongest earthquakes of February 2023 in SE Türkiye, we investigated the Coulomb static stress changes which were caused after the fault rupture of the four strongest events. The results are shown in Figure 4 at depths close to hypocentral depth of the next earthquake. In more detail:

- The investigation of the first earthquake (06.02.2023, 01:17 UTC, 7.7 Mw) and its effect on the second event (06.02.2023, 01:28 UTC, 6.8 Mw) was conducted at the depth of 6.2km, which is close to the hypocentral depth of the latter. The results in Figure 4a indicate that the first earthquake triggered the second one, as the first fault loaded stress on the second fault.
- The investigation of both first and second earthquake suggests that they played a major role in accelerating the occurrence of the third event (06.02.2023, 10:24 UTC, 7.5 Mw). The results in Figure 4b, calculated at depth of 8.6 km which is the hypocentral depth of the third fault, indicate that the third fault was loaded with stress after the first two shocks.
- On the contrary, in the last case, we investigated the total stress change from the three earthquakes and its impact on the fourth event, two weeks later (20.02.2023. 17:04 UTC, 6.3 Mw), at the depth of 22 km, which is close to the hypocentral depth of the fourth fault. The results depicted on Figure 4c indicate that the fourth fault was not affected (white area) from the stress change produced by the first three earthquakes.

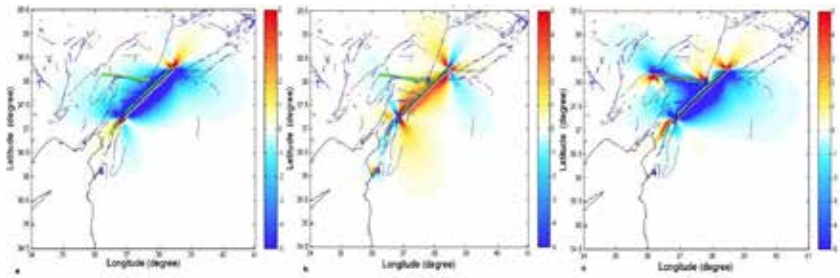

Figure 4: This figure shows the four modelled faults (1, 2, 3, 4) in Coulomb 3.3, along with the overlays of coastline (in black), regional faults (in blue) and the stress bar. The stress bar is coloured: in red tones for Δσf > 0 (loaded stress), in white for Δσf=0 (no stress change) and in blue tones for Δσf < 0 (unloaded stress). Specifically: a. depicts the 1st fault as source-fault (with slip) and the 2nd as receiver fault, being loaded with stess, b. depicts 1st & 2nd faults as source faults and the 3rd fault as the receiver fault, being loaded with stress, c. depicts the cumulative effect of the first three faults as source faults and the 4th fault as receiver fault, which stands in an uncharged area.

Summarizing, the correlation between static stress changes and the local structural pattern played a critical role in determining the stress transfer within the faults. The stress patterns in the region were redistributed after each of the four shocks, with particularly interesting results. At least three of the four strongest earthquakes were related, each one charging stresses for the appearance of the next one. The fourth fault did not receive significant stress increase from the prior events, likely due to its deeper hypocenter and less optimal orientation within the broader stress field. The regional faults that had generated earthquakes in the recent past (Elazig 2020 & Palu 2010) appear to be recharged with stresses, confirmed by the 6 M_W earthquake in Akusagi-Kale, Elazığ, Türkiye, on 16 October 2024. This highlights the importance of integrating structural data when interpreting stress transfer and seismic hazard in complex fault systems.

Abstract

The Hellenic DataBase of Active Faults (HeDBAF) is a national product of collaboration between scientists of all related to this subject academic and research institutes of Greece under the the auspices of the Earthquake Planning and Protection Organization (EPPO) and the supervision of its Seismotectonics Committee (Fig. 1). The main purpose of the geodatabase is to provide essential information to the scientific community and to whoever wants to have a synoptic or in detail information about the active faults of Greece, as well as to serve as a platform for geologists, engineers and the central and local administration, to in-depth studies. The HeDBAF geospatial database started to realize since 2021, including parametric and descriptive information about the active faults in the broader Hellenic region. The responsibility of implementation, management and hosting is held by the Hellenic Survey of Geology and Mineral Exploration (HSGME).

The HeDBAF adopts conceptual approaches and characteristics from other time-proven national databases of the world (e.g. INGV's DISS, IGME's QAFI, etc.). It is a multi-layered tool that hosts all available literature data (e.g. scientific articles, technical/project reports, thematic maps, etc.), targeting various groups of end-users: the primary target group is the scientific community which often needs medium- to small-scale information for geodynamic interpretations, large-scale data for local seismotectonic analyses, and appropriate parametric information for numerical modelling. The next target group is the engineers who need large-scale detailed surveying of the fault traces and ground ruptures, and fault models for the prediction of ground motion in the context of Seismic Hazard Assessment. Administration, government, security bodies and local authorities can benefit from this geodatabase as a decision-making tool for safety and rescue planning. Last, but not least, a broad range of citizens will be able to access principal theoretical and parametric information about active faults in areas they are interested in.

More important dataset includes faults with geomorphic marks, such as free faces, coseismic ruptures, fault scarps, triangular facets (flat-irons), or sometimes inferred faults based on geomorphological evidence, such as river deflections, linear mountain-fronts, *etc.* It should be mentioned that the geomorphological evidence is a complementary element for the more accurate geographical positioning of the fault trace and not for the existence of the fault. In the case of earthquake-related faults (seismic faults), the traces can correspond to primary ground ruptures. Among the purposes of this dataset is to provide also information necessary for *Surface Faulting Hazard* (SHA). This type of hazard assessment is crucial for building and infrastructure design, considering that a possible fault displacement could damage the foundations of any technical construction. Moreover, the detailed mapping of fault traces can contribute to fault linkage/segmentation scenarios. Such scenarios are also important, since they can inform us whether a possible rupture can be constrained or pass through neighbouring faults, increasing, thus, the magnitude potential.

The core of the geodatabase, i.e. the tectonic information, will be separated into two distinct, but interrelated, datasets: i) the Fault Traces (FT), and ii) the Fault Zones (FZ). The purpose of each dataset is to provide a different level of information covering different needs (Fig. 2). The former focuses on the mapping accuracy of faults, targeting on large- to medium-scale data (> 1:50,000). Faults originating from smaller scale maps are reassessed (if possible) using hi-resolution topographic data. Primary co-seismic ground ruptures are distinguished from geologically detected fault traces to better understand the surficial rupturing process for fault rupture hazard purposes. The Fault Zones dataset involves fault segmentation and earthquake rupture scenarios which are crucial for Seismic Hazard Assessment (SHA).

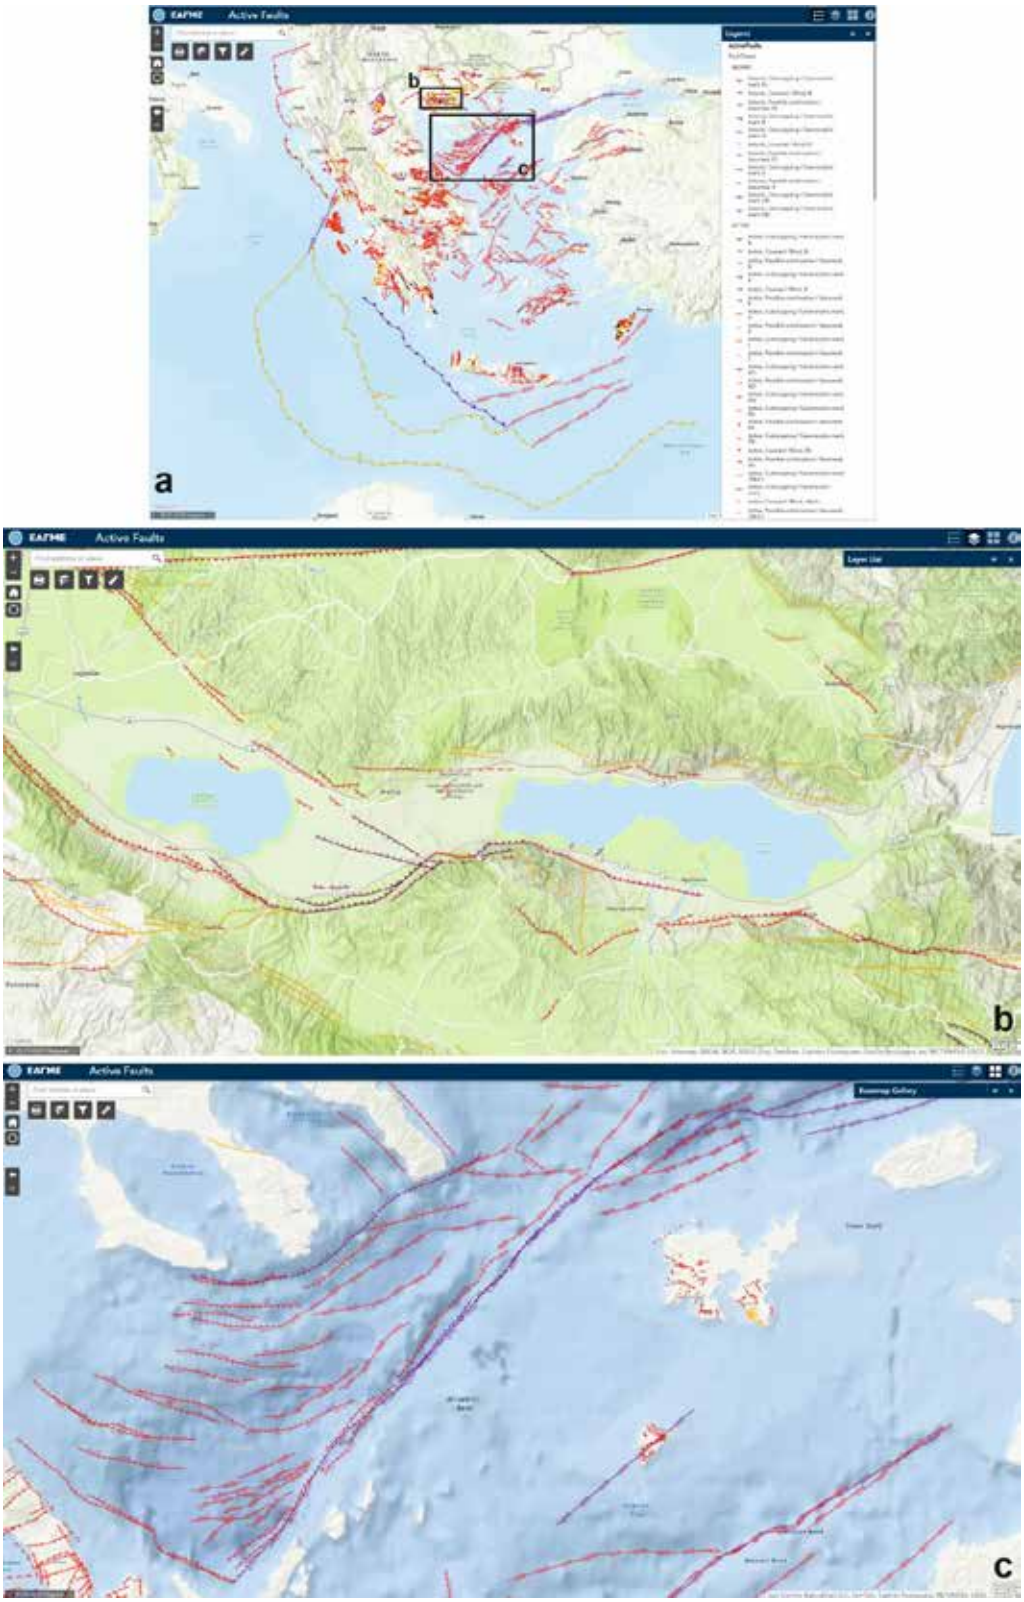

Figure 1. Snapshots of the Hellenic DataBase of Active Faults (HeDBAF) in its current status as seen in the dedicated website (https://activefaults.eagme.gr/en/) for various topographic backgrounds: (a) The broader area of Greece showing the locations of inset maps (b) and (c). (b) Focus on the Mygdonia Basin. (c) Focus on the North Aegean Basin, Lemnos and Aghios Efstratios islands.

Thus, the fault zones are represented by medium- to small-scale lineaments which also facilitate the visualization of large tectonic structures in small-scale maps. The HeDBAF, geodatabase is continuously updateable and upgradeable showing frequent improvements and enrichments.
Following the steps of the Database of DISS (DISS Working Group, 2021) and the Quaternary active faults database of Iberia QAFI (García-Mayordomo et al., 2012), the HeDBAF not only is the source of information, for most of the parametric information, clearly given (whether it is literature data, original data, empirical relationship, or expert judgement, all abbreviated as source-keys), but the methodology followed to extract this information is stated. This means that the end-user has at his/her disposal the origin of the parametric information and the distinction between real data or any other kind of estimation. In this way, the scientific and highly specialized working group of the geodatabase ensures that most of the parametric information will be filled in, leaving as few blank fields as possible.

The classification of the faults used in the Database is based on the definitions decided by the Seismotectonics Committee, as follows:

Seismic fault is defined as an active fault if its activation has been confirmed by a strong earthquake during the instrumental or historical period, by an observed surface seismic rupture or by a palaeoseismological investigation. It should be mentioned that the above definition does not exclude the existence of seismic faults identified by seismological, geophysical, geodetic or other instrumental observations.

A fault is characterized as Active when it documents displacement at least once during the Upper Pleistocene (in the last 126,000 years or so) and can therefore be the source of a future earthquake.
A fault is characterized as active when:

- it has produced a surface rupture associated with a historical or modern earthquake
- it has yielded soil ruptures dated during the Upper Pleistocene-Holocene period, as has been determined by excavating palaeoseismological trenches perpendicular to its trace
- it displaces or affects (e.g. folds) Upper Pleistocene-Holocene geological formations
- free faces with sclickenlines observed along the fault's length have not been eroded at places
- characteristic escarpments and tectonic scarps can be recognized along its length
- debris or talus cones develop at the base of the fault scarp
- morphotectonic structures (e.g. triangular facets, etc.) are shown along its length
- it cuts or displaces river or stream beds in a systematic way
- it demonstrates aseismic slip (proven by geodetic measurements or other indications)
- it is associated with seismic epicentres of the instrumental period or with the alignment of microearthquakes
- it has a structural relationship with another known active fault (it is subparallel, it branches, it has en echelon geometry, etc.)
- it is associated with active volcanism or hot springs
- the stress field of its last activation is roughly the same as the one given by the focal mechanisms in the same area.

A fault is characterized as Potentially Active when it documents displacement at least once during the Quaternary (in the last 2.600.000 years).
The Potentially Active faults:

- displace or affect (e.g. folds) quaternary geological formations but they have not been reactivated during the last 126.000 years
- there is no available geological data indicating their direct relation to strong earthquakes
- they show a small degree of correlation with the distribution of major earthquake epicenters of the instrumental period.
- geomorphological features (eg fault surfaces) along the fault traces are significantly eroded
- they have been identified on the basis of geophysical surveys in areas covered by recent deposits
- their direction is compatible with the active tectonic stresses prevailing in the area.

Non active faults (Inactive or Faults of Undetermined activity) are those for which there are no geological or other (seismological, historical, paleoseismological, geophysical) indications for their activation at least during the Quaternary period (last 2.600.000 years).

EXTENDED ABSTRACT 080

An investigation of the use of deep-neural-network-based seismic arrival time picking methods for the automatization of earthquake sequence monitoring: The case of the November 3, 2024 MW 5.3 Kassandra earthquake

Galanis O.[1], Panou A.[1]
(1) Aristotle University of Thessaloniki, Thessaloniki, Greece, ogalanis@geo.auth.gr

We use a pretrained deep neural network to pick seismic arrivals on continuous seismic records. With these picks we locate the events of an earthquake sequence.

Introduction

During the last decade, a number of machine learning techniques have been developed for seismology, and equally importantly, became available as open software. This, combined with the wide availability of open seismological data and open tools for their manipulation, sets the stage for significant improvements in both routine earthquake monitoring and seismological research. In the present work we investigate the use of deep-neural-network-based seismic arrival time picking methods for the automatization of earthquake sequence monitoring and we use the sequence of the November 3, 2024 M_W 5.3 Kassandra earthquake as a case study.

Data

On November 3, 2024, an earthquake of magnitude 5.3 (M_W) occurred off the coast of the Kassandra peninsula of Chalkidiki, Northern Greece, in an area of moderate seismicity. The subsequent aftershock sequence consisted of hundreds of events (indicatively, 430 earthquakes of magnitude 1.5M_L or larger were detected by the automatic location system of the Seismological Station of the Aristotle University of Thessaloniki, within the two months following the mainshock). A selected subset of these events was manually located and included in the bulletin of the Seismological Station of the A.U.Th. These events are shown in Figure 1.

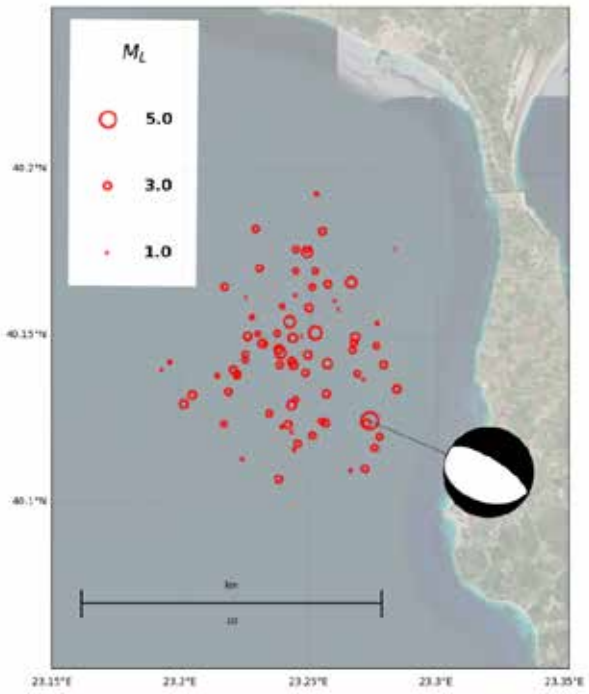

Figure 1. The epicenters of events with a manual solution included in the bulletin of the Seismological Station of the A.U.Th. The beachball plot corresponds to the focal mechanism of the mainshock (Mw=5.3, A.U.Th.).

The input data used in the present study, is the continuous recordings of broadband and strong motion stations in operation in the area around the sequence. These stations are selected from the around 350 stations available to the Seismological Station of A.U.Th., of which 50 are maintained by the A.U.Th. itself while the rest are provided by the other members of the Hellenic Unified

Seismological Network and other partners. The routine procedure is to first automatically calculate hypocenters and magnitudes in real time with the SeisComP seismological software package, which are then refined by designated human analysts. Analysts are instructed to at a minimum perform a manual analysis of every event for which the automatic magnitude (M_L) is 2.5 or greater. This results in two datasets, one of relatively higher quality but limited in size by the available humanpower of the Seismological Station and one of relatively lower quality but more extensive.

In the present study, we use deep-neural-network-based seismic arrival picks to locate the sequence, in order to obtain a dataset of sufficient quality and sufficient size to describe the spatial and temporal distribution of the events.

Implementation

We used the SeisBench toolbox (Woolam et al. 2022) which provides, among other tools, deep neural network models trained with a range of training datasets. Comparing models and training sets is out of the scope of the present work, so we used the EQTransformer model (Mousavi et al., 2020), trained with the Instance dataset which is a good starting point for most cases (Münchmeyer et al., 2022). A sample of the results is shown in figure 2. For associating the picks produced by EQTransformer, we used the GaMMA associator (Zhu et al. 2022). After association, each pick is associated with a specific event. In the final step the events are located using the NonLinLoc software (Lomax et al. 2014), which is also the software used for the routine manual location of earthquakes. For the routine manual location, we use a 1-D velocity model, and we did not change this for the present work. The end product of the process is a catalog of the events of the earthquake sequence. It also has to be mentioned that in addition to all the above software, we had to develop tools for the downloading of the data, as well as manipulation, bookkeeping and reformatting. This also included tools to rapidly visually inspect phase picks and phase associations.

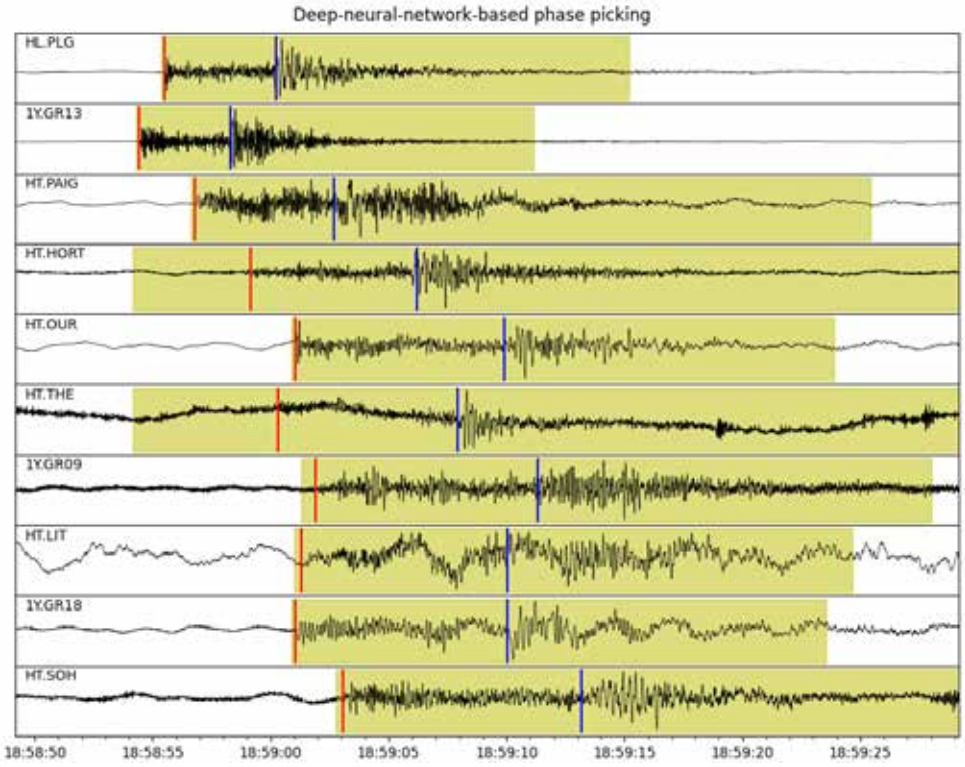

Figure 2. Example of the results of deep-neural-network-based picking. The yellow shadowed area corresponds to the time window characterized as the detection of an earthquake by the model. The red lines correspond to the P arrivals (technically the times where the probability of a P arrival is maximized) and the blue lines correspond to the S arrivals. The event shown has a magnitude of 1.7 (M_L) as determined by the automatic earthquake location system.

Results

The picking – association – location procedure resulted in the events shown in Figure 3. 1085 events were located in total. 11 foreshocks were detected, the first one occurring in October 31st. Although we scanned for P and S wave arrivals for the period starting in October 1st, not a single event was detected in the area of interest until the last hour of the month. This gives an indication of the system's resilience to false detections. The aftershocks persisted for the months following the mainshock with an average of more than one event per day during February 2025.

The focal depths of these events are < 20 km but they are not well constrained. This does not seem to be a problem of the location procedure as it was also observed in the far more rigorous manual locations. The error in the epicenter appears to be at least as small as that of the manual epicenter judging by their spatial distribution, especially taking into account that the deep-neural-network-based sample of earthquakes is about an order of magnitude larger than the manual sample. To confirm this, we also performed a double-difference relocation (hypoDD, Waldhauser and Ellsworth, 2000, Waldhauser, 2001) of all the events. The results of this relocation are shown in Figure 4.

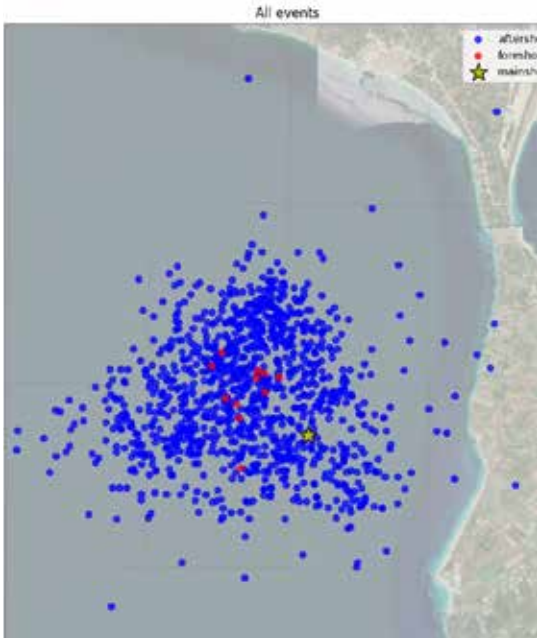

Figure 3. All the events located. The mainshock is marked with a star, while foreshocks and aftershocks are marked by red and blue points respectively.

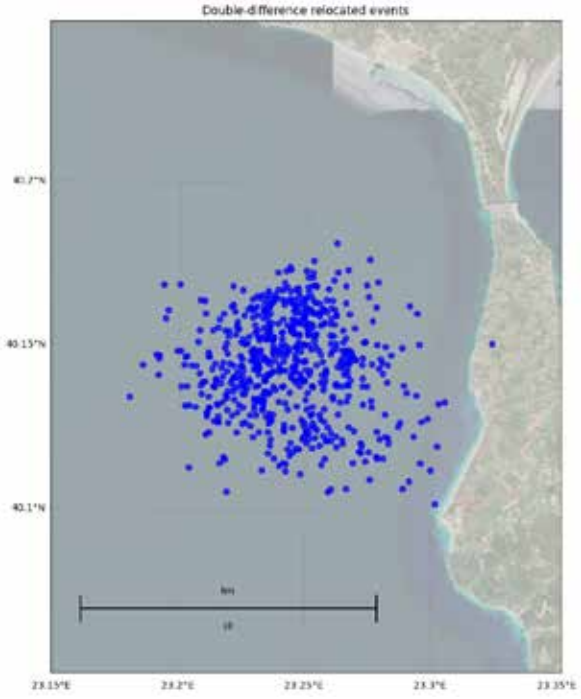

Figure 4. All the events relocated by the double-difference algorithm

The geometry of the fault is not apparent by the epicenter distribution, but taking into account the published focal mechanism it appears that the fault length is at most 10km which is compatible with an event of this magnitude or a slightly larger one. In a real-world application this sort of information would be helpful in the evaluation of the earthquake sequence the hours following the mainshock. For this reason, we mapped the events that occurred in the 12h following the mainshock. The results are shown in figure 5. We conclude that during this particular earthquake sequence there was no significant temporal change in the spatial distribution of the epicenters.

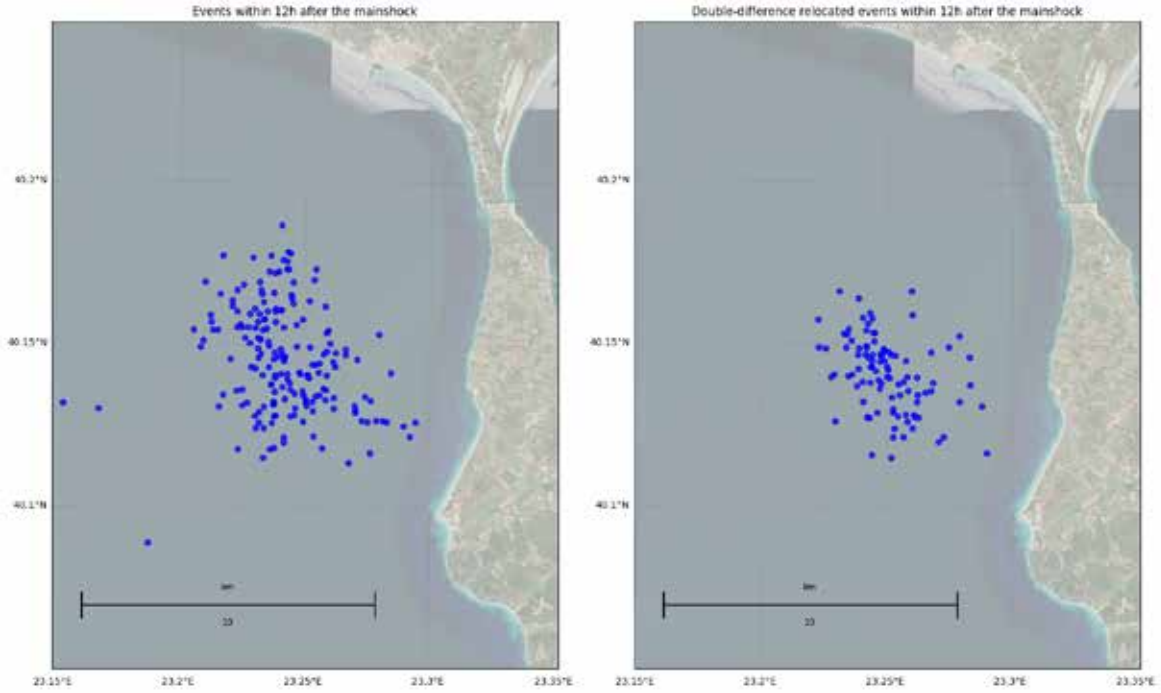

Figure 5. The events that occurred the 12 hours following the mainshock as located by NonLinLoc (left) and the subset that was successfully relocated by hypoDD

Finally, we calculated the rate of occurrence of the aftershocks, as the number of detected events within a 24h moving window. The results are shown in Figures 6, 7 and 8. We conclude that the aftershock sequence is very typical in this respect, as the rate of occurrence of aftershocks follows Omori's law in the short term (days) as well as in the long term (months).

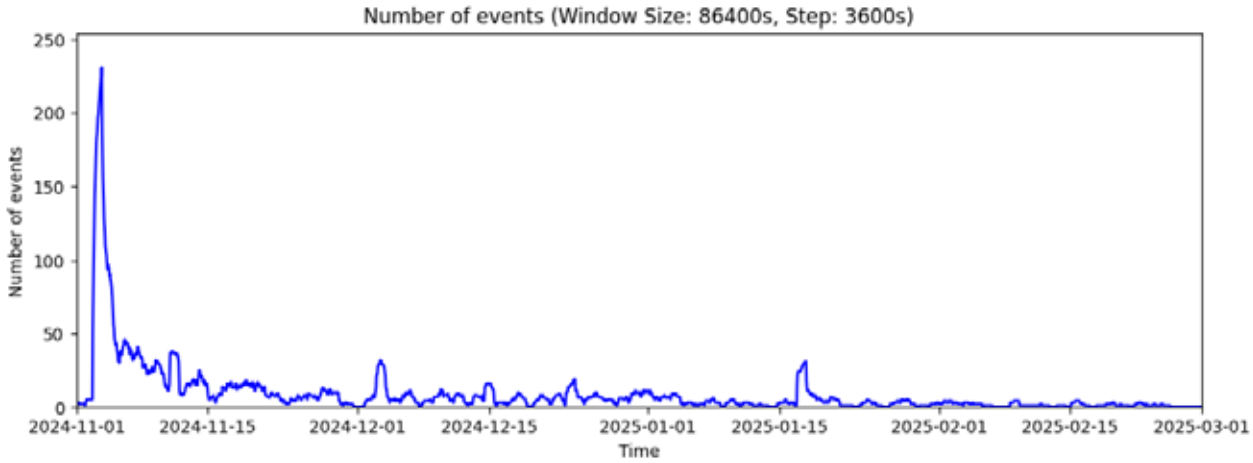

Figure 6. The rate of occurrence of earthquakes given as the number of detected events within a 24h moving window for the period covered by the present study.

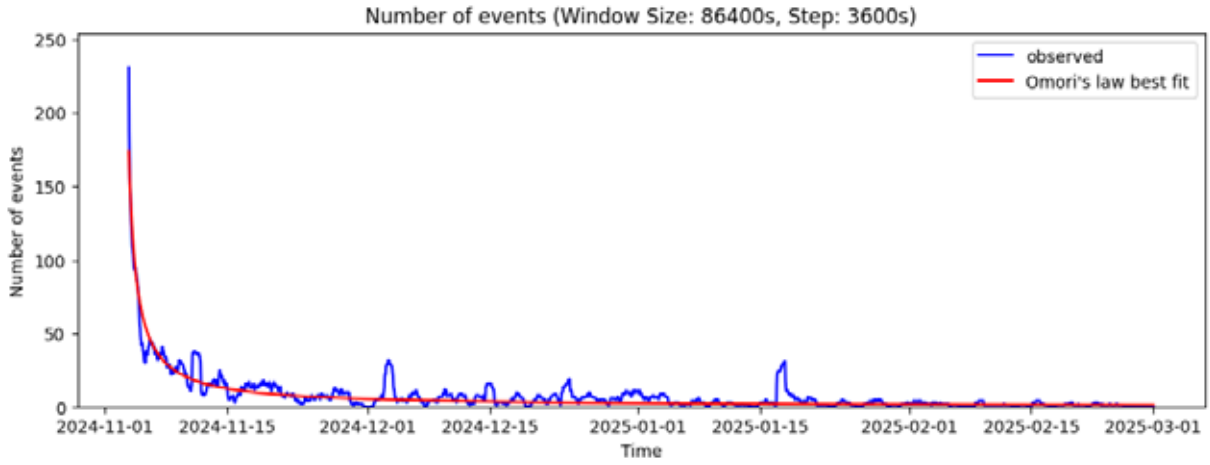

Figure 7. The rate of occurrence of aftershocks given as the number of detected events within a 24h moving window starting at the origin time of the mainshock. The rate of occurrence is shown with a blue line, and the least squares best fit for Omori's law is shown with a red line.

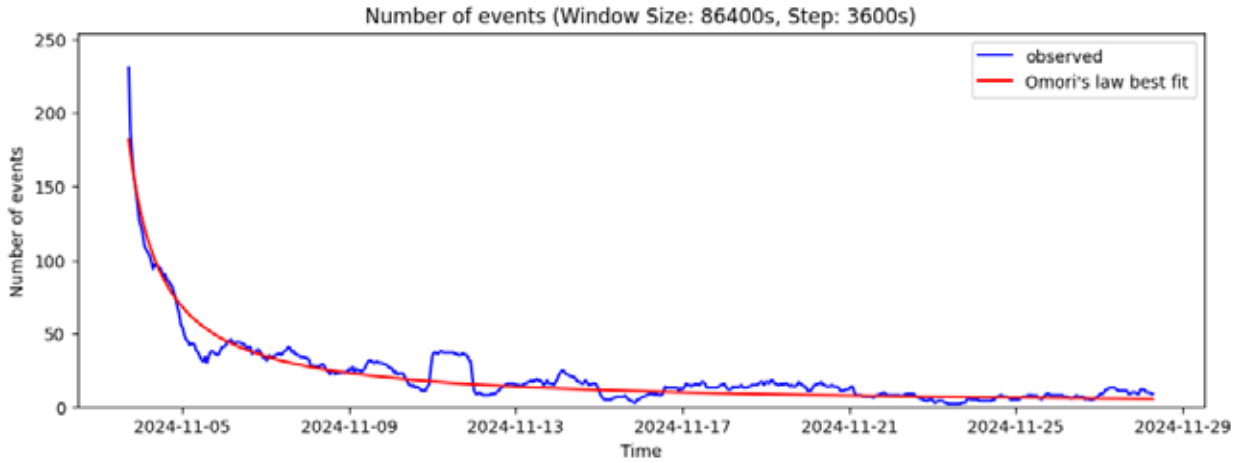

Figure 8. The rate of occurrence of aftershocks given as the number of detected events within a 24h moving window for a few weeks following the mainshock. The rate of occurrence is shown with a blue line, and the least squares best fit for Omori's law is shown with a red line.

Conclusions

Deep-neural-network-based seismic arrival time picking methods, can be used in combination with other tools and methods and using relatively modest computational resources, for the monitoring of earthquake sequences. This sort of automatization is a satisfactory compromise between the higher quality manual locations and larger quantity of "traditional" automatic pickers. We applied them retrospectively to a moderate size earthquake sequence, and we plan to use them in real time in the future.

Data sources

All graphs and maps were created with the Matplotlib library (https://matplotlib.org/). When not stated otherwise, managing and processing seismological data was performed with ObsPy (https://www.obspy.org/). The backgrounds of the maps were developed by ESRI (https://www.esri.com/). We used data from the FDSN networks: 1Y, BS, EG, HA, HI, HL, HP, HT, KO and MK (https://www.fdsn.org/networks/)

EXTENDED ABSTRACT 081

Evolution of map-making from prehistoric times to the Middle Ages

Galazoudi E.[1], Bathrellos G.D.[2], Skilodimou H.D.[2], Koukouvelas I.K.[2], Nikolakopoulos K.[2]
(1) National & Kapodistrian University of Athens, Athens, Greece, egalaz@uoa.gr, (2) University of Patras, Patras, Greece

Introduction

The history of cartography—the art and science of map-making—is rich and fascinating, spanning millennia of human history. The relationship between humans and the environment dates back to ancient times. Most ancient cultures considered nature sacred (Manolas, 2010).

This connection between man and the environment is reflected, for example, in literary works, art, and maps. Maps have always been among the most important tools for comprehending the world and humanity's place in it, dating back long before the invention of writing.

Prehistoric humans used maps to depict their environment and to transmit their knowledge to future generations (Livieratos, 2007). Ancient Greeks considered themselves part of the natural environment, a perspective that influenced their daily lives, philosophy and religion. In antiquity, maps were created to help people understand and navigate the world.

Objectives

This paper describes the evolution of cartography or map-making from Prehistory to the Middle Ages. It explores the purposes of map-making, highlights the first examples of maps, discusses the contributions of ancient civilizations to map-making, of technology to the evolution of maps, and the role of geopolitical conditions in the formation of maps.

It also describes the significance of maps in understanding our world and the evolution of related theories. It examines the findings and observations concerning their thematic content and materials used in map-making during this period. It also presents the evolution of theories regarding the shape of Earth, its position in the Universe, and maps orientation.

Methods

The methodology for this paper initially included the search and collection of relevant bibliographic references. This bibliography includes Greek and international references about:

- the objectives and purposes of map creation
- the earliest examples of maps
- the contribution of ancient civilizations to the development of map creation
- the influence of geopolitical conditions on the formation and evolution of maps

The bibliography was searched and collected through Greek libraries, bibliographic databases, repositories of Greek - foreign Academic Institutions and online resources.

Subsequently, all the data collected was classified and processed. The maps were analysed in detail based on:

- their thematic content,
- the material used in their construction,
- the evolution of the Earth's outline and shape,
- the evolution of orientation over time.

The findings and observations derived from the data analysis were synthesized to draw conclusions, which are described in the concluding section.

Results

The first maps date back to the Paleolithic era (40,000 to 10,000 BC) and were created before the development of writing. Their purpose was educational and contained simple representations of the environment of primitive man. The material for recording primitive maps is rocks, known as petroglyphs (Brotton, 2015).

Babylonians introduced the fundamental principles of cartography, namely orientation and scale. They created the first map in 2500 BC, using clay tablets - the material - to make maps. They represented properties, city plans, as well as the world. The Babylonian view of the Earth was flat, circular and surrounded by the ocean (Snow et al., 2018).

By the end of the pre-Christian era, the ancient Greeks had laid the foundations of scientific cartography through three significant advances. First, Alexander the Great's expedition extended the then-known world to the Indus River, expanding geographical knowledge and reinforcing the need for cartographic mapping (Hunt, 2000). Second, Eratosthenes proved the sphericity of the Earth and calculated its circumference with remarkable accuracy. Third, Hipparchus invented a system of meridians and parallels, highlighting the need to develop map projections (Hunt, 2000).

Generally, the ancient Greeks contributed decisively to the evolution of cartography, introducing scientific and mathematical principles that formed the basis for its later development. They recognized the spherical shape of the Earth, leading to a more

accurate geographical depiction (Livieratos, 2007). They used geometric methods and developed instruments for measuring geographical quantities. They focused on scientific observation through measurements to understand the universe. They invented projections and, through them, the mathematical organization of the Earth's surface while connecting measurements with precise calculations, such as Eratosthenes' measurement of the Earth's diameter, a pioneering transition from empirical to scientific observation (Livieratos, 2007).

Cartography during the Middle Ages remained stagnant. Maps or mappae mundi showed significant differences from ancient and modern times (Harley & Woodward, 1987). Their purpose was educational as well as to represent the time's geographical, religious and mythological concepts. T and O-type maps were religious and represented the world with Jerusalem in the center and the East at the top of the map (Woodward, 1987). One type of map showed the world as a circle divided into seven geographical zones - the "climates" of Eratosthenes - or the five zones of the Roman writer Macrobius (Hunt, 2000). Portolans are maps that appeared in the 13th century and depicted the coasts, intending to help sailors in their travels (Tolias, 1999).

Table 1. Evolution of the beliefs about Earth's place in the Universe: From Antiquity to Renaissance

Period	Earth's place in the Universe	Important Philosophers/Scientists
Antiquity	Geocentric model	Aristotle (384-322 BC),
	Heliocentric model	Aristarchus of Samos (310 BC - 230 BC)
	Geocentric model	Claudius Ptolemy (85-165 AD)
Middle Ages 5th to 15th century AD	Geocentric model	Official position of the Roman Catholic Church
16th century	Heliocentric model	Nicolaus Copernicus

The place of the Earth in the Universe has been an issue that has concerned humans throughout time. Table 1 shows the evolution of the perception.

In Antiquity, the dominant belief was the geocentric system, in which the Earth was the center of the world. The Sun, the planets and the Stars revolve around the Earth (Livieratos, 2007). However, Aristarchus of Samos (310 BC - 230 BC) introduced the theory of a heliocentric system (Crowe, 1990), in which the Sun is the center of the Universe and the Earth orbits around it, which was not adopted.

The geocentric system was maintained in the Middle Ages, with the official position of the church being that the Earth is stationary and the planets revolve around it. Copernicus refuted this view in the 16th century.

Table 2. Evolution of the theories about Earth's shape. From Antiquity to Middle Ages.

Period	Map	Person	Earth's shape	Orientation
8th century BC	Shield of Achilles	Homer	Flat circular	
600 BC	Babylonian world map	Babylonians	Circular disk	N
550 BC	Anaximander map	Anaximander	Circular disk	
510 BC	Anaximander map	Hecataeus	Circular disk	
580-500 BC		Pythagoras	Spherical and rotation around an axis	
340 BC		Aristotle	Spherical	
250 BC		Eratosthenes *	Spherical	N
270-180 BC		Crates **	Spherical	
180-120 BC		Hipparchus***	Spherica	
85 BC		Poseidonius ****	Spherical	
1st century BC	Geographical	Strabo	Spherical	
2nd century AD	Geographia	Claudius Ptolemy	Spherical	N
536 AD		Cosmas	flat and elongated	S
Middle Ages 5th – 14th century AD		Mappae mundi	One - dimensional or flat, with circular or rectangular shapes that did not reflect the real geomorphology of the earth	E

*First measurement of the Earth, **Created the first Globe, *** Invented a system of meridians and parallels, ****Second measurement of the Earth

The beliefs about the shape of the Earth.

The shape of the Earth has been another topic that has preoccupied people since ancient times. Table 2 displays the transition from simple initial beliefs to more complex scientific theories about the shape of the Earth.

In antiquity, there were differing beliefs about the shape of the Earth:

1. Flat Circular Disk: This idea was held by the Babylonians, Homer, Anaximander, Hecataeus, and the Ionians, who believed the Earth was a flat disk.

2. Spherical Shape: In contrast, philosophers such as Pythagoras, Aristotle, Eratosthenes, Crates, Hipparchus, Posidonius, Strabo, and Ptolemy supported the theory that the Earth is spherical. They based their conclusions on observations of stars and various natural phenomena over time. Eratosthenes played a key role in confirming the Earth's spherical shape by calculating its circumference.

In the Middle Ages, maps depicted the world as one-dimensional or flat, with circular or rectangular shapes that did not reflect the Earth's actual geomorphology. These maps often illustrated the world as a flat disk surrounded by water.

The shape of the Earth played a crucial role in the significant geographical discoveries of the late Middle Ages. An example was the discovery of America in the late 15th century. It prompted the exploration of new sea routes and the establishment of trade relations, while scientific contributions from Arab geographers and European scholars improved the knowledge and confidence of seafarers. This new concept played a significant role in reviving geographical knowledge and initiating the era of great discoveries.

In addition, the above table also illustrates how map orientation has evolved over time.

In Babylonian maps, the orientation was initially towards the North. However, the earliest maps created by the ancient Greeks did not have a precise orientation. It was not until the introduction of geographical coordinates that they began to orient their maps towards the North, as seen in Ptolemy's map. This description resulted from the astronomical, geometric, and physical observations made by the ancient Greeks.

During the Middle Ages, most mappae mundi were oriented toward the East for religious reasons. An exception to the above is the map of Cosmas the Indicator, which was oriented towards the South. The Arab maps were oriented towards the South to align with Mecca. The evolution of map orientation underscores the profound cultural significance of mapmaking.

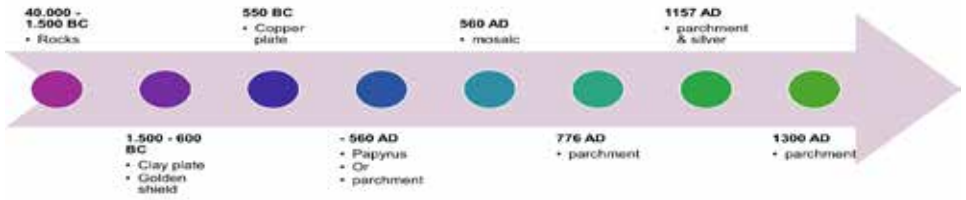

Figure 1. Evolution of the material used to make maps through time.

The above figure presents the evolution of the material used to make maps. Specifically, the depiction of maps began in the Paleolithic era, when prehistoric people drew their environment on rocks. Then, in Antiquity, it progressed from the clay tablets of Babylon to Homer and the golden shield of Achilles to the bronze tablet of Anaximander. During the Middle Ages, the most significant number of maps (or tablets) were either made of papyrus or parchment. Then, in Antiquity, from the clay tablets of Babylon to Homer and the golden shield of Achilles, we move on to the bronze tablet of Anaximander. In Antiquity, most maps (or tablets) were made of papyrus or parchment.

The transition from papyrus to parchment resulted from a combination of factors such as durability compared to papyrus, which was vulnerable to moisture and brittle. This durability allowed the preservation of texts for a more extended period, which was crucial to conserving religious texts and scriptures (di Curci, 2003). In addition, ease of use, availability, and the need for religious writing made parchment an essential material in the history of writing and cartography (di Curci, 2003). This transition began in the fourth, and by the end of the eighth century, most maps used parchment as constructed material.

In the Middle Ages, most maps were made of parchment. Exceptions are the Madaba mosaic map (560 AD) and the

Tabula Rogeriana map (1157 AD), which is made of parchment and silver. Towards the end of the Middle Ages, maps of animal skin (vellum), such as the Carte Pisane (1300 AD), were also made of parchment (Brotton, 2015).

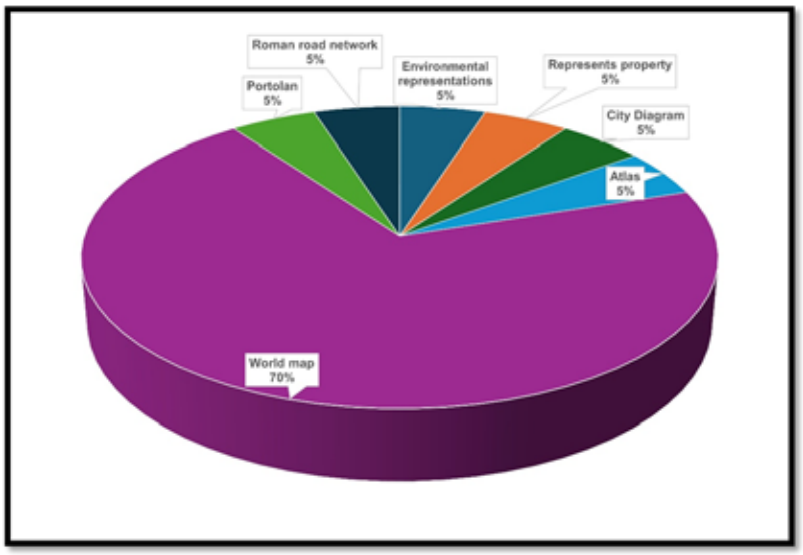

Figure 2. Distribution of types of maps, from Prehistory to the Middle Ages

Figure 2 presents the distribution of types of maps, from Prehistory to the Middle Ages, highlighting the diversity across numerous types.

World maps account for the most significant percentage of concerns, which indicates man's interest in understanding the World on a global scale.

These maps were not only geographical but often incorporated both philosophical and religious concepts of the World.

The remaining types of maps are in the same percentages: Portolans, environmental representations, representations of property, city diagrams, geographical atlases, as well as maps of the Roman road network.

Conclusions

The high percentage of World maps demonstrates humanity's inclination to understand the Earth, which was not only geographical but often incorporated both philosophical and religious concepts of the world.

The materials used for making maps have changed over time. In the past, people used rocks and clay tablets. Later, they made maps from metal, papyrus, and parchment. This progression illustrates technological advancements and emphasizes how these innovations have improved our comprehension of the world.

In Antiquity, the geocentric model of the Universe was dominant until Aristarchus of Samos proposed a heliocentric view, which was largely ignored. During the Middle Ages, the geocentric perspective continued to be upheld and supported by Church doctrine, demonstrating the enduring influence of ancient ideas.

Early thinkers like the Babylonians and Homer viewed the Earth as a flat disk. In contrast, philosophers such as Pythagoras and Aristotle later argued for a spherical Earth. During the Middle Ages, maps often depicted a flat world, ignoring true geomorphology.

Babylonian maps oriented northward, while early Greek maps lacked clear orientation. As the Greeks began to use geographical coordinates, they started orienting their maps to the north. In contrast, medieval mappae mundi were often oriented eastward for religious reasons, and Arab maps pointed south.

Abstract
In this contribution, we demonstrate the operational status of a new GNSS infrastructure in the western Gulf of Corinth (Greece) that is based on the collaboration of a multidisciplinary research team and on low-cost equipment. Our low-cost instrumentation includes a multi-GNSS dual-frequency chip (Ublox ZED F9P module) mounted on a Raspberry-Pi 4 compute module IO board together with an industry-standard MEMS accelerometer. It provides signal tracking for multi-GNSS systems (GPS, GLONASS, Galileo and BeiDou). The GNSS data are collected 24 hours 7 day 365 days per year, quality-checked and processed by use of the PRIDE-AR open-source software. The E, N, Up velocities for two sites (GEDP & KRHN) were estimated on the IGS20 reference frame. We tested our results against the velocities of neighbouring permanent GNSS stations with overall good agreement.

Introduction
There is a continuous need for integrating multi-parameter instrumental observations and measurements with Satellite Earth observation data towards continuous monitoring of the environment and infrastructures. This task attains more importance within the tectonic and seismically active area of the Greek “Supersite” (Fig. 1; Achaia, western Corinth Gulf). The significant level of geohazards in this region have made necessary the implementation of new technological approaches that could offer reliable augmentation to permanent networks (both geodetic and seismological; Nikolakopoulos et al. 2023). In this contribution, we demonstrate the design, construction and installation of a new GNSS infrastructure that is based on the collaboration of a multidisciplinary research team (funded by the PROION project) and on low-cost equipment.
The aim of the PROION project (https://proion-hellas.eu) was the development of a platform for the continuous monitoring of high importance infrastructures such as public buildings and dams. The methodology combines instrumental and remote sensing measurements along with fuzzy logic networks methods and machine learning algorithms (Nikolakopoulos et al. 2023). Specifically, measurements obtained by three-axis accelerometers, low cost GNSS receivers and Persistent Scatterer Interferometry (PS-InSAR) are fused and validated with high-precision 3D reference data derived from TLS surveys and UAV campaigns. The processing is based on soft computing algorithms while very accurate deformation maps are utilized for making decisions about the current and the future state of each infrastructure.
Our low-cost instrumentation includes a multi-GNSS dual-frequency chip (Ublox ZED F9P module) mounted on a Raspberry-Pi 4 compute module IO board together with an industry-standard MEMS accelerometer. It provides signal tracking for most global-coverage GNSS systems (GPS, GLONASS, Galileo and BeiDou). The GNSS data are collected 24/7/365, quality-checked and processed by use of open-source software. The combined-synergistic use of these new sensors is compatible with ground motion data provided by GNSS reference stations and accelerometers used by seismic agencies. Current work includes collection, reformatting, processing and archiving daily data from three test sites using 4G telemetry. The GNSS data support the on-going, pre-operational monitoring of three test sites (Fig. 1; Asteri dam, Department of Geology U. Patras, Krini landslide; Ganas et al. 2022) together with InSAR Copernicus data (Tsironi et al. 2022). For the first time, the displacement velocities of the NOA low-cost GNSS stations have been estimated to provide additional geodynamic information in an area with high rates of deformation. In this contribution we will present results for two sites GEDP (Patras; Fig. 1) and KRHN (Krini village; Fig. 1), respectively.

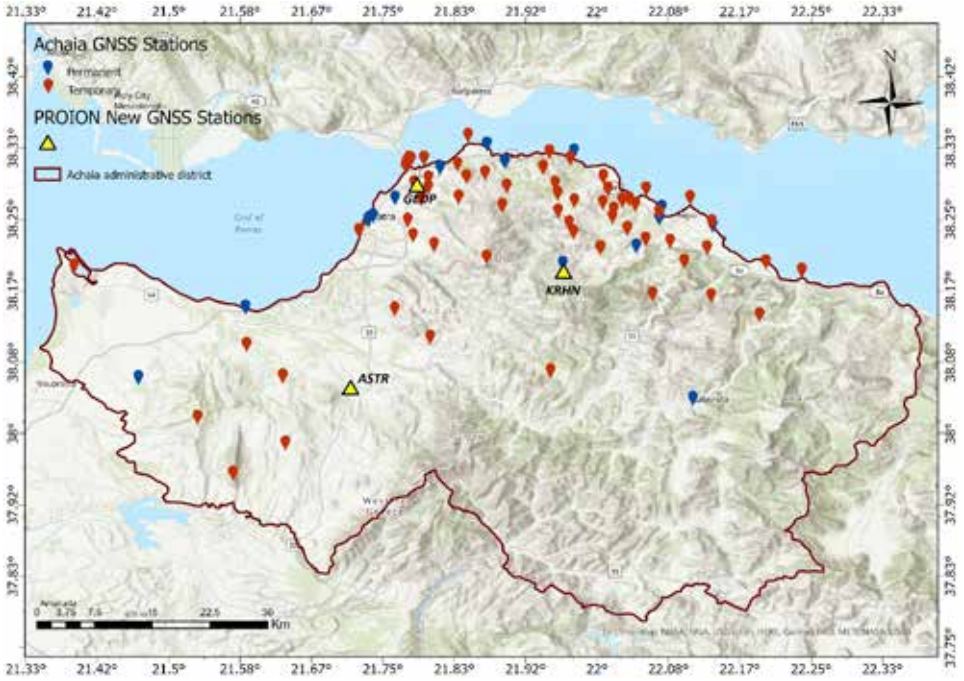

Figure 1. Relief map showing GNSS low-cost installations (yellow triangles; KRHN, GEDP, ASTR) in Achaia (part of the western Gulf of Corinth). Blue and red pins show other GNSS stations in the area.

Data and Methods

In actively deforming areas such as rift systems, it is essential to sample the deformation field thoroughly in both time and space to a) map the pattern of ground changes as well as the speed and direction of movement and b) constrain active fault source models. Surface displacements, tilts, and dilatation are easily measurable with modern geodetic techniques, such as the Global Navigation Satellite System (GNSS; Partheniou et al. 2019; Ganas et al. 2013, 2020; Briole et al. 2021).

In 2021 NOA established a local network of three (3) GNSS stations around the south coast of the Gulf of Corinth (Fig. 1; code names KRHN, GEDP and ASTR; Ganas et al. 2022). All stations were selected on horizon-free buildings, either on bedrock or on syn-rift sedimentary rocks, so that we make sure our data products record either tectonic or local motions. The benchmarks were drilled inside the roof tops and metallic bolts were placed (Fig. 2). GEDP and KRHN are new installations; KRHN occupied the same benchmark as the CRL station KRIN (https://nfo.crlab.eu/KRIN). Continuous measurements have been conducted on this network on a yearly basis since then by use of dual-frequency geodetic receivers (Ganas et al. 2024). With a combination of repeated GNSS measurements and continuous monitoring by 1-D InSAR (i.e., Tsironi et al. 2022), it is now possible to measure ground deformation over broad areas around the three GNSS sites and with satisfactory temporal and spatial resolution.

The data sampling interval was 1 s, and the data were collected on a 24 h basis. The RINEX files that were processed contain 8 observables of GPS satellites: C1C L1C D1C S1C C2W L2W D2W S2W. All station records were complete. Each station has been analyzed independently using the Precise Point Positioning (PPP) method which computes coordinates of each station separately. The low-cost data set was processed to obtain 24-h position solutions using the PRIDE-AR software (V3.0; Geng et al., 2019). Final products from the Wuhan IGS Analysis Center were employed for satellite orbits, clocks, attitude, and bias corrections. Daily files containing Earth Rotation Parameters (ERP) were also included in the processing. The latest ANTEX file published by IGS, including extensions for the station antenna, was also used. Zenith Total Delay (ZTD) was estimated using a stochastic walk model with a process noise of 0.0004 m/√s. The Vienna Mapping Function 3 (VMF3) was used as the troposphere delay model. Tidal

corrections, including solid Earth tides, ocean tides, and pole tides, were applied with the FES2004 model as reference. Daily position files are converted into an annual series of positions, in which we obtain the displacements that have occurred since the beginning of our time series. The linear trend of the position time series was estimated using the Hector software (Bos et al. 2013). The N, E, Up position time series for station GEDP are shown in Fig. 3 (left panel) and for station KRHN in Fig. 3 (right panel), respectively.

Figure 2. Field photographs (2023) showing the GNSS low-cost installations a) top panel: at the Department of Geology University of Patras (code name GEDP). View to the west b) bottom panel: at the building in village Krini (code name KRHN). View to the east).

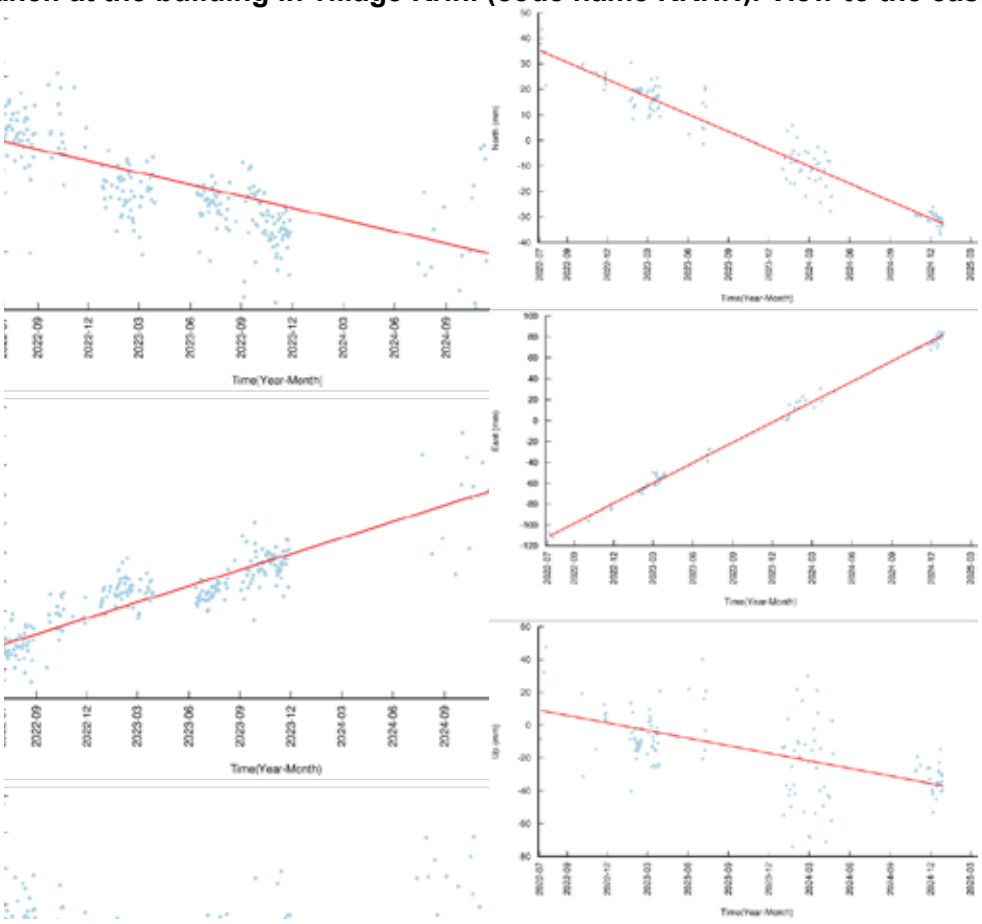

Figure 3. left) displacement vs time diagram of GNSS station GEDP (measurements 2022 – 2024), right) displacement vs time diagram of GNSS station KRHN (measurements 2022 – 2024). Three panels are shown from top to bottom (North, East, Up components). Missing data is due to telemetry gaps.

Results and Conclusions

The low-cost geodetic data were sampled at 1-s intervals, however, for data processing the RINEX files were resampled at 30-s. This is normal when daily coordinates are computed because the default PRIDE-AR configuration is to process 30-s RINEX files. The velocities for two sites (GEDP & KRHN; Fig. 3) were estimated on the IGS20 reference frame (Table 1). For comparison we provide the velocities of the permanent GNSS station PAT0 as reported by a) the Nevada geodetic laboratory (Blewitt et al. 2018; http://geodesy.unr.edu/NGLStationPages/stations/PAT0.sta) and b) by Briole et al (2021). PAT0 is located a few hundred metres to the SW of station GEDP, inside the U. Patras campus. The overall velocity trends between the two stations are in good agreement. We attribute the small differences in all three (3) velocity components to the short duration of the data for station GEDP (2 years) vs PAT0 (14 years) and to the different reference frames used (IGS20 for the low-cost data vs. ITRF14 for the permanent station data). The geology of the Patras University Campus (Palyvos et al. 2007) consists of Quaternary deposits, Plio-Pleistocene sedimentary rocks and unconsolidated soils. Characteristic lithologies include coastal sands, fluvial sands and gravels, Holocene deposits, weathering mantle of Plio-Pleistocene sediments, as well as alluvial and colluvial deposits.

A good agreement is also observed between the velocities of KRHN and KRIN (Table 1; see North and Up components). This station is located inside a slow-moving landslide on the eastern slope of mountain Panachaikon (Fig. 1), which is also monitored by InSAR (Tsironi et al. 2022). The Krini landslide is included in the landslide inventory of north Peloponnese (Koukis et al. 2009) and its formation/activation is attributed to a combination of lithology (Flysch), rainfall and proximity to the large active faults of the Gulf of Corinth. We note that station KRHN is co-located with a NOA meteorological station https://penteli.meteo.gr/stations/krini/ so that the GNSS displacement pattern may correlated with rainfall intensity and duration, especially during winter months. Such a correlation was already found for station KRIN (Tsironi et al. 2022).

Table 1. GNSS station velocities (East, North, Up) and their uncertainties. Values are in mm/yr. Station KRIN and PAT0[1] velocities are after Briole et al. (2021), PAT0 are after the Nevada Geodetic Laboratory (Blewitt et al. 2018).

Point	vEast	vE-unc	vNorth	vN-unc	vUp	vU-unc
KRHN	77.63	0.77	-27.17	0.58	-18.44	4.15
KRIN	111.60	1.30	-31.30	0.60	-19.70	1.30
GEDP	11.03	0.84	-4.03	0.74	-2.22	1.72

Abstract
Santorini is an active stratovolcano emplaced within a region of extensional faulting in South Cyclades, Greece. A two-month-long seismic crisis reaching Amorgos (NE of Santorini), together with GNSS measurements made before and during the crisis, provide insights into the relations between the volcano dynamics and its surroundings. The GNSS data show that Santorini inflated since the summer of 2024. We model this inflation with a magma source of ~ 8 × 10^6 m^3 located ~3.5 km under the north-central floor of the caldera, near the inflation centre of 2011-2012. The inflation phase ceased around 20 January 2025. Contemporaneously, the seismic activity, shifted to the north-east of Santorini near the islet Anydros. This phase lasted about ten days, before leading into a most intense phase that produced ground deformation measurable at large distances over the South Cyclades.

Introduction - Data and Methods
The Santorini volcanic Centre (Fig. 1; Thera, Thirasia, Kammeni etc.) is located within the Aegean micro-plate, which overrides the subducting Tethys lithosphere in a SSW direction. The subduction of Africa over the Cenozoic resulted in calc-alkaline volcanism which is presently distributed along the South Aegean Volcanic Arc, comprising volcanic islands of Quaternary age. The Santorini volcano has been activated during the historical era, producing important explosive eruptions (e.g., Parks et al. 2012). The seismicity of the broader area is related to the Quaternary NW-SE extensional regime, as well as to the volcanic processes (Bohnhoff et al., 2006; Dimitriadis et al., 2009; Briole et al. 2021). In 2011 - 2012, ground deformation was detected by use of GPS and Envisat satellite data confirmed that Santorini have risen as much as 14 cm between January 2011 and March 2012 (Papoutsis et al., 2013).
Since the summer of 2024 the Santorini volcanic Centre entered a new phase of unrest as GNSS data indicate the start of deformation onshore Thera, followed by an increase of the seismicity rates since January 2025. The seismic events were detected first inside the caldera, then spreading with intense activity towards the northeast until the islet Anydros, spanning an overall distance of 30 km, displaying a NE-SW orientation (Figure 1). The seismicity pattern indicates swarm characteristics with larger events not exceeding M_L = 5.3 according to the catalogue of the National Observatory of Athens (NOA, https://www.gein.noa.gr/services/cat.html). This intense phase generated significant activity in the Greek and international scientific community, which worked together to provide rapid scientific assessments of the phenomenon for the purposes of crisis management by the authorities. Figure 1 shows a map of the seismicity and the active faults (ticks on the downthrown block) from the NOAFAULTs database (Ganas, 2024).
In this extended abstract, we analyse the geodetic observations from eleven GNSS stations (Fig. 1): four located on Santorini, including two operating in 2011-2012 and used in previous works (e.g. Lagios et al., 2013), six located on the neighbouring islands, and one installed on 12 February on the islet of Anydros near the centre of the crisis. Figure 2 shows the time series of coordinates (East, North, Up) of GNSS station SANT calculated using the SCRS-PPP software. We also used InSAR time series analysis (ESA Copernicus satellite imagery) to monitor the ground deformation (Figure 3). A sequence of deformation phases appears in the time series of coordinates. There is initially a slow inflation starting during summer 2024, then a second phase that starts around January 20 and lasts until around February 3, followed by the most intense phase that ends on February 16. A fourth phase is underway at the time of writing this extended abstract. The second phase correlates in time with the seismicity shift to the north-east of Santorini. We model this inflation using the software WebObs (Beauducel et al. 2020; Briole et al. 2017) with a magma source of ~ 8 × 10^6 m^3 located ~3.5 km under the north-central floor of the caldera, near the inflation centre of 2011-2012. The inflation phase ceased around 20 January 2025.

Geodetic monitoring of the Methana volcano (central Greece) using campaign GNSS data: preliminary results

Ganas A.[1], Carnemolla F.[2], Karamitros, I.[1], Madonis N.[1], Georgakopoulos V.[1]
(1) National Observatory of Athens, Institute of Geodynamics, Athens, Greece aganas@noa.gr
(2) University of Catania, Department of Biological, Geological and Environmental Sciences, Catania, Italy

Abstract

This work presents the results from six (6) years of GNSS campaign observations on the Methana volcano, central Greece. The observations were collected by occupying five (5) benchmarks using dual frequency geodetic receivers during the period 2018 – 2024. The Methana data set was processed to obtain 24-h position solutions using the GIPSY-X software. For the first time, the displacement velocities of the NOA campaign GNSS stations have been estimated to provide additional geodynamic information in an active volcano area with two permanent stations.

Introduction

Methana peninsula is an active volcano, approximately 50 kilometres southwest of Athens (Central Greece, Fig. 1). The last onshore eruption took place in 230 BC in the Kameni Chora lava dome while the last offshore took place in 1700 AD north of Kameni Chora at a submarine volcano. Methana consists of mostly andesitic and dacitic rocks comprising lava flows and domes (Suesskoch et al. 1984). Volcanic domes are the most characteristic features of Methana, and are primarily andesitic to dacitic composition, are widely distributed across Methana and concentrated in the northern and central areas. They are marked by steep topographies and rugged terrains. Their widespread distribution points to multiple centers of volcanic activity over an extended geologic timeframe. A major increase in volcanic products has been determined at about 0.29–0.34 Ma (Pe-Piper and Piper, 2013), mostly on E–W faults, that was followed by minor andesite flows in the NW of the peninsula. In addition, the available magnetotelluric data (Tzanis et al. 2020) detected what appears to be a geothermal reservoir located underneath the central domes at a depth of approximately 1 km below sea level.

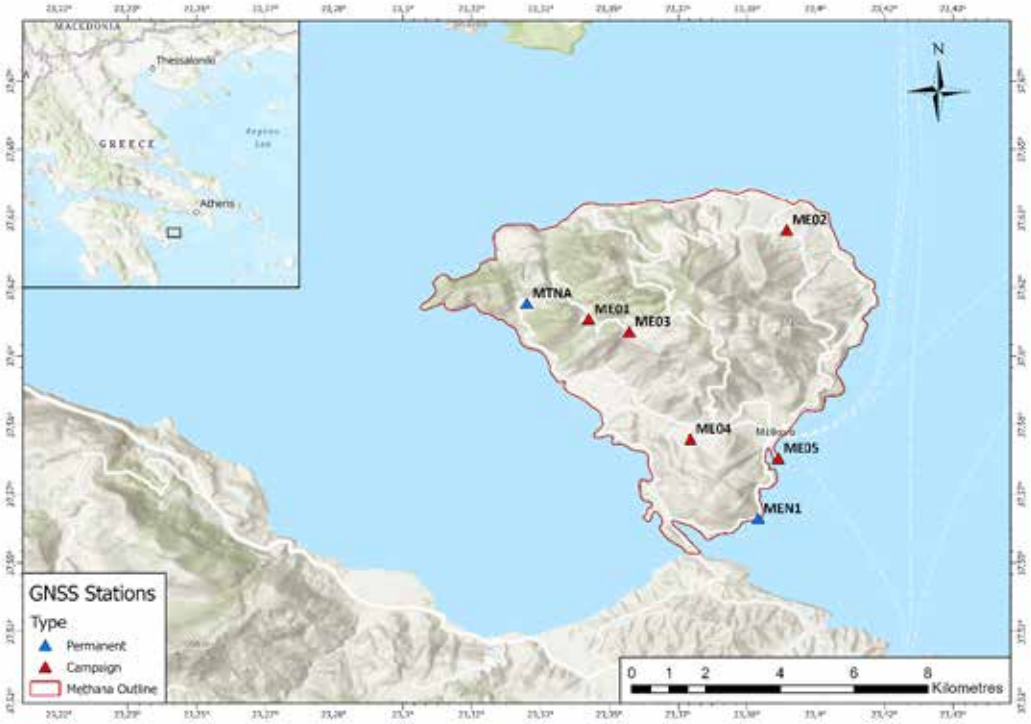

Figure 1. Relief map showing GNSS stations (solid triangles) in Methana peninsula. Inset map shows Methana location.

Data and Methods

In active volcanoes it is essential to sample the deformation field thoroughly in both time and space to adequately a) map the pattern of ground changes as well as the speed and direction of movement and b) constrain volcanic source models. Surface displacements, tilts, and dilatation are easily measurable with modern geodetic techniques, such as the Global Navigation Satellite System (GNSS; Ganas et al. 2016; Briole et al. 2021).

In 2018 NOA established a local network of five (5) geodetic benchmarks around Methana volcano (Table 1, Fig. 1). The local network was established on 20 and 21st October 2018 by Dr Athanassios Ganas and Mr. Ioannis Karamitros, MSc geologist. All points were selected on bedrock areas, either volcanic or limestone, so that we make sure our data products record either tectonic or volcanic motions. The benchmarks were drilled inside the bedrock and metallic bolts were placed (Fig. 2). Episodic measurements have been conducted on this network on a yearly basis since then by use of dual-frequency geodetic receivers. With a combination of repeated GNSS 3-D surveys and continuous monitoring by 1-D InSAR (i.e., Gatsios et al. 2020), it is now possible to measure ground deformation over broad areas in all sides of the volcano and with satisfactory temporal and spatial resolution.

Measurements have been conducted on the local network in 2018, 2019, 2020, 2023 and 2024 with dual-frequency GNSS receivers (LEICA GS08+). The data sampling interval was 10-s & 15 s, and the data were collected on an 8 h basis (2018 and 2019) and on 24-48 hrs (2020 onwards). The RINEX files contain 8 observables of GPS satellites: C1C L1C D1C S1C C2W L2W D2W S2W. All station records were complete. Each station has been analyzed independently using the Precise Point Positioning (PPP) method which computes coordinates of each station separately. The Methana data set was processed to obtain 24-h position solutions using the GIPSY-X software (version 2.2; Bertiger et al., 2020). The processing was performed using the final fiducial-free GPS orbits computed by the Jet Propulsion Laboratory. Ocean tidal loading was modeled using the FES2004 ocean tidal model (Lyard et al., 2006) and the wet zenith troposphere was modeled by the Global mapping Function (Boehm et al., 2006). Moreover, we used the antenna calibration file provided by the IGS and the second order ionospheric correction.

Table 1. List of the NOA local GNSS network locations around the Methana Volcano.

Point	Location	LONG	LAT	Occupation
ME01	Agia Sotira	23.345	37.609	2018, 2019, 2020, 2023, 2024a, 2024b

Results and Conclusions

The Methana volcano geodetic data were sampled at 10-s & 15-s intervals, however, for data processing the RINEX files were resampled at 30-s. This is normal when daily coordinates are computed because the default GIPSY-X configuration is to process 30-s RINEX files. In addition, the station velocities were computed directly by GIPSY-X. The software has a set of scripts (*NetSplit.py*, *staFit.py, staSeries.py* etc.) able to compute time series, to detect outliers and to fit seasonal terms and finally to calculate the East, North & Vertical (Up) velocities based on the position time series. The velocities were estimated on the IGS20 reference frame (Table 2).

Geodetic monitoring using campaign observations could present significant drawbacks compared to continuous GNSS stations, mainly in the lack of data continuity, lower precision, and inability to monitor short-term phenomena (transients) or provide real-time data. Nevertheless, the recorded data quality of the Methana campaigns is high (Fig. 3; results from the Anubis software, open-source version). The GNSS velocity vectors of all volcano stations with available data are plotted in Fig. 4 (red are campaign, blue are permanent). There is notable agreement in the North component of the velocity between the neighbouring stations ME05 – MEN1 and MTNA – ME01 but there is a deviation on the East component which is under investigation.

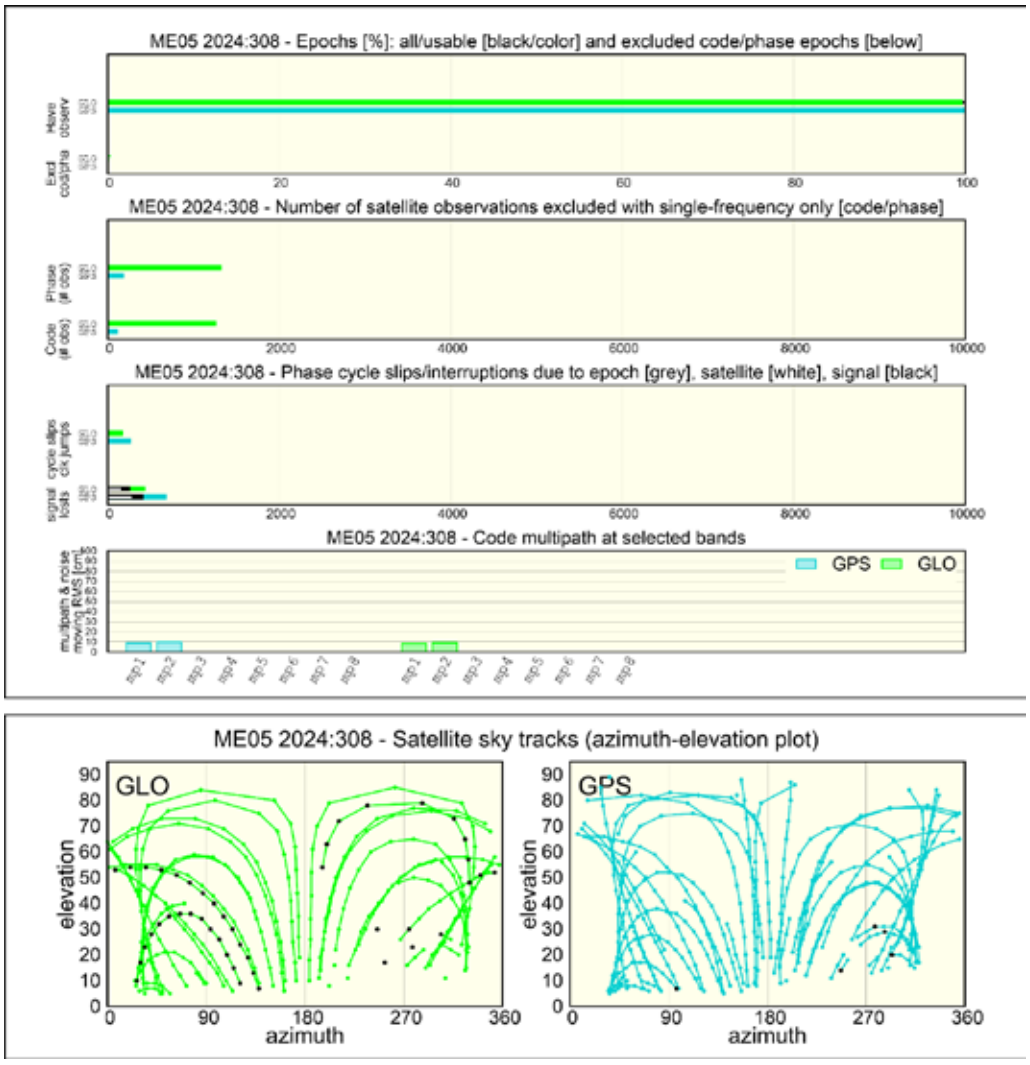

Figure 3. Data quality plot (GPS and GLONASS satellites) for station MEO5 (year 2024 DOY 308): upper panel) quality metrics for satellite observations, bottom panel) sky satellite tracks plot.

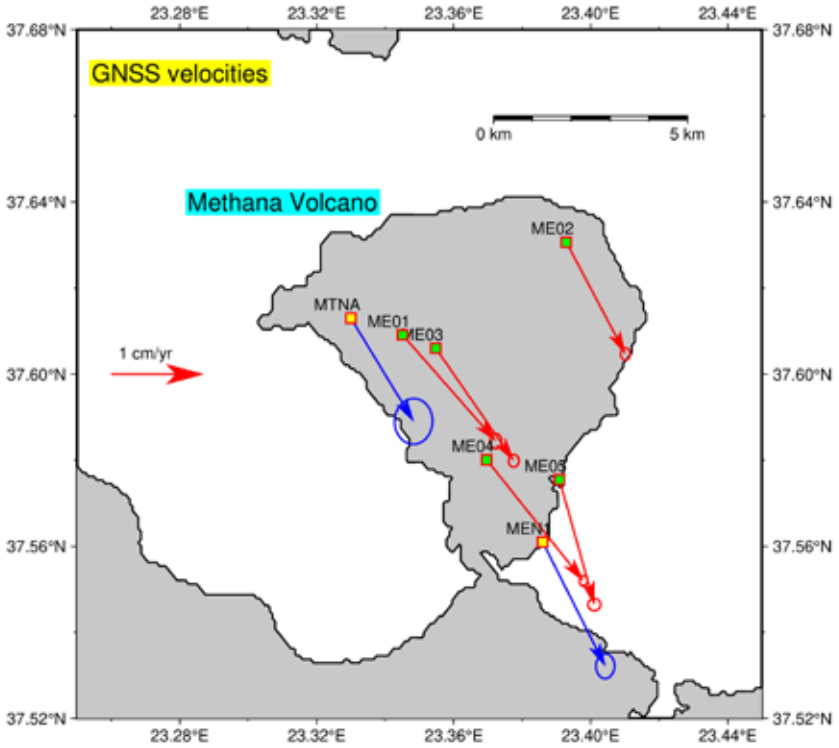

Figure 4. Map showing GNSS velocity vectors on the Methana volcano (campaign period 2018-2024). Blue vectors show permanent stations processed by NGL.

Table 2. GNSS station velocities (East, North, Up) and their uncertainties. The reference frame is IGS20 for the campaign stations and ITRF2014 for the permanent ones, respectively. Station MTHA velocities are provided by the EPOS Analysis Centre SGO-EPND and NTUA (Anastasiou and Papanikolaou pers. Commun.). NGL is the Nevada Geodetic Laboratory solution (Blewitt et al. 2018). Values are in mm/yr. Station MTHA, MENA and MEN1 are the same site with different code names. MTNA is an EPOS GNSS stations (EPOS, 2025).

Abstract
In this short paper, we update on the findings of a joint geodetic and seismological investigation of Milos (western Cyclades islands, Greece) since 2022 when we published out first short report in BGSG. The integrated monitoring includes the use of geodetic data (InSAR and GNSS) and the continuous recordings of a 24/7/365 local seismic network established by NOA in 2021 and upgraded in 2023. Our objective was to investigate the ground deformation and seismicity patterns and detect activity along fault zones of the island. We present evidence for on-going activity at 5-9 km depths along a NW-SE fault crossing Milos.

Introduction
The South Aegean Volcanic Arc (Kassaras et al. 2020), and in particular the Milos Island in western Cyclades offers a high potential for deep geothermal energy due to the well-known geothermal anomaly (Fytikas, 1977). Milos is a dormant stratovolcano with the most recent volcanic activity recorded about 380 ka-90 ka ago (Fytikas et al., 1986). The oldest K-Ar date on the lowest volcanic outcrops in the SW coast of Milos, gave an age of 3.5 Ma. Basement rocks occur in the SW, S and SE parts of the island. The seismicity around Milos is both shallow (4-15 km; Ganas et al. 2022) and intermediate depth (70-90 km), however, until 2021no clear patterns had emerged due to the lack of sufficient seismic stations. Several swarms have been reported in the literature, linking seismicity and ascent of magmatic fluids but without strong evidence (Sachpazi and Hirn, 1991; Baltatzis et al., 2001).

Figure 1. Relief map showing seismic stations (blue marks) and GNSS stations (red marks) in Milos Island. Inset map shows location of Milos in the south Aegean Sea.

Based on detailed chemical and isotopic analyses Wu et al. (2011) identified three types of hydrothermal vent fluids at Milos: cave vents, submarine brine vents and seawater-like vents. Using this distinction of measured samples, they are suggesting a conceptual geological model that consists of a shallow reservoir (<248°C) which is separated from a deep reservoir (>313°C) where subcritical phase separation happens. This work presents the monitoring strategy and

the preliminary results. We installed a network of campaign & continuous GNSS (see Fig. 1) and INSAR Copernicus data are available in continuous processing (yearly rounds). Our aim is to monitor local surface displacements before and finally during the production states of the geothermal plants. GNSS and INSAR are two spatial geodetic methods with millimeter accuracy. GNSS provides information about the absolute 3D displacement at some point location while InSAR gives high spatial information (100-m pixel size) of relative displacement.

Data and Methods

During May 2021 and May 2023 NOA installed a local seismic network of seven (7) stations in the SE and East Milos (Fig. 1; blue dots). The sensors are GEOBIT C100 and were placed inside shallow (2-m) boreholes. Data telemetry is real-time (at 100 sps) using a commercial GSM network. The seismic network of Milos had a fair response to the main demands such as the increase in detectability of the local microearthquakes, as well as the characterization of seismic properties of the area such as the origin of the recorded noise (natural, anthropogenic). The earthquake magnitudes range from 0.4 to 3.4 on the local magnitude (M_L) scale. The recorded activity is mainly concentrated inside the Gulf of Adamas and in Southern Milos, along the NW-SE striking fault (Ganas et al. 2022), which might be associated with the March 1992 earthquake sequence (Delibasis and Drakopoulos, 1993; Papanikolaou et al. 1993). In 2021 NOA established a local network of three (3) geodetic benchmarks at SE Milos (Fig. 1). The local network was established on 25th September 2021 by Dr Athanassios Ganas and Mr. Ioannis Karamitros, MSc geologist. All sites were selected in bedrock areas, to ensure that our receivers record either tectonic or volcanic motions. The benchmarks were drilled inside the bedrock and metallic bolts were placed. Episodic measurements have been conducted on this network on a yearly basis since then by use of dual-frequency geodetic receivers. In May 2023 NOA installed a low-cost GNSS station in western Milos (Fig. 1; code MILN) following the procedures established by the project PROION (Ganas et al. 2024). This station started recording 1-s GNSS observations on 12 November 2024. With a combination of repeated GNSS 3-D surveys and continuous monitoring by 1-D InSAR (i.e., Tsironi et al. 2024), it will be possible to measure ground deformation over broad areas in all sides of the geothermal site of Milos, and with satisfactory temporal and spatial resolution.

In terms of SAR geodetic data (1-D displacement time series) we used archived SAR Copernicus imagery (C-band) (Fig. 2). For the InSAR time series analysis we applied the SBAS algorithm that is part of LiCSBAS, an open-source package (Morishita et al., 2020). The available interferograms from the LiCSAR platform include 828 (ascending orbit) and 771 (descending orbit, respectively. During the phase unwrapping, decorrelated areas in the interferograms are masked where the phase noise coherence is < 0.2. Wrapped and unwrapped interferograms were geocoded with a pixel spacing of 0.001 degree (~100 m) and converted to the GeoTIFF format. The accuracy of this technique is about 2-3 mm/yr (Morishita et al. 2020; Tsironi et al. 2024).

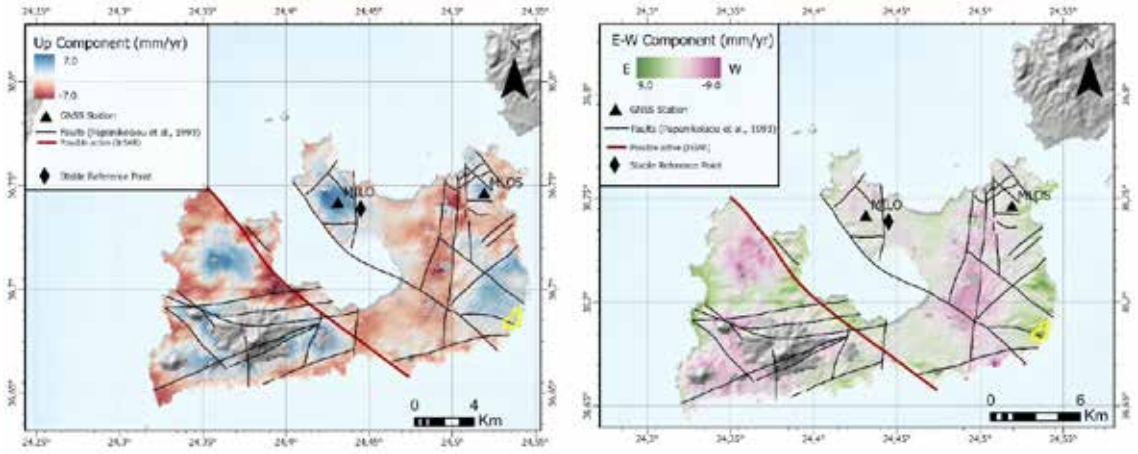

Figure 2. left panel) Up-Down ground motion map in units mm/yr, right panel) East-West velocity map based on InSAR data. Black lines indicate faults after Papanikolaou et al. (1993). The red line is an active fault based on InSAR. Diamond symbol indicates the reference point used in InSAR processing. MILO & MLOS are GNSS stations on the island. Grey areas indicate no data.

The InSAR data processing (period 2016-2024) resulted in the production of Up-Down and E-W velocity maps (Fig. 2; left is vertical and right is E-W motion) which indicates that there is divergent ground motion (opening) across the NW-SE fault onshore Milos (see red line in Fig. 2). The velocity difference across the fault reaches 1 cm/yr, that is well above the error. Moreover, the InSAR data provide evidence that this fault is active, and its surface trace can match an east-dipping fault plane where microseismicity is present (Fig. 3). A second area of interest is the mapped subsidence along the Zafeiria depression in east Milos (reaching 7 mm/yr.; Fig. 2 left) which abuts a N-S normal fault (west-dipping; Papanikolaou et al. 1993). The newly-installed GNSS station MILN will provide additional constraints to the InSAR results when its secular velocity is estimated with confidence (Fig. 3; after a period of 3-4 years; Briole et al. 2021). In western Milos there is no other geodetic point of reference while due to the rugged relief the atmospheric contribution to the InSAR signal may be considerable.

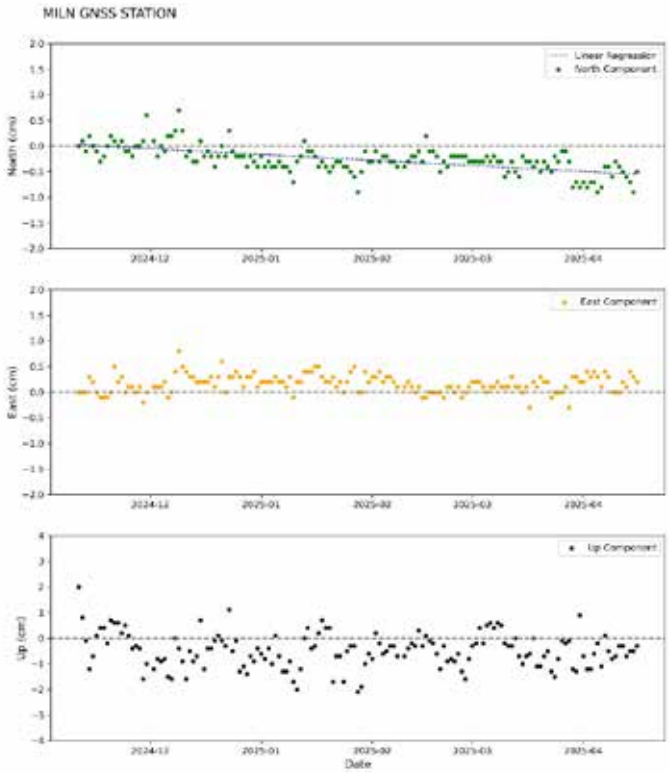

Figure 3. Graphs showing position time series of the low-cost GNSS station MILN (Agia Marina, western Milos). The daily positions were estimated with the on-line CSRS-PPP processing tool from the 30-s observations (code and phase) collected by the u-blox dual-frequency receiver and geodetic antenna. The panels show time series in North, East, Up components, respectively. Units in cm.

Results and Conclusions

During 2021-2024 the local seismic network recorded hundreds of microearthquakes in the broader Milos area, the majority of which occurred at shallow depths (< 10 km; Fig. 4). In order to improve the locations of hypocenters of the initial catalogue, which consists of 109 manually analyzed events and 589 additional detections made with the template matching technique (Chamberlain et al., 2018), we applied double-difference relocation with the HypoDD code (Waldhauser, 2001). Many small earthquakes are concentrated in the middle of the island (Gulf of Adamas) in tight spatial clusters, due to their strong waveform correlation. The clusters are aligned in a NW-SE orientation, following the strike of the main fault line that crosses Milos Island to the west of the epicenters (Papanikolaou et al. 1993). The overall length of

the seismicity belt is 8 km and it is located on the eastern side of the Gulf of Adamas and in the airport area. Fig. 4 shows a seismicity map, where different colours / sizes represent different depths / magnitudes. The map indicates that the clustered seismicity beneath the Gulf of Adamas is located at focal depths of 6±1 km. Assuming a dip of 60° towards NE for the main fault that bounds the western shores of the Gulf (Fig. 2), its plane would roughly cross the hypocenters. It should be noted, however, that for a more precise determination of the absolute hypocentral depths, a local velocity model is required. This could become possible with the accumulation of more data from the local network in the future.

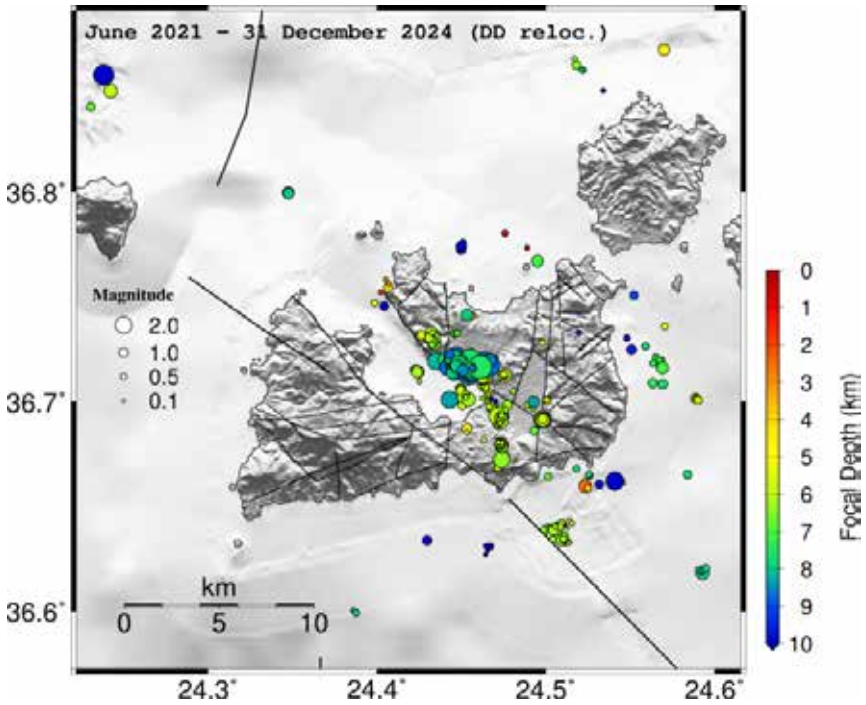

Figure 4. Seismicity map of Milos Island (period June 2021-2024) after relocation using the double-difference method (HypoDD).

Abstract

In this short paper, we update on the development of the NOAFAULTs geodatabase since 2013. Our objective was to create a nation-scale database of active faults in Greece and its adjacent regions, supporting the seismicity monitoring at the National Observatory of Athens (NOA) in tandem with an associated web-based query system. In the latest version V6.0 we added new data and fault traces, corrected for missing data, reviewed overlapping fault traces, added new thematic layers, and studied the kinematic and geometrical relations from the parametric data. NOAFAULTs can be used to investigate the ground deformation and seismicity patterns in Greece and surrounding areas and to detect new activity along fault zones. The Greek government, research institutions, and companies have widely used the active faults data from the previous versions of the database.

Introduction – Data and Methods

The NOAFAULTs geospatial database of active faults of Greece was first published in 2013 at BGSG (versions 1.0 & 1.1; Ganas et al. 2013; http://dx.doi.org/10.12681/bgsg.11079). Version 2.1 was published in 2018; Ganas et al. 2018); Version 3.0 was published in 2020 http://doi.org/10.5281/zenodo.4304613; Version 4.0 was published in 2022 https://zenodo.org/record/6326260; Version 5.0 in 2023 (Ganas et al. 2023; https://doi.org/10.5281/zenodo.8075517) followed by Version 6.0 in 2024 (https://doi.org/10.5281/zenodo.13168947).

The NOAFAULTs dataset was created towards compiling a digital database of fault traces, geometry and additional attributes (kinematics, slip rate, associated earthquakes etc.) following the Adria faults community effort in 2007 (Piccardi et al 2007). It has been constructed from published fault maps (that are contained in individual scientific papers) in peer-reviewed journals since 1972. The number of papers that have contributed with fault data in version 6.0 is 145. The authors have modified the fault trace in cases where the original map scale was too coarse, and the topography data (DEM) indicated a large distance between the digitized fault and the trace of the mountain front (in case of normal faults). No unpublished data are included in the database apart from the PhD theses of Caputo (1990), Ganas (1997), Valkaniotis (2009), Zervopoulou (2010) and the Kineta normal fault (fault code GR 3261) that was recently mapped by AG and it is part of a larger study under preparation. Selected fault data were also digitized from the neotectonic fault map series of Greece (Lekkas, 1995, 1996; Mountrakis et al. 1996). Data from neighbouring countries (Albania, North Macedonia, Turkey; e.g., Emre et al. 2018) were also incorporated as active fault systems in the Aegean crosscut national boundaries. The standard commercial software ARCGIS has been used to design and populate the database. The fault layer was produced at NOA by on-screen digitization of fault traces at the original map-scale (as drawn by the reference paper it was taken from) and is available through our web portal application https://arcg.is/04Haer supported by ESRI. The web-content of the database incorporates 27 thematic layers such historical seismicity, seismic and geodetic networks, isodepths of the subducted African slab, geodetic velocities (Briole et al. 2021) and many others. The capability to overlay geospatial data with near real-time earthquake epicentres, achieves an optimal monitoring of areas of high interest.

In version 6.0 (see Fig. 1), the number of 3088 active faults are included. 92% of the active faults are normal faults, 4% are strike-slip faults and only 3% represent the reverse faults. Also, reliable data on slip rates is available for 160 faults. Limited data on instrumental and historical seismicity are linked to 175 and 130 active faults, respectively. Data on fault lengths, slip per event etc. when available may be used to extract kinematic relations such as those pioneered by Wells and Coppersmith (1994).

In addition, a) surface-rupturing geological data and b) data on the proximity of epicentres of strong seismic events to the traces of active faults allows the identification of 173 rupturing faults (seismic faults; both exposed and blind) that are included in version 6.0. The NOAFAULTs database shows that nearly 52% of its active faults imply high seismic risk level in the broader area of Greece. These active faults can generate surface faulting or strong ground motions that can cause serious damage to buildings and infrastructures and therefore represent a significant hazard, particularly in the densely populated and industrialized areas of Greece. Since 2022 NOAFAULTs has contributed to the EFSM20 database (https://www.seismofaults.eu/efsm20; Basili et al. 2022).

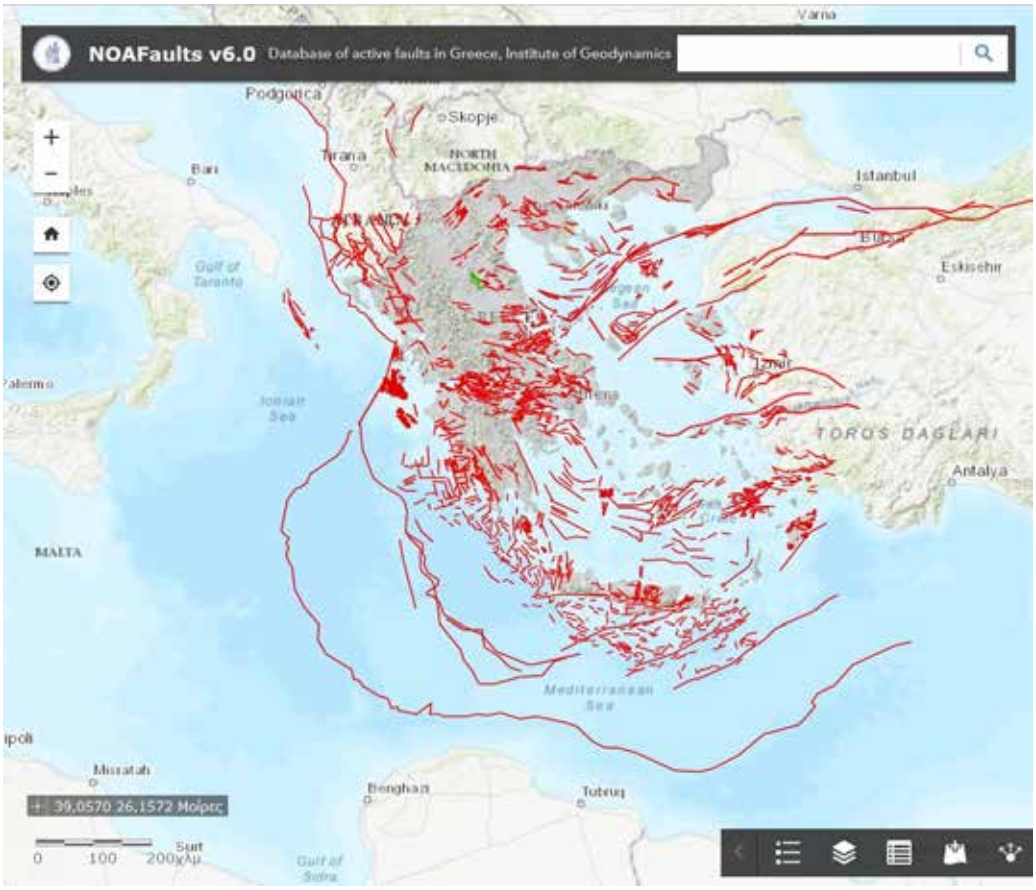

Figure 1. Relef map showing the NOAFAULTs V6.0 fault traces (red lines) in the broader Aegean area.

Results and Conclusions

Active faults serve as sources of strong and destructive earthquakes. Studies and investigations of active faults are necessary for anti-seismic protection and planning and for disaster prevention (Piccardi et al 2007; Emre et al. 2018; Maldonaldo et al. 2021). This study presents the updated nation-scale database of active faults in Greece and its adjacent regions, in tandem with an associated web-based query system. This database includes the active faults data included in 145 peer-reviewed scientific publications during the period 1972-2024. The data integration originates from regional-scale studies and surveys conducted at reference scales from 1:5.000 to 1:500.000. The information collected from these studies and surveys encompasses field mapping, geophysical profiles, measurements of offset horizons and landforms, C^{14} and cosmogenic isotope dating, as well as geometric and kinematic parameters of both exposed and blind faults, earthquake sequences and their characteristics. These data have been acquired and analyzed utilizing a uniform technical standard framework and reviewed by NOA experts. Our system hosts this database accessible through a Web Geographic Information System (GIS) application, enabling browsing, querying, and downloading functionalities via a web browser. Users can incorporate map layers and obtain fault data in OGC-compliant GIS software for further analysis through these services. The Greek government, research institutions, and companies have widely used the active faults data from the previous versions of the database.

Future Objectives

Our aim for the next version of the database (V7.0) is to review the existing data so that the fault traces are digitized in such a way that every user can correctly represent the kinematics of the faults, as well as to correct existing ambiguities. Another important step into the development of the NOAFAULTs is the application of a semi-automatic procedure towards filling out the attribute fields for each new digitized fault trace that will be considered for inclusion into the database.

(1) University of the Aegean / Department of Geography, Mytilene, Greece, geoha22003@aegean.gr

Introduction / Background

Forests cover 39% of the EU's land area. In recent years, large forest fires have repeatedly affected Europe, in particular the Mediterranean countries (EEA, 2024). Particularly, the year 2023 has recorded the highest temperatures in the history of humanity. The year 2023 was a tipping point for the wildfires in Greece (first in EU countries with 42% of the total burnt area), which suffered the largest wildfire ever recorded in Europe. Following the destructive wildfires on the island of Rhodes in July, dozens of new wildfire ignitions in August across the country have been recorded. The most severe one was located in its northeast region, including the Dadia-Lefkimi-Soufli Forest National Park. European Forest Fire Information System (EFFIS) estimates that over 94,000 hectares of natural land were burnt in this single wildfire. Over 45,000 hectares of forests went into flames in Greece, and 65% of areas burnt were within the country's biodiversity reservoir of Natura 2000 (ESOTC, 2023). Fire danger is influenced by weather in the short term, and by climate when considering longer time intervals. In this work, the emphasis is on observed changes of weather and climate patterns on regional scale, as well as trend assessment in climate indices. The extremes considered include temperature extremes and precipitation, as well as compound events. Climate strongly influences fire activity, and the sequence of multiple weather and climate extremes, such as co-occurrence of hot and dry events, leads to more severe fires. Positive temperature, negative humidity and zonal wind anomalies correlate with large fires (Smith et al., 2020). According to the recent report of the United Nations Economic Commission for Europe's International Cooperative Program on Assessment and Monitoring of the Effects of Atmospheric Pollution on Forests (ICP Forests, 2023), it was identified that the outbreaks of forest mortality and their occurrence is partly explained by the simultaneous occurrence of extreme heat and drought events. Weather and climate play an important role in fire occurrence. Therefore, this study aims to provide local-scale understandings of the climatological characteristics of temperature and total precipitation in two Protected Areas in Greece, the National Park of Dadia ("Dadia") and the nature reserve Vounokalathos in Southern Rhodes ("Rhodes"). Therefore, the object of this study is the detailed climatological analysis of these two forest areas in Greece that are among the Protected Areas, which were most affected by the major fires of 2023. The analysis in this study is divided into three parts. The first is the climatological analysis based on key meteorological indicators of Climate Change. Using observed data in the regions of interest from 1981 to 2023, this study characterizes changes observed over the last 43 years for two key climatic parameters (e.g. mean, maximum and minimum air temperature at 2m and precipitation), at the annual and seasonal scales. Second, the analysis of meteorological observations in each site of interest was carried out through calculations of the deviations (commonly called anomalies) of average min/max/mean temperature and total precipitation from the average/total represented by the 30-year normals (1991-2020) according to the standards and requirements of the World Meteorological Organization (WMO). Third, assessment of the co-existence of positive temperature anomalies and negative precipitation anomalies (warm/dry) during the same fire season for the observed period (1981-2023) at each site were conducted. The detection of Dry-Warm each year's fire season is based on the pre-calculated temperature/precipitation anomalies from the 1991-2020 average. We showed that, in "Dadia" the fire season of 2023, with the greatest ecological disaster ever recorded in the region, is described as Dry-Warm, while for "Rhodes" Dry-Warm detected in 2020 and 2021 fire seasons. The results suggest a general trend towards higher temperatures. The statistically significant climatic indices that, according to scientific literature have been linked to both the risk of severe forest fires, stress and tree mortality in forest ecosystems (Carnicer et al. 2022; Guion, et al. 2022; Jones et al. 2022), are defined and examined in this study. Trends in extreme temperature indices were statistically more significant than trends in extreme precipitation indices in both sites of interest.

Objectives

The primary objective of this study is to analyze the trends and variability of extreme weather indices in the Dadia-Lefkimi-Soufli Forest National Park ("Dadia") and the nature reserve Vounokalathos in Southern Rhodes ("Rhodes") study sites of Greece. A secondary objective is to determine whether climate change has caused temporal changes in meteorological elements in the regions of interest. Detecting changes in the temporal patterns of temperature and precipitation is a prerequisite for developing effective adaptation options and strategies for the future. By examining patterns and changes in the local climate system, the study provides new insights into the climate-induced impacts on wildfire activity, as they put into perspective the underlying combinations of weather and climate conditions that are conducive to wildfires based on daily climate data for the period 1981–2023.

Methods

To understand and evaluate the meteorological dynamics, precipitation patterns, and other fundamental climatic elements shaping the environmental landscapes of the study sites, this study employs trend and statistical analysis methods. The methodology consists of three main parts: the selection of the geographical sites in which the indices would be assessed; the collection of daily meteorological data to calculate averages for each parameter at monthly, seasonal and annual timescales, as well as long term averages for the climatological reference period of 1991-2020 (climatological analysis). Additionally, 27 climate indices are calculated on an annual timescale for the observed period (1981-2023) at each site, and finally the performance (existence, magnitude, and statistical significance at 95% level of confidence of potential trends) of the indices is analyzed using Kendall's Tau correlation coefficient and Theil-Sen slope estimator methods (trend analysis). Figure 1 presents a time series graph that shows the annual values of all 27 indices for the observation period and linear regression tests of climate indices. Linear decadal trends are represented by solid red lines, while dashed lines (blue color) represent 10-year smoothed moving average. The study sites are located in two forest areas in Greece that were among the Protected Areas, which were most affected by the major fires of 2023, namely the National Park of Dadia ("Dadia") and the nature reserve Vounokalathos in Southern Rhodes ("Rhodes"). These two sites were selected due to their significant biodiversity that is threatened by the negative impacts associated with the increased, uncontrolled large-scale forest fires over the past decade (Spanos et al., 2021). The climatological analysis is based on long-term observational datasets of meteorological parameters, including temperature, precipitation, wind speed, wind direction and relative air humidity. Meteorological data used in this analysis were obtained from the National Aeronautics and Space Administration Prediction of Worldwide Energy Resources (NASA POWER) satellite-based weather system as a single-point dataset. The analysis also used fire point records from EFFIS. The extreme indices were calculated by using the 'ClimInd' package (Reig-Gracia et al., 2019). Climate indices integrate changes in the frequency, intensity and duration of key extreme climate indicators, as defined by the Expert Team on Climate Change Detection and Indices (ETCCDI). For the calculation of indices, daily values of mean temperature (TM), maximum temperature (TX), minimum temperature (TN), and daily precipitation (RR) are required. Specifically, a total of 27 climate extreme indices were estimated for each location, 15 temperature and 8 precipitation indices. Table 1 provides a description of climate indices. In the second part of the detailed climate analysis, we consider seasonal statistics to analyze "hot and dry" compound extremes focus on precipitation deficits and high temperatures over a common period, in this case fire seasons per year for the observed period (1981-2023) at each site. The condition for characterizing a fire season of a given year as "Dry-Warm" is when the deviation of total precipitation is <10% and the deviation of maximum temperature >0.5 °C. We calculated the anomalies of precipitation and maximum temperature in order to produce the Figure 2 with "Dry-Warm" anomalies located in quadrant I (top-right) and those with wet-cold in quadrant III (bottom-left). It should be noted that for easier interpretation, in the case of the fire season's total precipitation parameter the deviations are expressed as a percentage, with the mean set at 0% instead of 100% (Royé, 2020).

Table 1. Definitions and units of climate air temperature and precipitation indices used in this study.

Indices	Definitions	Units
TXx / TNx	Annual maximum value of daily TX / TN (the hottest days / warmest night of the year)	°C
TX10p / TN10p	Percentage of days when TX < 10th / TN < 10th percentile (cold days / nights) of the year	% days
TN90p	Percentage of days when TN > 90th percentile (warm nights) of the year	% days
XTG / BIO10	Annual max of TM / Mean Temperature of Warmest Quarter of the year	°C
DD17	Difference days above/below Tx17 (days TX > 17 °C)-(days TX < 17 °C)	days
TR	Annual count of Tropical Nights of the year (days TN > 20 °C)	days
WSDI	Annual count of days with at least 6 consecutive days when TX > 90th percentile	days
GD4	Growing degree days. Sum of degree days of TG over 4 °C	degree days
HD17	Heating degree days. Accumulated degree when TG is below 17 °C	degree days
HI	Heat Index. Combines TM and relative humidity to determine equivalent temperature	degree days
STX32	Sums TX32. Sum of degree days when TX ≥ 32 °C on the interval June-August.	degree days
TA_O / TM_S	Growing season (April to October / May to September) mean TM of the hear	degree days
WKI	Winkler index Sum of degree days > 10 °C of TG (April 1 - October 31)	degree days
BIO18	Precipitation of Warmest Quarter of the year	mm
GSR	Growing season (April to October) total precipitation	mm
RTI / PRCPTOT	Annual total precipitation / Annual total precipitation on wet days (rainfall ≥ 1 mm)	mm
R95tot	Annual rainfall that exceeded the 95th percentile in the period from 1981 to 2023	mm
D95p	Very wet days of the year. Days with precipitation > 95th percentile.	days
DR1mm / DR3mm	Wet days 1 / 3mm. Total number of wet days ≥ 1 / ≥ 3mm of the year	days
R10mm	Annual count of days with rainfall ≥ 10 mm	days
SDII	Simple Daily Intensity Index. Mean precipitation on wet days, with rainfall ≥ 1 mm for one year	mm/day

Results

The results of the climatological analysis indicated that 2023 is ranked as the warmest for both sites of interest, according to historical mean temperature data for the period 1981-2023. On the other hand, annual precipitation shows a mixed signal. According to the analysis of the precipitation anomalies (deviations from the long-term mean 1991-2020), it shows that 2008 marked the driest year for "Dadia" and 1990 for "Rhodes" in more than 40 years. Specifically, the calculated annual precipitation deviations for both sites for the period of 1981-2023 showed -44.9% of the mean annual precipitation (569.6 mm) for "Dadia" and -47.8% of the mean annual precipitation (626.2 mm) for "Rhodes" according to the 1991–2020 climatology. The deviations of 2023 average annual mean temperature from the 1991-2020 mean, were 1.9ºC for "Dadia" and 1.0ºC for "Rhodes" above reference mean. Analysis of the climate indices revealed a general warming trend in both sites, which is consistent with global warming (Carnicer et al., 2022). Table 2 presents the decadal trends for the two Greek sites during the period 1981–2023, with bold numbers indicating statistically significant slopes, $p < 0.05$). Increases in the TNx index (see Table 2 and associated plots) indicate a rising potential for Tropical Nights, consistent with global trends for this index (Dunn et al., 2020). Table 2 indicates that computed index related to Tropical Nights (TN > 20 °C) has positive decadal trends for both sites. Decadal increasing trend in Tropical Nights (TR) is more prominent in "Dadia", statistically significant decadal trend amounting to 10.3 days per decade respectively; TR has a statistically significant positive trend at "Rhodes", amounting to 5.6 days per decade (Table 2). The increasing intensity of Tropical Nights is clearly evident in "Dadia", where the value of tropical nights recorded in 1993 increased almost six times, from 10 in 1993 to 56 in 2023, the highest value observed during the 1981–2023 period (Figure 1). In contrast, "Rhodes" increased at a rate of about half of (5.6 tropical nights per decade) the northern "Dadia" (Figure 1). The TXX index observed at "Dadia" has been around 40°C for 12 out of the 43 years (1981-2023), reaching 43.3°C in 2007 (maximum) and 41.4°C in 2023. In "Rhodes", the maximum and minimum value of TXX is 36.6°C (2021) and 36.4°C (1989) respectively. The northern site (latitude > 40 ◦N) have statistically significant linear increasing decadal trends than the site in the southern Greece (latitude < 40 ◦N) in the annual maximum values of TX (TXx), as displayed in Figure 1. The TXx has statistically significant positive trend of 0.6◦C at "Dadia", when there was no statistically significant trend at "Rhodes" (Table 2). Dry conditions are also observed by precipitation indicators, where in 2023 the duration of precipitation during the germination period of the plant (GSR) decreased by 17% compared to 2022, while extreme precipitation indicators increased, for example the DR95tot, which increased by 26% in one year, and the D95p, which increased by 5 days in total since 2022. Trends in GSR of statistically significant increasing values are indicative, with a value of +24.2 per decade at "Dadia" (Table 2). For the warm season duration index (WSDI), both sites showed significantly increasing trends. Strong decreasing trends in cold days (TX10p) and cold nights (TN10p) indices were found at both sites. In general, a weak trend towards drier conditions is observed in "Rhodes", which is in good agreement with previous studies on climate trends in the Mediterranean region and Greece over the recent decades (Kostopoulou et al., 2005; Giannakopoulos et al.,2011; Kostopoulou et al., 2012; Lelieveld et al., 2014; Kostopoulou et al., 2023). A statistically significant upward trend was identified for the extreme climate index STX32 throughout the study period only at "Dadia". Additionally, the annual mean temperature index for the April-October growing season (TA_O) showed a positive trend of 0.3°C/decade in "Rhodes" and 0.4°C/decade in "Dadia". Likewise, the annual mean temperature index for the May-September season (TM_S) showed a significant positive trend of 0.5°C/decade in "Dadia", followed by "Rhodes" with a trend of 0.3°C/decade (Table 2). Figure 1 reveals that the magnitude of heat extremes increased significantly, while cold extremes decreased at a faster rate. Precipitation changes varied between the sites (Figure 1). Results showed a significant increase in temperature and a decrease in precipitation only in "Rhodes" site, indicating a warming and drying trend due to climate change. High rate of change in both regions was observed in the DD17, with a statistically significant positive trend of 12 (20.4) days per decade at "Dadia" ("Rhodes"), as displayed in Table 2.

Table 2. Decadal trends in annual climate indices for 2 Greek sites during the period 1981–2023 (numbers in bold indicate statistically significant slopes, $p < 0.05$).

Indices	«Dadia»	«Rhodes»	Indices	«Dadia»	«Rhodes»

A temperature of 18ºC is generally used as the baseline for calculating the scores, as reported in the study by Karagiannidis et al. (2024). Therefore, the findings highlighting a warming trend of the regions under study are particularly concerning. Evergreen oaks can recover better after dry periods than deciduous oaks, as they continue their growth after the summer drought. Low soil water availability in spring is more detrimental to deciduous oak growth (Valeriano et al., 2021). According to the results, a decreasing trend in the HD17 index was found in both study areas. In “Dadia” forest, degree days <17°C are decreasing at a rate of about 128 per decade, while in the “Rhodes” forest, the decrease is quite slower, at about 44 degree days per decade (Table 2). In parallel, the same findings of decreasing trend, were found by Doshi et al. (2023), for the European continent. Conversely, all other degree day indices showed an opposite trend, with the largest increase in the rate of change found in growing degree days (GD4) index (sum of degree days of TM over 4 °C), which increased by 175.5 (125.3) degree days per decade at “Dadia” (“Rhodes”), as shown in Table 2. These findings again agree with those of Doshi et al. (2023), where the GD4 index showed the highest upward trend across all months in Europe. The trend patterns of some extreme precipitation climate indices show geographic variation, large and expected variability, in contrast to the remarkable consistency of extreme temperature climate indices across both study locations. All precipitation indices exhibited increasing trends in the “Dadia” region in the northern parts of the country, while some decreasing trends were observed at “Rhodes” in the southernmost part of the country (Figure 1). Moreover, at the southernmost site of “Rhodes”, the rate of decrease in the total annual precipitation (RTI) reaches 31.5mm/decade (Figures 1). These results for the locations of interest are in general agreement with global findings (IPCC, 2007, 2023; Boegelsack et al., 2018).

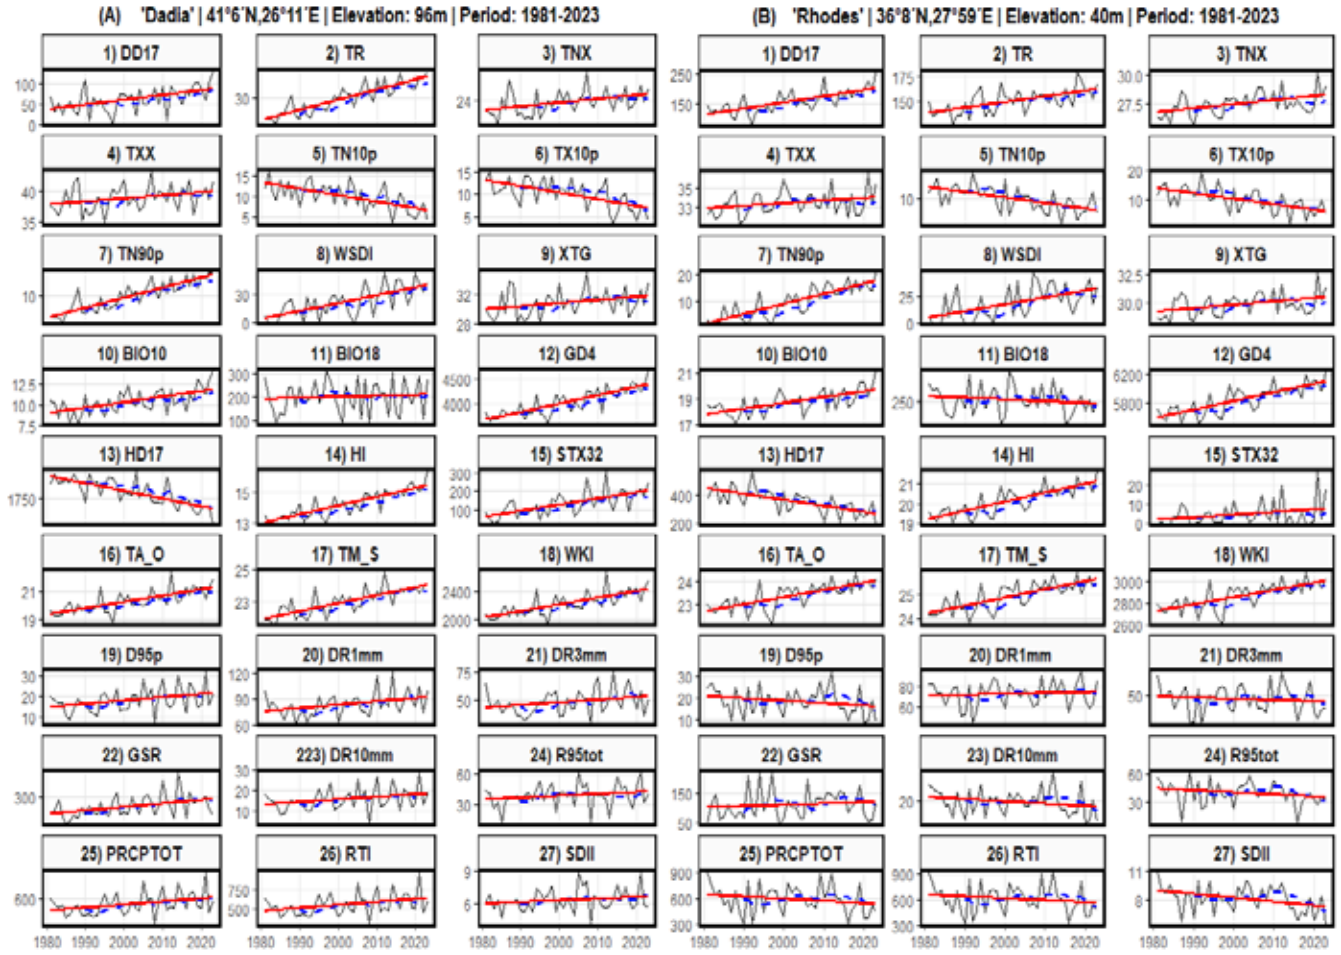

Figure 1: The annual trend magnitudes of all climate indices in (A) “Dadia” and (B) in “Rhodes” (1981-2023).

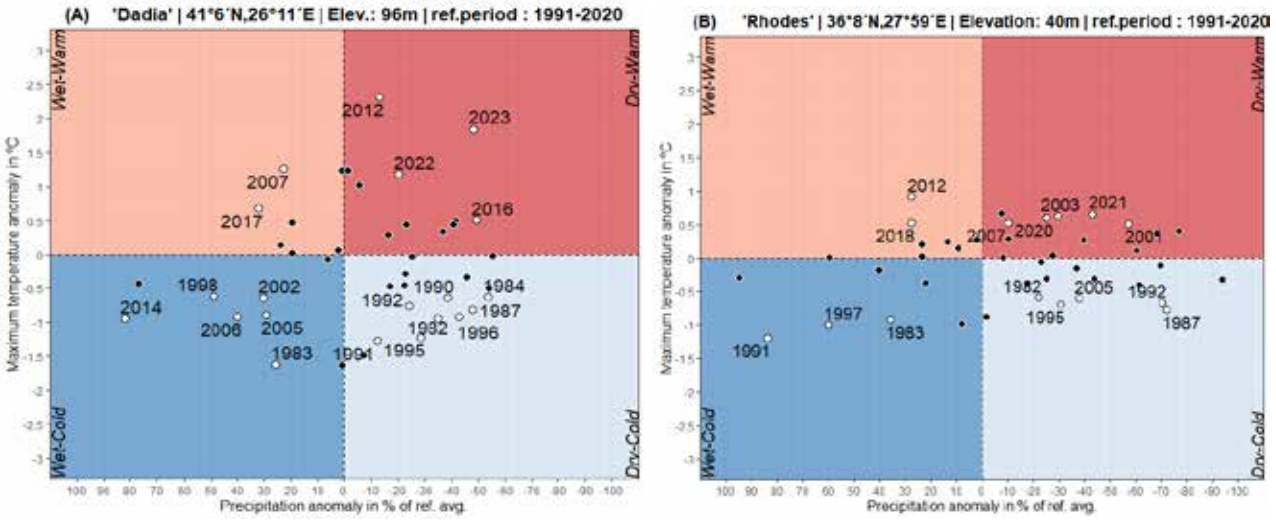

Figure 2: Temperature (maximum) and Precipitation Anomalies in Fire Season (May to October) from 1981 to 2023 (A) in "Dadia" and (B) in "Rhodes" site. Each chart shows each year's characterization as Wet-Warm (top left), Wet-Cold (bottom left), Dry-Warm (top right) and Dry-Cold (bottom right) in quadrants.

The most catastrophic fire season of all, 2023 in "Dadia", is classified as Dry and Warm (Figure 2). Maximum temperature anomalies were 1.8°C above the 1991–2020 average (28.2°C), and a decrease in precipitation amount of 48.4% (mean 214.1 mm). The maximum temperature increased by 0.7 °C compared to 2022. The 2013 fire season's maximum temperature deviation increased from 0.5°C above the 1991–2020 average to 1.8°C over 10 years (2013-2023) and precipitation anomaly values recorded from -40.8% deviation into -48.4% of reference period in the same decade. Respectively in "Rhodes", in 2023 fire season the estimated maximum temperature anomalies were 0.6°C above the 1991–2020 average (26.7°C), and a decrease in precipitation amount of 7.4% (mean 89.8 mm) (not shown in Figure 2). In the same decade from 2013 to 2023 fire season's estimated anomalies of temperatures increased from 0.03°C in 2013 to 0.6°C in 2023 and precipitation anomalies of 2013 increased from -27.6% to -7.5%. Although the 2023 fire season wasn't characterized as Dry and Warm (thus it is not shown in Figure 2), 2022 had remarkable deviations. Maximum temperature anomalies in fire season estimated 0.3°C above the 1991–2020 average, slightly smaller deviation than 2023. Precipitation anomalies in the 2022 fire season estimated negative at 39.6%, a huge difference from 2023 with the enormous damages in the natural reserve of Vounokalathos. According to the literature, the assessment of extreme drought events at both annual and three seasonal scales, i.e., previous winter (December-February), current spring (March-May) and current summer (June-August) best captures absolute water availability (Adams et al. 2017, Senf et al. 2020, Bose et al. 2024). So, these estimations from the year before the disastrous 2023 may be explained the fire severity. Also, 2020 and 2021 fire seasons were estimated as Dry and Warm in "Rhodes" (Figure 2). Thus, three consecutive fire seasons were characterized by favorable fire-weather conditions. Overall, the magnitude of the "Rhodes" 2023 fire season's Dry and Warm event was smaller (in terms of amplitude) compared to the "Dadia" event.

Conclusions

We analyzed the observed climate-driven changes in summer wildfires in two typical Mediterranean forest regions in Greece. The analysis indicates that the northernmost site is most impacted by hot extremes and compound hot-dry extremes, with changes being sensitive to temperature index used, while the southernmost site is most impacted by dry extremes and compound hot-dry extremes, with changes not being sensitive to the precipitation index used. In addition, we propose that climate change affects temperature and precipitation patterns, creating drier and extremely warm conditions that are more likely to lead to forest fires. This strengthens the evidence that climate change increases the frequency and/or severity of fire weather, with a high fire risk due to a combination of high temperatures, low humidity, low rainfall, and often high winds at the sites of interest. However, establishing a direct causal link between a single case and climate change remains challenging as some events would still occur even without climate change. It is therefore important to understand the changes in frequency and intensity at which these events occur. Moreover, it is concluded that to be effective, the management of forest ecosystems and forest fires must be accompanied by long-term knowledge of all the parameters associated with forest fires (climate, vegetation, soil, topography, etc.), which vary locally. More research is, of course, necessary to fully understand the effects of heat stress, which should be supported by real-time data collection and analysis in the field.

Introduction / Background

Floods are one of the natural disasters that pose a real threat for communities all over the world, especially in areas of low altitude with mild slopes and in coastal zones, impacting thus significantly human life. Floods may result in loss of human life, property damage, infrastructure damage and subsequent economic losses (Guha-Sapir *et al.,* 2014; Pabi *et al.,* 2021; Venkataramanan *et al.,* 2019). Another serious flood implication is the displacement of people, which can be temporary or long-term, depending on the severity of the flood and the availability of resources to support those who have been displaced (International Federation of Red Cross and Red Crescent Societies, 2021).

Thus, there is need for proactive flood disaster risk management (Pabi *et al.,* 2021), for any flood type like flash floods, river floods and flooding in urban areas, which can be greatly facilitated nowadays by remotely sensed information (Ajmar *et al.,* 2017)]. The EU Directive 2007/60 requires EU member states to take a number of measures to reduce the negative impacts of floods on human health, the environment, and economic activities, including the identification of areas at risk of flooding, the development of flood risk maps and management plans, and the implementation of flood risk reduction measures. As climate change is expected to bring more frequent extreme precipitation events, floods are expected to pose a serious threat for human society and environment and within this context flood hazard mapping is of major importance for urban and spatial planning and land use management (Hosseini *et al.,* 2020; Ran *et al.,* 2019).

There are several methods to identify flood prone areas, but the main tool is numerical modeling. The conventional way is to identify the catchment which runoffs to the vulnerable area and implement a hydrological rainfall-runoff model which derives a flood hydrograph at the catchment outlet. Except for the previous framework, there are several approaches such as multi-criteria decision-making tools, statistical methods, and Machine Learning techniques [Hosseini *et al.,* 2020; Rafiei-Sardooi *et al.,* 2021), which can be incorporated in the general methodology.

As previously mentioned, the EU Directive 2007/60 is the main tool for the European Union to define the strategy and to derive the policies for flood management. However, this framework has some drawbacks: a) the inundated areas are produced using numerical modeling, which in general suffer from uncertainties. Moreover, the low quality or even the lack of historical data from flood events makes the calibration of the required parameters no feasible and hence uncertainty is increased; b) Flood Hazard Maps are one snapshot in a specific time moment and they cannot incorporate all the changes which affect the flooded area, such as the land use modifications, the urbanization, the construction of several manmade structures, the rainfall variability over time, etc.

Therefore, there is a gap between this static tool of EU Flood Hazard Maps and the real world which changes every day. During the last years, Remote Sensing (RS) techniques to identify the inundated areas after a flood event are rising and indicate a potential. For example, researchers used Sentinel-1 images in order to assess the performance of hydraulic modeling in a historical flood event (Zotou *et al.,* 2020)] Other researchers developed the FLOMPY toolbox to identify flooded areas in the past using Sentinel-1 images (Karamvasis *et al.,* 2021) and they used Synthetic Aperture Radar approaches to support flood modeling (Zotou *et al.,* 2022). There are also works utilized the Google Earth Engine (GEE) based on Sentinel-1 images, in which they identified the flood susceptibility of an area, namely which areas are more vulnerable to be flooded based on historical and topographic data (Mehravar *et al.,* 2023) or they focused on the built-up area effect on flooding.

To the best of our knowledge, flood hazard mapping is based on hydrological modeling while there is no approach that uses remote-sensed and constantly updated images of flood data which can be used to assess the output of the EU Flood Hazard Maps. Besides, this is the first time a constantly updated flood hazard assessment tool is available for use by every interested stakeholder. In this work, a methodology for the assessment of flood hazard and the associated socioeconomic implications is presented based on the land cover dataset produced by Artificial Intelligence (AI) namely Dynamic World (Brown *et al.,* 2022), which is updated constantly following the revisit time of Sentinel 2, i.e., two to five days, and provides information on flooded areas at a 10 m spatial resolution. The

assessment is built within GEE platform, and evaluates the flooding probability at the pixel level, computing the number of times each pixel is categorized as flooded in the Dynamic World dataset for a given time period.
The methodology is applied in the River Basin District (RBD) of Thrace in NE Greece and it was compared against the latest Flood Hazard Maps developed for the study area according to the requirements of the EU Directive 2007/60 (EU Parliament, 2007). Our work highlights the advantages of using near-real time updated information on floods, complementary to the EU Flood Hazard Maps which are derived for a specific time moment. Its simplicity makes it an ideal instrument to overcome barriers encountered between scientific advances and policy adjustments, since it is implemented within a simple GEE code, and hence it is also readily available for use in other areas around the world. Apart from that, we also applied the tool in the region of Thessaly, Greece, in order to identify the flood impact after the recent catastrophe due to the Storm Daniel which hit the Mediterranean basin in early September of 2023.

Methods / Results

The flood hazard assessment approach presented herein builds on the global near-real time land use/land cover (LULC) product Dynamic World (Brown *et al.,* 2022), which is the result of the joint effort of Google and the World Resources Institute. It is available through the GEE platform and can be viewed in the GEE public data catalog. Aim of this initiative was to release a global LULC dataset, updated in near-real time that could capture the dynamic nature of Earth's surface. A detailed description of the methodology and training material can be found in the Dynamic World web page (Google and World Resources Institute Dynamic World App., 2024). Dynamic World is produced applying Artificial Intelligence (AI) principles using GEE and AI Platform. It is based on the European Space Agency's Sentinel-2 Top of Atmosphere (TOA) images, which are classified into 9 land use / land cover classes, using deep learning techniques. It has the spatial resolution of the original Sentinel-2 TOA product, i.e., 10 m, and it is updated globally every 2-5 days depending on the location, following the revisit time of Sentinel-2. The classification technique assigns per-pixel probabilities across nine land cover classes: Water, Trees, Grass, Crops, Shrub and Scrub, Flooded Vegetation, Built-up Area, Bare Ground, Snow and Ice. The Dynamic World classification has been applied to all historic Sentinel-2 TOA images, i.e., from June 2015 and it is constantly updated as soon as new images become available.
Concerning the flood hazard assessment presented in this work, the class of Flooded Vegetation is of particular interest, as it describes vegetated conditions related to flood. In the Dynamic World, each land cover class is represented by a different band. In this work, each pixel in every Dynamic World image of the study area, demonstrating the highest probability in the Flooded Vegetation class, is considered to be flooded area and it is assigned a value of 1, whereas in all other cases the pixel is assigned a zero value. Summing the values of each pixel across the whole time series, i.e., from June 2015 until today, corresponds to the number of times the specific pixel is viewed in flood conditions. All computations were performed within the GEE Platform with a Java Script code freely available using the link provided in the data availability section. The whole process is schematically depicted in Figure 1.

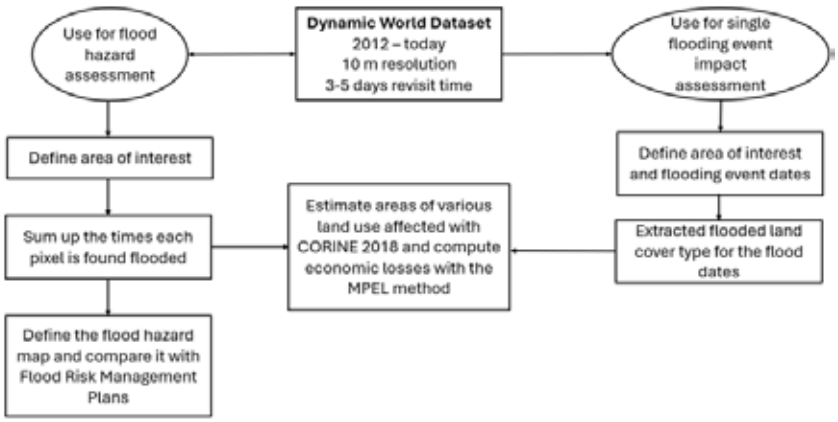

Figure 1. Flow chart of the flood hazard mapping approach

The results obtained with DW dataset in the Thrace RBD are shown in Figure 2a, whereas Figure 2b shows the frequency of flooding of various flooding areas. Comparison of the two independent datasets in Thrace Water District, which occupies an area of 11,250 km^2, revealed certain areas where Dynamic World did not detect flood conditions whereas the Flood Hazard Map indicates them as inundated area which corresponds to the rainfall with return period

of 100 years. This is expected since the two datasets correspond to different repeat periods and does not mean that DW underestimates or the Flood Hazard Map overestimates flood hazard conditions. Those areas correspond to 444,3 km^2 (Figure 3). The areas that both datasets assign as flood cover 122.7 km^2. However, the most interesting outcome is that there is an area of 194.6 km^2 which has been observed as a flooded area at least once since 2015 in DW. This is a certain miss of the 100-year return flood data set. Those areas are observed along the eastern and northeastern areas of Thrace WD, within the basin of River Evros.

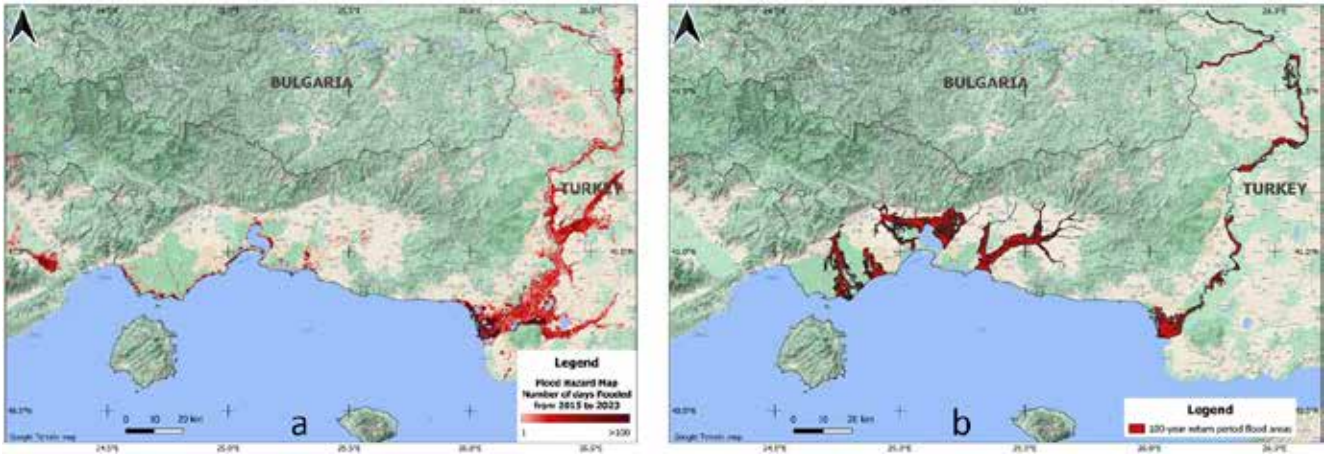

Figure 2. a) Flood Hazard Map of the broader Thrace RBD based on the methodology presented herein, covering the 2015 – 2023 period**, b)** 100-year return period Flood Hazard Map as defined for Thrace RBD, Greece

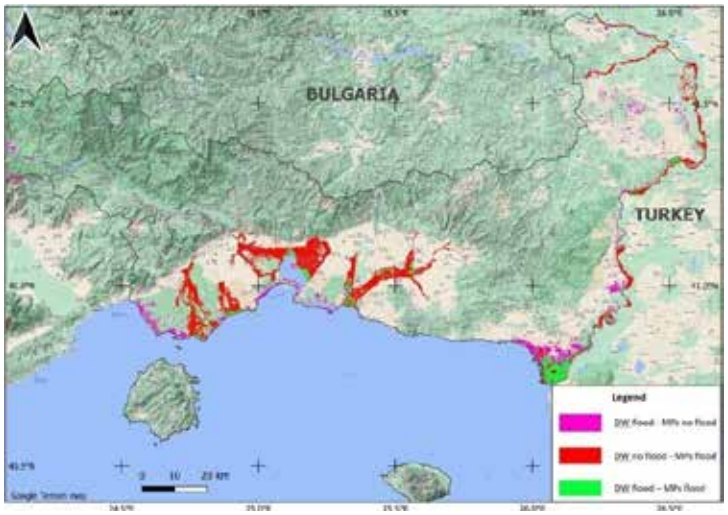

Figure 3. Comparison of the Flood Hazard Map of the Thrace RBD based on the methodology presented herein against the 100-year Flood Hazard Map based on the Flood Management Plan

Except for the application of DW in Thrace, we defined the flooding area prior and after the recent Medicane Daniel. Specifically, a tremendous flood event occurred in early September 2024 as a result of Storm Daniel, which caused dramatic impacts mainly on the region of Thessaly, in Central Greece (Figure 4). More than 750 mm of rainfall were recorded at the meteorological station of Zagora village near Mount Pelion, which approximates twice the annual rain of Athens (Nasa Earth Observatory, A Deluge in Greece). In Figure 5 the flooded area is plotted against how many times it is flooded, demonstrating that the flood impact of Daniel changed dramatically the distribution of flooded areas, with more than 50 km^2 observed as flooded for the first time.

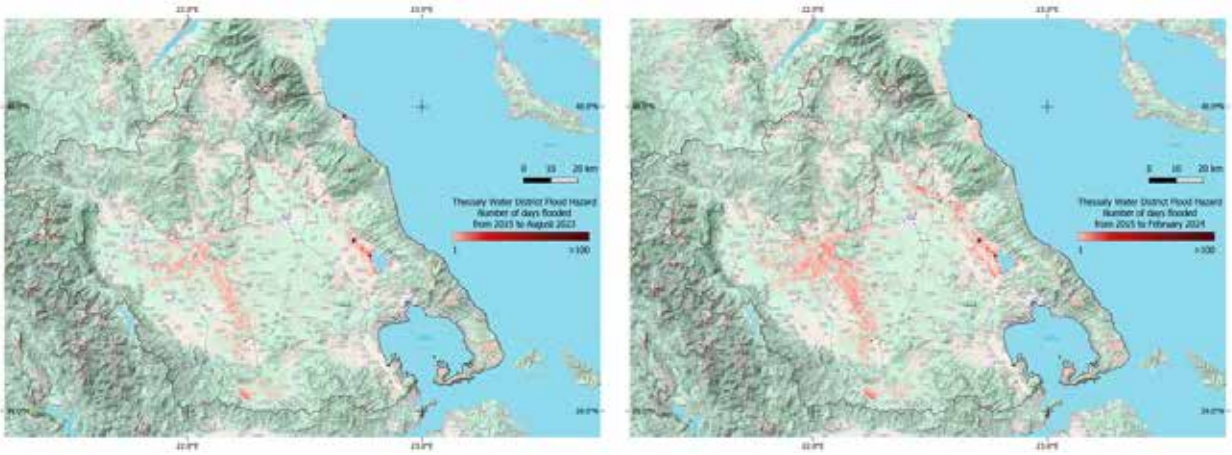

Figure 4. Flooded area prior to storm Daniel (left) and after storm Daniel (right)

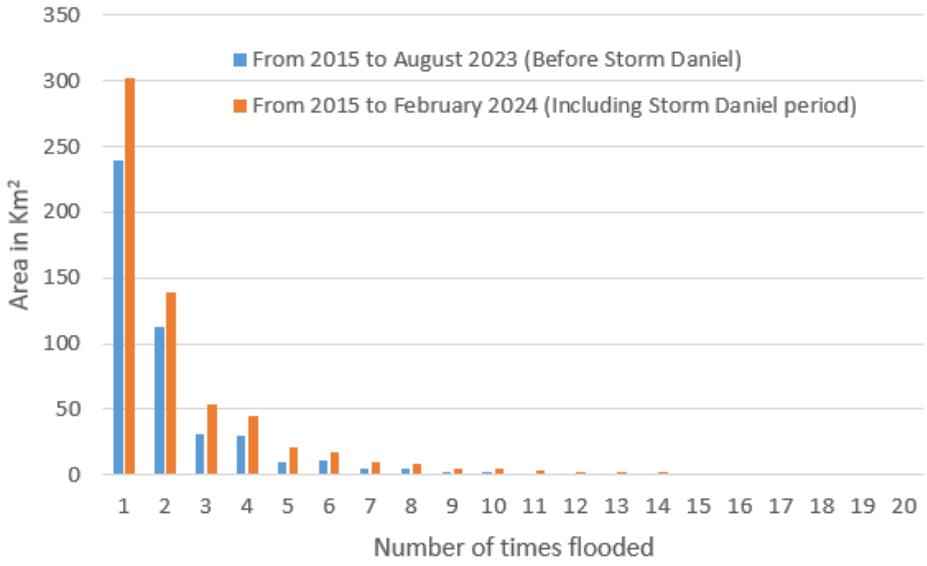

Figure 5. Flooded area against how many times is flooded before and after storm Daniel

Conclusions

In this work, we developed an open tool based on remote sensed images obtained by the Google Earth Engine, and specifically on Sentinel 2 images, for identifying the time series of flooded areas with a continuous update. This tool is implemented in the Thrace water district (Greece) and the outcome of the proposed tool is compared with the corresponding Flood Hazard Maps of the EU Directive 2007/60. It is found that there are discrepancies between the model product (i.e. the Flood Hazard Maps) and the real-world picture. We applied DW tool for identifying the flooded area after the recent Storm Daniel, which hit Greece in September of 2023 and specifically the region of Thessaly. Our major findings are presented in the following paragraphs.

First, we shall keep in mind that the conventional Flood Hazard Maps within the Flood Management Plans, are created on a probability basis using modeling tools and should be regarded as future potential flooding areas. Besides, these maps are derived assuming that there are no changes at the configuration of the vulnerable area. Our results indicated that there is space for improvement in those Flood Hazard Maps combining information from satellite-based observations. The DW dataset approach, presented in this work, offers a means of verification of the modeling results, especially by enhancing them in flooded areas which are not depicted in the Flood Hazard Maps. Regarding the reliability of this dataset, it should be noted that it has been rigorously examined and tested with a large Expert Consensus dataset and the results indicated top qualitative performance in each comparison category among the examined land cover datasets. Hence, the presented methodology, taking advantage of emerging techniques and datasets, helps policy makers acquire better and timely information on flood hazard, so as to improve the planning of protective measures.

Second, Sentinel 2 mission has a global coverage and covers all Earth's continents, large islands, along with inland and coastal

water bodies, with a revisit frequency of 5 days. However, cloud cover may restrict acquisition of useful images, resulting in lower data availability in flooded areas with increased cloud cover and therefore the results obtained with DW dataset should be regarded as the minimum number of days the specific area is observed as flooded. It is very likely that some flood events are not detected by satellite observations due to cloud cover and are not included in the DW dataset. As the methodology is based on AI classification, there is always a slight possibility of misclassification, i.e., a dry pixel may appear falsely flooded and vice versa. Nevertheless, DW is an extensively evaluated dataset of high accuracy. Since it is a constantly updated dataset, its quality is expected to improve in the future versions. The probability for a specific area to have no RS history data is very low and thus the methodology works at the global scale. Moreover, since the Sentinel 2 mission operates from 2015, the data history covers a relatively short time period, which however can be extended back to early '80s combining data from Landsat missions. This can be a very challenging future extension of the present work.

Finally, the growing production of freely available datasets related to environmental monitoring based on remote sensing and AI technologies can be used to tackle the tremendous impacts on natural and human ecosystems due to flooding. The innovation of our approach consists of:

- The development of an algorithm using the Google Earth Engine platform in order to utilize the high-spatial resolution of the Dynamic World data.
- The deployment of a user-friendly tool which can be used for the effective communication of scientific findings to government and policy makers but also to all community actors and will encourage social acceptability of improved flood anticipation policies.
- The evidence of the usefulness of the tool, demonstrating the inadequacy of the River Flood Management Plans against the outcome of the tool in the Thrace Water District.

Introduction

Santorini and Nisyros are considered the most important caldera-type volcanoes in terms of volcanic risk in the South Aegean Active Volcanic Arc, Figure 1A). The recent earthquake swarms in the Christiana-Santorini-Kolumbo volcanic system between Santorini and Amorgos Islands have been causing concern not only in Santorini and neighboring islands, but also in Türkiye since the end of January 2025. The possibility of a volcanic eruption in this volcanic field reminded us of widespread tephra units in the geological past such as the Santorini Minoan tephra, spread to western Anatolia. Therefore, the other active volcanic field of the SAAVA, Kos-Nisyros-Yali, closer to Turkish mainland becomes more important. Terrestrial medial/distal tephra sequences are especially valuable in the case of island arc volcanoes where most of the tephra deposited within the sea and not readily accessible. The purpose of this study is to document the medial Nisyros tephra on Datça peninsula (Muğla, SW Türkiye) and discuss how they contribute to the understanding of tephrochronological issues in the proximal region.

Kos-Nisyros-Yali Volcanic Field and Nisyros Medial Tephra

Kos-Nisyros-Yali, is the site for one of the most powerful eruptions in the Quaternary (i.e. Kos Plateau Tuff, Keller et al., 1990) (Figure 1B). Despite the well constrained geology, distribution and chronology of tephra units of Santorini, there are some uncertainties in tephra distribution and eruption frequency for Nisyros volcano. The $^{40}Ar/^{39}Ar$ age of Kos Plateau Tuff (KPT) eruption is 161.3 ± 1.1 ka (Smith et al., 1996), and Nisyros-Yali are considered post-KPT volcanic centers. The geochronology of the Nisyros tephra units has been constrained just recently. The K-Ar method was the most widely used for the pre-caldera Nisyros tephra units, but did not provide accurate ages (e.g. Keller et al., 1990). Absence or rarity of K-bearing phases or excess Ar in some crystals were problems related to K/Ar dating, resulting in older ages. Other methods (^{14}C, O isotopes, fission track) were employed for the caldera-forming tephra, and use of distal marine tephra for stratigraphy and correlation also produced conflicting and wide range of ages.
Regarding the Nisyros tephra dispersal, only caldera forming rhyodacitic/rhyolitic Lower and Upper Pumice units (63.1 ± 4.7 ka and 58.4 ± 2.7 ka, respectively; Popa et al., 2020) were considered significant in the literature. Even if deposited on neighboring islands or Turkish coast, pre-caldera tephra was thought to be eroded later on (Longchamp et al., 2011). However, pre-caldera Kyra unit (previously estimated as 24-38 ka) was reported in one locality on Datça (0.9 m) and Tilos (1.2 m) (Keller et al., 1990; Sterba et al., 2011).

Results

In order to contribute to the tephrochronology of Nisyros volcano, we conducted field studies and tephra hunting on Datça peninsula, that revealed 6 new outcrops and confirmed the occurrence of Nisyros Kyra reported earlier (Gençalioğlu-Kuşcu and Uslular, 2018). We collected andesitic and dacitic pumice lapilli deposited on KPT with an unconformity in between (Figure 2). Zircon, monazite, and apatite crystals were separated from Datça pumice fall tephra for U-Th/He geochronology, and abundant apatite crystals proved to be useful. Plagioclase and hornblende crystals were also separated for $^{40}Ar/^{39}Ar$ geochronology from another Kyra tephra location. The weighted mean of combined $^{40}Ar/^{39}Ar$ and (U–Th)/He ages was calculated as 133.5 ± 3.4 ka (Gençalioğlu Kuşcu et al., 2020).

Conclusions

Identification of new medial Nisyros tephra on Datça Peninsula, together with their detailed characterization

contributes to the proximal tephrochronology of Nisyros volcano. The weighted mean age of 133.5 ± 3.4 ka for Kyra tephra conforms with the recent ages of younger explosive and effusive units, revealing a more precise tephrostratigraphy. As a caldera volcano accumulating silicic magma, Nisyros possesses volcanic risk to surrounding islands and Turkish mainland. Therefore, medial tephra distribution and identification, correlation and geochronology of these tephra units are vital to get the full picture of this relatively less known, but potentially dangerous volcanic system. Further volcanological and geochronological work is needed to determine the distribution of medial tephra and determine the eruption frequency for the Nisyros volcano.

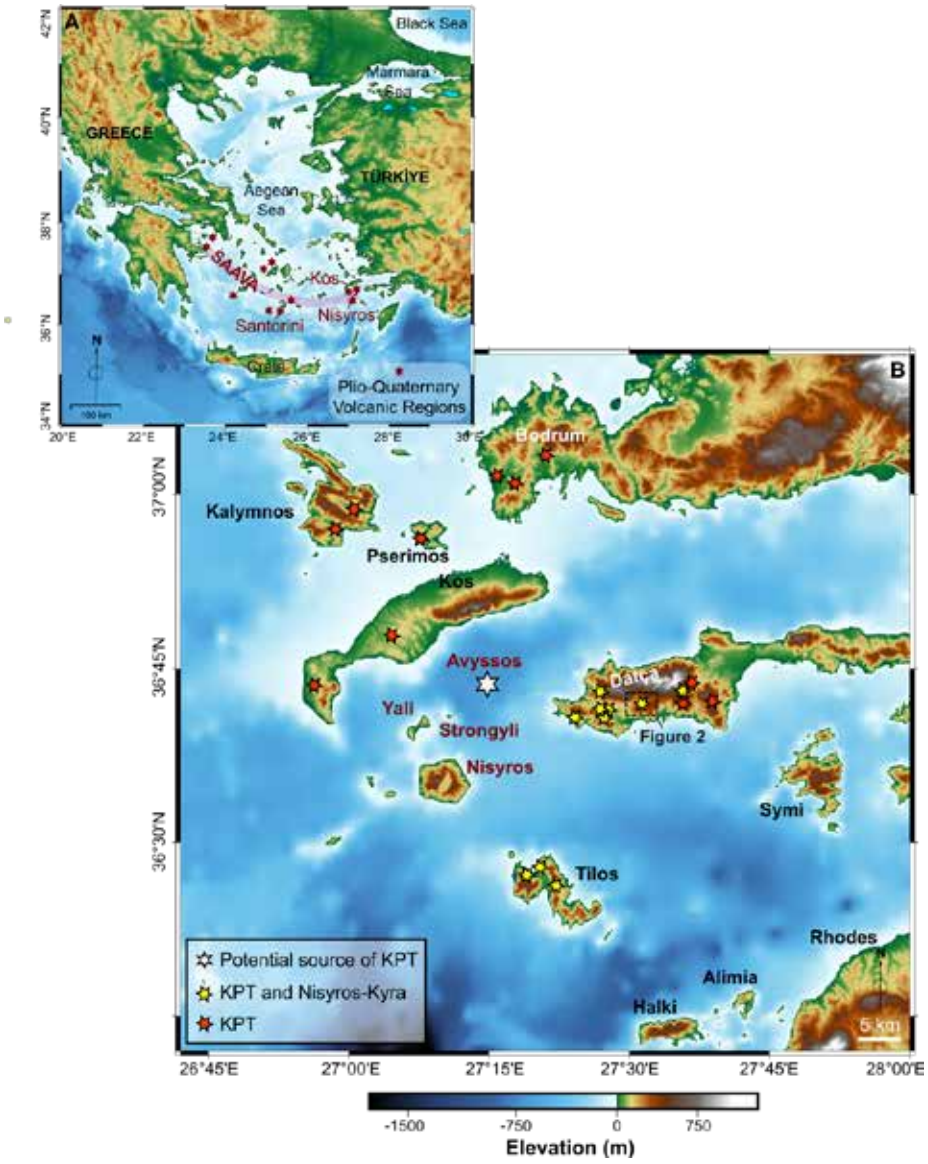

Figure 1A. Map showing the volcanic centers of the South Aegean Active Volcanic Arc (SAAVA); B. DEM image (30-m resolution SRTM) showing the Kos-Nisyros-Yali volcanic system. Occurrences of KPT on Datça-Bodrum Peninsulas and neighboring islands are modified from Ercan et al. (1984), Allen et al. (1999), Pe-Piper et al. (2005), and Gençalioğlu Kuşcu (2012). Nisyros Kyra tephra on Datça peninsula and Tilos island are from Gençalioğlu Kuşcu and Uslular (2018) and Sterba et al. (2011), respectively. The rectangle on the Datça peninsula shows the Sındı location of Figure 2, where Nisyros Kyra overlies the KPT and fluvial deposits.

Figure 2. General view of the andesitic Kyra fallout overlying the KPT and fluvial deposits on Datça peninsula.

EXTENDED ABSTRACT 090

Evaluation of PAHs sorption behavior in coals and cokes

Georgaki M. [1], Karapanagioti H.K.[2], Wojtaszek-Kalaitzidi M.[3], Kalaitzidis S.[1*]
(1) Department of Geology, University of Patras, Rio-Patras, GR 265 04, Greece, skalait@upatras.gr (2) Department of Chemistry, University of Patras, Rio-Patras, GR 265 04, Greece (3) Institute of Energy and Fuel Processing Technology, 1 Zamkowa Street, Zabrze, Poland

Research Highlights

This study investigates the sorption behavior of phenanthrene in coals and cokes, highlighting the influence of coal rank and maceral composition on phenanthrene sorption capacity.

Introduction / Background

Organic petrography has become an important tool in environmental research, particularly in studying the sorption capacities of polycyclic aromatic hydrocarbons (PAHs) in various types of coal (e.g., Ligouis *et al*., 2005; Kalaitzidis *et al*., 2006; Yan *et al*., 2011). This is important as it provides insights into the interactions between PAHs and organic matter, which are critical for predicting the behavior and environmental fate of these pollutants in natural systems. PAHs refer to a broader category of harmful and toxic organic pollutants widely distributed in nature (Van der Oost *et al*., 2003; White *et al*., 2016; Patel *et al*., 2020). Some of these compounds can be mutagenic or carcinogenic in living organisms, leading to their classification as priority pollutants (ATSDR, 1995).

Phenanthrene ($C_{14}H_{10}$) belongs to PAHs and is a hydrophobic organic pollutant, due to its potential toxicity to humans and other living organisms, as well as its prevalence and persistence in the environment (Hussar *et al*., 2012). It is commonly used in sorption studies as a model organic chemical and is also used in this study. Previous studies showed that the sorption of phenanthrene in low-rank coals is controlled, among others, through the inertinite content (e.g. Kalaitzidis *et al*., 2006).

Objectives

In the current study, the sorption behavior of phenanthrene in a series of various rank coals such as lignite, bituminous coals, semi-anthracite and anthracite, as well as naturally coked coals and industrial cokes, is examined (Figure 1). The rank series represents a wide range of coal basins and coal-forming periods, ranging from Gondwana coals from Australia and South Africa, Laurasian coals from China and Poland, and Neogene lignite from the Czech Republic, thus demonstrating variable physical and chemical characteristics and most importantly, maceral contents (Table 1). The main purpose of this study is to evaluate the impact of coal rank upon sorption attributes, but also to test the hypothesis that sorption will increase proportionally to carbonized material (e.g. inertinite content) in higher-rank coals, as it was observed for low-rank coals (Kalaitzidis *et al*., 2006).

Methods

In total twenty-two samples were analyzed, comprising lignite (ERT_3,_4), bituminous coal (ERT_5,_6,_7,_10,_11, _12,_13,_14,_15,_16), anthracite (ERT_1,_2,_8,_9), naturally coked coals (ERT_18,_19) and industrial cokes (ERT_17,_20,_21,_22). On the representative samples proximate, ultimate and petrographical analyses were conducted. Proximate analysis was performed according to ASTM (D3174; D3175; D3302, 2004). Ultimate analysis was carried out using a Carlo Erba EAGER 200 Automatic Analyzer according to ASTM D5373, 2004. Maceral analysis was performed according to ISO 7404-3 (2009) using a Leica DMRX coal-petrography microscope (ICCP, 1998, 2001; Sýkorová *et al*., 2005; ASTM D5061, 2007; Pickel *et al*., 2017). Vitrinite reflectance (Ro%) and bireflectance (Rbi%) were measured according to ISO 7404-5 (2009) using Leica MPV/SP spectral photometer and AxioImager M1m/Zeiss+MSP 400 Spectrophotometer.

Additionally, all samples were tested for their sorption capacity in batch triplicate reactors at the same initial phenanthrene concentration (Co) of 250 μg/L. Based on the sorption and petrographical analysis results, nine samples were selected for further sorption experiments of phenanthrene at concentrations (Co), ranging from 20 to 200 μg/L (Kleineidam *et al*., 1999; Karapanagioti and Sabatini, 2000; Karapanagioti *et al*., 2001), as well as for BET analysis.

The surface area, pore volume and pore size distribution of selected samples were determined by nitrogen gas (N_2) adsorption-desorption with the Tristar 3000 Analyzer (Micrometrics® GA, USA) using the Brunauer, Emmett, and Teller (BET) equation, at the Laboratory of Heterogeneous Catalysis, Department of Chemistry of the University of Patras.

Results and Discussion

Proximate analysis determines that the moisture varies from 0.7 to 10.0 wt% (on an as-received basis). The ash yield shows a high variability with values ranging from 2.5 to 64.8 wt% (db). The volatile matter yields vary from 2.9 to 58.8

wt% (daf). The carbon content of the samples ranges from 59 to 95 wt% (daf). Hydrogen and nitrogen fluctuate from 0.3 to 6.2 wt% and 1.1 to 2.3 wt% (daf), respectively. Sulfur content varies from 0.1 to 3.9 wt% (daf).

Table 1. Samples characteristic, rank, results of proximate and ultimate analyses, vitrinite reflectance and bireflectance.

VM: volatile matter; Ro%: vitrinite reflectance; Rbi%: bireflectance; ar: as-received basis; db: dry basis; daf: dry, ash-free basis.

The petrographical analysis indicates that huminite is the dominant maceral group in the lignite samples ranging from 85.6 to 92.6 vol%, on an organic matter basis. Vitrinite is the dominant maceral in the bituminous coal and anthracite samples, ranging from 56.9 to 100 vol%, where two of them (ERT_8,9) were anthracite A with 100 vol% vitrinite. Inertinite content in lignite samples is generally low (<9 vol%), while in bituminous coal and anthracite, it ranges from 3.3 to 40.7 vol%. Liptinite content is up to 10.6 in lignite and bituminous coal samples. Naturally coked and coke samples were dominated by binder phase (69.6-95.0 vol%) and less filler phase (5.0-30.0 vol%).

The phenanthrene sorption distribution coefficient (Kd, $Kd = qe \times Ce^{-1}$) at the same initial phenanthrene concentration (Co) of 250 µg/L ranges from 1,024 to 37,329 L/Kg, with samples ERT_14 and ERT_1 displaying the lowest and the highest values, respectively. Of the 9 samples selected for further sorption experiments, samples ERT_3, ERT_18, and ERT_19 show the highest sorption capacity at both high (Co=180 µg/L) and low concentrations (Co=15 µg/L). Anthracite (ERT_1) exhibited nonlinear sorption behavior (Freundlich exponent N > 1), while bituminous coals (ERT_6, _11, _14 _15, _16), showed a correlation between inertinite content and sorption nonlinearity (N < 1). Coke samples (ERT_18, _19) displayed the highest organic carbon-normalized sorption capacity (Koc, $Koc = Kd \times foc^{-1}$) at low phenanthrene concentrations.

The BET analysis reveals that the surface areas vary from 1.0 to 41.2 m^2/g. Pore volume ranges from 0.0056 to 0.062 cm^3/g. Samples ERT_18 and ERT_19 with high surface area also exhibit high pore volume. The pore size ranges from 62 to 303 Å.

Considering the above, the sorption behavior seems to be affected by the coal rank, except for the lignite (ERT_3) sample. However, if the organic carbon content is considered, it follows the same pattern observed in a previous study (Kalaitzidis *et al*., 2006), which found a positive correlation between inertinite content and Koc, indicating that as inertinite content increases, sorption capacity also increases.

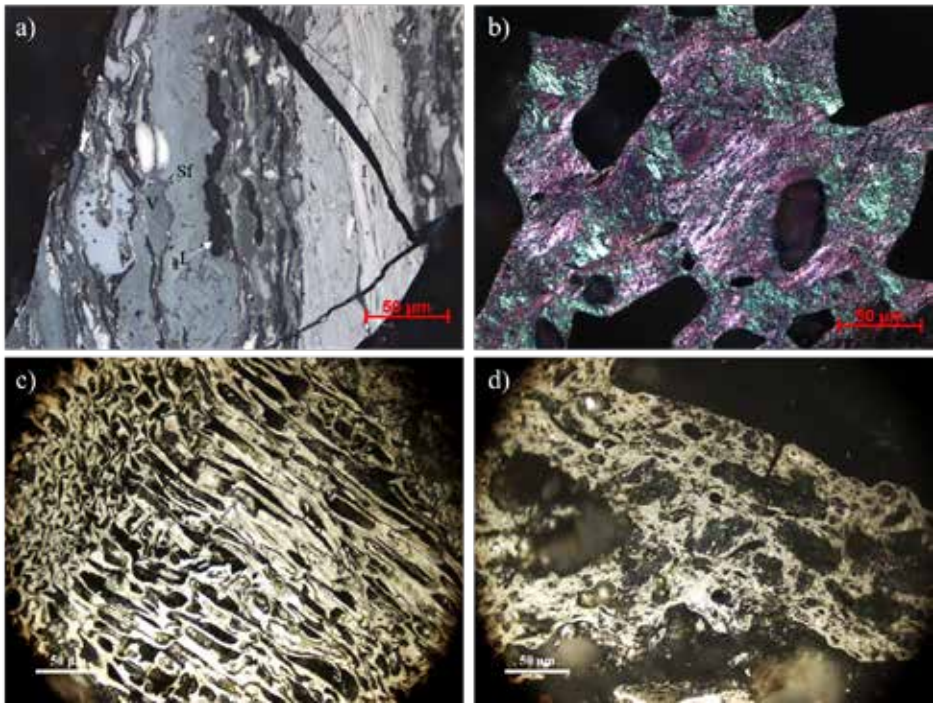

Figure 1. Photomicrographs of selected samples; a) ERT_14 bituminous B coal, V: vitrinite, Sf: semifusinite, L: liptinite, I: inertinite; b) optical texture of coke sample ERT_20; c) view of inertinite in naturally coked coal ERT_19; d) view of naturally coked coal sample ERT_18.

Conclusions

The anthracite (ERT_1) exhibited the highest sorption capacity (Kd) from all samples, but also its behavior was totally different from the rest samples. Anthracite had a nonlinear Freundlich exponent (N) higher than 1, which suggests that the more the sorbed phenanthrene the higher the affinity of the sorbent for phenanthrene. Bituminous coals (ERT_6, _11, _14 _15, _16) sorption behavior seemed to be affected by the inertinite content in terms of their nonlinearity (N<1); nonlinearity increases (N decreases) with increasing inertinite amount. The two coke samples (ERT_18, _19) demonstrated the highest sorption affinity (Koc); which is the sorption capacity normalized for the fraction of organic carbon content for phenanthrene at low concentrations.

Acknowledgments

The authors would like to thank Ms. Vasiliki Kostopoulou and Mr. Dimitrios Bampagenes for conducting laboratory experiments. Dr. Dimitrios Vachliotis, Laboratory of Instrumental Analysis, Faculty of Sciences, University of Patras, is also acknowledged for performing the Carlo Erba analysis.

Introduction / Background

Globally, groundwater is a primary source of water supply and irrigation, often with a balanced distribution (Wada et al., 2012). However, in Greece, water distribution is uneven, both temporally and regionally, with a significant portion of its main water resources being used for agricultural purposes. The chemical status of groundwater in mainland Greece is characterized as particularly degraded (Karavitis et al., 2024). The main sources of groundwater degradation are industrial and mining zones - heavy metal pollution, which is harmful even at low concentrations – the seawater intrusion, and the use of fertilizers and pesticides in areas of agricultural intensification (Dokou et al., 2015).

Objectives

Systematic groundwater monitoring ensures good water quality for water supply and agricultural irrigation in Greece, especially in Thessaly and Peloponnese, regions characterized by intense agricultural activity. The purpose of the study is to determine the distribution of groundwater parameters in the studied regions, the overall groundwater quality of these, and the identification of possible factors that influence groundwater system.

Methods

Based on the "National Water Monitoring System" (Ministry of Environment and Energy), this study aims to include all recently available data of 2019 on the hydrochemical characteristics of groundwater in Greece. This data includes measurements of physicochemical parameters, such as pH, temperature, electrical conductivity (EC), sulfate (SO_4), nitrate (NO_3), total chromium (Cr_{total}) and total phosphates (PO_4), from monitoring stations in the regions of East and West Peloponnese and Thessaly. The available groundwater variables were analyzed using statistical tools in SPSS software version 16.0 and RStudio Desktop (Dammi et al., 2021). Multivariate statistical methods (MSMs) were applied to identify trends and differences in groundwater quality in studied regions of Greece with increasing agricultural activity (Praus 2005; Belkhiri et. al. 2010). Varimax rotation approach and Kaiser normalization, combined with principal component analysis (PCA), which is included in factor analysis (R-mode FA) , were applied as an exploratory tool to identify potential sources of groundwater pollution (Ma et al., 2014).

The limits of detection (LOD) and quantification (LOQ) are the most crucial data that researchers evaluate when assessing approach validity. The parameters LOD and LOQ define analyzed concentrations that may be accurately quantified. The LOQ indicates the lowest concentration that can be quantitatively determined with sufficient accuracy, whereas the LOD indicates the lowest detectable concentration (Taleuzzaman 2018). At chemical concentrations below the limit of quantification, half the value was assigned. References state that censored data are either removed or replaced with specified data, usually half of the LOQ (Cantoni et al., 2020).

Results

The chemical composition of groundwater samples, both from Peloponnese and Thessaly varies significantly (Table 1). Both a descriptive analysis and a test for normality to the data distribution were carried out. The pH, an important parameter for assessing water quality, ranges from slightly acidic to slightly alkaline in the studied regions, mainly within World Health Organization (WHO) limits. WHO recommends a pH of 6.5 to 8.5 (WHO 2008). Although pH does not directly affect human health, it is closely associated with the physicochemical properties of water. Electrical conductivity (EC) is frequently differentiated in water quality data in both the Peloponnese and the Thessaly, indicating moderate to high dissolved salt content. Water hardness is influenced by anions such as chloride and sulfate, as well as calcium and magnesium cations. The Peloponnese and Thessaly regions frequently have significant concentrations of both calcium and magnesium ions. Groundwater's chloride concentrations varied, with some samples having higher concentrations than the permissible limit of 250 mg/L (8062 mg/L). Significant concentrations of chloride in water are frequently used as an indicator of groundwater pollution (Panno et al., 2006). Nevertheless, geological factors, including seawater intrusion in coastal aquifers, or deep saline groundwater upwelling, may also cause naturally high

chloride concentrations in some areas. This could be related to high salt levels, marine pollution, and other activities (such as the use of chemicals in industry or agriculture. In both studied areas, some samples observed high nitrate (534 and 526 mg/L) and sulfate concentrations (2534 and 2423,4 mg/L), possibly due to the use of fertilizers in agriculture, indicating serious water pollution. In Thessaly, high concentrations of nitrite, ammonium and chromium total are observed in some samples, exceeding internationally accepted drinking water limits. In the Peloponnese, the values of these elements, although lower compared to Thessaly, exceed the permitted limits in some cases, especially for total chromium and ammonium samples.
The spatial distribution of trace element concentrations in the groundwater varied significantly. Despite a few exceptions, it was observed that most samples for trace elements (Cr total, Cr^{6+}, Pb, As, Cd, Ni) are either equal to or below the limit of quantification (LOQ or LOD); as a result, trace elements were not used in the factor analysis. This method provides a more accurate representation of the data and enables more accurate statistical analysis.

Table 1. Descriptive Statistics of Groundwater Quality Parameters in studied regions

	Peloponnese (n=235)				Thessaly (n=307)			
Parameter	**Minimum**	**Maximum**	**Mean**	**Std. Deviation**	**Minimum**	**Maximum**	**Mean**	**Std. Deviation**
pH	6,19	8,43	**7,45**	0,27	6,19	9,84	7,59	0,43
Temperature (°C)	9,5	31,6	18,3	2,59	9,5	31,6	18,06	2,55
Electrical Conductivity (EC, μS/cm)	230,5	**24900**	1223,65	2047,97	114	**24900**	1135,74	1815,65
Dissolved Oxygen (DO)	1	7,8	4,42	1,32	1	9,3	4,71	1,56

Bicarbonate (HCO_3^{-})	47,28	486,93	301,25	70,88	23,19	851,84	306,46	101,92
Chloride (Cl^{-})	3,51	**8062**	**205,58**	685,30	1,38	**8062**	**171,18**	602,55
Sulphate (SO_4^{2-})	2,57	**2534,5**	84,26	194,13	2,57	**2423,4**	79,06	176,47
Nitrate (NO_3^{-})	0,06	**534**	33,38	61,47	0	**526**	32,29	57,22
Nitrite (NO_2^{-})	0	0,26	0,02	0,03	0	**1,87**	0,05	0,17
Total Phosphates (PO_4^{3-})	0	0,46	0,01	0,04	0	0,364	0,02	0,04
Ammonium (NH_4^{+})	0	**1,73**	0,02	0,12	0	**4,16**	0,04	0,27
Chromium dissolved (Cr)	0	**50,28**	2,91	4,94	0	**50,16**	3,13	4,96

According to Table 2, in the two studied regions, the porous aquifer is the most prevalent aquifer, with a percentage of 48.1% in the Peloponnese and 53.1% in Thessaly. For the supply and storage of groundwater, porous aquifers are frequently important, especially in urban or agricultural settings (Daskalaki & Voudouris, 2008). Porous aquifer's materials are characterized by high permeability, which facilitates the rapid movement of water within the aquifer. This fact creates ideal conditions for storing and pumping groundwater. Increased permeability also makes them more susceptible to contamination by industrial activities or fertilizers, as it makes them accessible quickly to water (Burri et al., 2019).

Table 2. Type of aquifer

	Peloponnese		Thessaly	
	Frequency	**Percent (%)**	**Frequency**	**Percent (%)**
Karst	98	41,7	106	34,5
Porous	**113**	48,1	**163**	53,1
Excavated rocks	24	10,2	38	12,4
Total	**235**	100	**307**	100

In total, there are 307 monitoring stations in Thessaly and 235 in Peloponnese. However, the sample size used in the Kaiser-Meyer-Olkin (KMO) test and Bartlett's Test of Sphericity is smaller due to a lack of measurements for certain groundwater quality parameters at specific monitoring stations. Degrees of freedom (df=120 and df=105, respectively) in Bartlett's test resulted from the factor analysis's inclusion of 16 variables for Peloponnese and 15 for Thessaly. Table 3 shows the KMO statistics values for each case that was studied. KMO statistics values for each region are 0,51 and 0,67, respectively, indicating marginal to moderate suitability for the method (Shrestha, 2021). At $p < 0,001$, Bartlett's test of sphericity is highly significant, indicating that at least some of the variables of the correlation matrix have significant correlations with one another. In this case, the test values are 4819,16 and 4699,34, and the corresponding significance level is less than 0,001 (Silva et al., 2014).

Table 3. Kaiser-Meyer-Olkin (KMO) and Bartlett's Test of Sphericity

		Peloponnese	Thessaly
	KMO	**0,51**	**0,67**
Bartlett's Test of Sphericity	**Approx. Chi-Square**	4819,16	4699,34
	df	120	105
	Sig.	<0,001	<0,001

This study used principal component analysis (PCA) as the factor extraction method. PCA is often used to identify significant factors which influence groundwater quality, and it may minimize the number of variables without losing information (Bodrud-Doza et al., 2016). According to Table 3, the first four components explain 72,46% of the total variation in Peloponnese, while the other five frequent components account for 77,44% in Thessaly. These elements constitute the essential information of the initial data. The additional variables have an insignificant portion.

Table 3. Total Variance Explained in two regions

Component	Peloponnese						Thessaly					
	IE			RSSL			IE			RSSL		
	Total	**%V**	**C%**	**Total**	**%V**	**C%**	**Total**	**%V**	**C%**	**Total**	**%V**	**C%**
1	6,80	42,50	42,50	6,60	**41,23**	41,23	6,01	40,04	40,04	5,62	**37,47**	37,47

Extraction Method: Principal Component Analysis; IE:Initial Eigenvalues; %V: % of Variance; C%: Cumulative %;RSSL:Rotation Sums of Squared Loadings

Table 4 highlight the factor loadings after the rotation in each case. In Peloponnese, the first factor is responsible for 41.2% of the total dataset's variation. EC, sodium, chloride, sulfate, potassium, magnesium, and ammonia are the variables in this component with the highest loading coefficients. This factor reflects areas with elevated levels of inorganic salts and metals, which is strongly correlated with salinity. The salinity is primarily attributed to seawater intrusion into the aquifer, leading to an increased concentration of dissolved ions in the water (Han et al., 2015). While ammonia is present in this component with the intrusion ions, it is not a direct indicator of seawater intrusion. Instead, ammonia concentrations are monitored by processes such as organic matter decomposition, which is commonly increased in aquifers with a lack of oxygen (Moore & Joye, 2021). The second factor accounts for 12.8% of the total variation in the data, with high loadings on the nitrate and nitrite variables. This factor indicates agricultural contamination (agricultural runoff) since it contains nitrates, which are commonly found in fertilizers and organic sources, while nitrites are often associated with biogeochemical processes (Rivett et al., 2008; Khan et al., 2018). Their association usually reveals specific nitrogen cycle processes as well as the system's redox state. In oxygenated conditions, nitrite, an unstable intermediate, is frequently transformed to nitrate, indicating that nitrate dominance may be the last stage of oxidation (Nowka et al., 2015). A strong positive loading on the bicarbonate variables, which indicates their relationship to the geochemistry of carbonate rocks and the natural processes of CO_2 dissolution in the soil, characterizes the third component, which accounts for 12.1% of the total variation in the data. At the same time, it has a moderate negative loading on dissolved oxygen and pH, indicating the potential for inadequate oxygenation,

which can be linked with reductive environments or increased biological activity (Koch et al., 1985). The fourth factor expresses 6.3% of the total variation in the data and presents a high loading on the total phosphate's variable, indicating the use of phosphate fertilizers, and therefore potential pollution from fertilizer use and crops (Cheraghi e al., 2012).

Respectively in Thessaly, the first factor expresses 37.5% of the total variation in the data. Respectively in the Peloponnese, the first factor is characterized as a salinity factor, with high loadings on the variables EC, sodium, chloride, sulfate, potassium, and magnesium, describing the salinity and ionic concentration of the water. The second factor represents 11.2% of the total variation in the data and is characterized by a high positive moderate loading on the nitrate variable and a moderate positive loading on the calcium variable. Nitrates are related to the use of fertilizers in crops and to runoff from agricultural activities (Whang & Li, 2019). The existence of moderate calcium loading indicates that agricultural activities may occur in areas with a high geological presence of calcium or that calcium in rocks is dissolved from soils because of water inputs. The third factor is related to low oxygen or organic pollution environments, having a high positive loading on the variable's nitrite and ammonia. The simultaneous presence of both ions implies that reductive processes increase in low-dissolved oxygen environments, probably due to organic matter decomposition. The fourth factor is mainly related to physicochemical characteristics such as dissolved oxygen, temperature, and pH, reflecting the oxygenation processes in the aquatic environment. (Babatunde 2024). A high loading of dissolved oxygen (DO), a moderate negative loading for Temperature, and a moderate positive loading with pH are observed. The fifth factor expresses 7.5% of the total variation of the data and shows a high loading on the variable phosphate salts in water, which is related to agricultural (use of phosphate fertilizers) and biological sources. Phosphates are frequently indicators of eutrophication, or excessive nutrient enrichment of water, which can result in algae development and the degradation of quality of water (Cheraghi e al., 2012; Kundu et al., 2015).

Conclusion

The degradation of groundwater quality makes agricultural production and public health difficult, as drinking water can be enriched with toxic metals. The analysis of hydro chemical data confirms the need for systematic monitoring of the region's stations and management of groundwater quality, especially in areas with high agricultural activity. This study identified significant relationship between anthropogenic variables and water quality parameter concentrations in groundwater wells. Overall, the type of aquifer has an important role in the creation of hydrogeological conditions and the vulnerability of areas to various environmental and anthropogenic stresses (Ashraf et al., 2017). The dominance of porous aquifers in the studied areas indicates increased water storage and transport capacity but at the same time

increased sensitivity to pollution from agricultural activities or other anthropogenic sources of pollution (Machiwal et al., 2018). The presence of sulfate (SO_4), nitrate (NO3), and chloride (Cl) indicates possible contamination due to anthropogenic activities affecting the quality of groundwater. The high concentration of nitrates and sulfates results from chemical pollution from agricultural (e.g. pesticides and fertilizers) and industrial activities, while the increased concentration of chlorides (Cl) is usually associated with excessive amounts of water in coastal areas (Akhtar et al., 2021).

Multivariate approaches like factor analysis can use and correlate numerous parameters. Factor analysis was performed to interpret the statistical methods according to the available data, proving to be a helpful tool for monitoring the groundwater quality. According to the results, this method provides the distribution and origin of water parameters. However, this study shows that additional data are required for the analysis of elements, including trace elements, with sufficient quantified values, so that the factor analysis does not overestimate or underestimate the influence of anthropogenic factors (e.g. industrial or agricultural activity). The estimation of the distribution and the improvement of the measurement methods of trace elements are necessary for the accurate analysis of hydrogeological processes and anthropogenic influences, as well as for enhancing the accuracy of statistical models, facilitating the identification of pollution sources. Furthermore, it is easier and more dependable to evaluate the results when they are presented utilizing Geographic Information Systems techniques (Mathenge et al., 2023; Xu & Zhan 2023). More extensive research can assist in developing a long-term groundwater management strategy for different objectives. Above all, it seems helpful to analyze geographical zones to identify high-pollution areas, the causes of pollution, particularly for heavy metals, and the agricultural applications that have an impact on nitrate levels.

Acknowledgements

The authors gratefully acknowledge the support of the National Monitoring Water Network and HSGME for providing open data that significantly contributed to the completion of this research. This study was conducted as part of the PhD dissertation, funded by the Athens Water Supply and Sewerage Company (E.Y.D.A.P.) within the framework of the IKY-EYDAP Scholarship Program for the academic year 2024-25.

Abstract

This study presents a methodology automatically detecting and extracting geological lineaments on Amorgos Island using satellite data and open-source software. The approach utilizes Landsat 8 satellite images and employs a newly developed Python-based algorithm, GeoLine, for automated lineament detection. The results demonstrate a dominant NE-SW orientation of lineaments, which aligns with previous geological studies of the region. The extracted lineaments show a 53% correlation with existing geological maps, confirming the reliability of the proposed approach.

Introduction

Geological lineaments represent structural discontinuities such as faults and fractures and play a crucial role in geoscientific studies. The ability to extract and analyze these features using remote sensing has been a growing research area. Various remote sensing techniques, including manual, semi-automated, and automated methods, have been employed for lineament detection (Tsilavo et al., 2006). The choice of techniques depends on the research objectives and available datasets, such as optical and radar imagery (Yathunanthan et al., 2014).

This study focuses on the automated extraction of geological lineaments using open-source software. By leveraging satellite data and computational techniques, it aims to develop an efficient and reproducible methodology for detecting geological structures, contributing to advancements in structural geological analysis.

Geological setting

Amorgos Island is located in the southeastern part of the Attic-Cycladic Crystalline Complex of Greece. This region formed as a result of the northward subduction of Gondwanan fragments beneath the Eurasian plate (Pe-Piper and Piper 2002; Papanikolaou 2021). The island's geology includes metamorphosed clastic sequences, carbonates, and flysch deposits, which are divided into three regions: northeastern, central, and southwestern (Figure 1, Laskari et al., 2022). The rocks of Amorgos have undergone multiple deformation events, particularly in the later stages, including alpine and neotectonic faults. The latter are associated with the 1956 offshore earthquakes (Papadopoulos and Pavlides 1992). Therefore, Amorgos provides an ideal setting for applying the automatic detection and extraction method of geological lineaments.

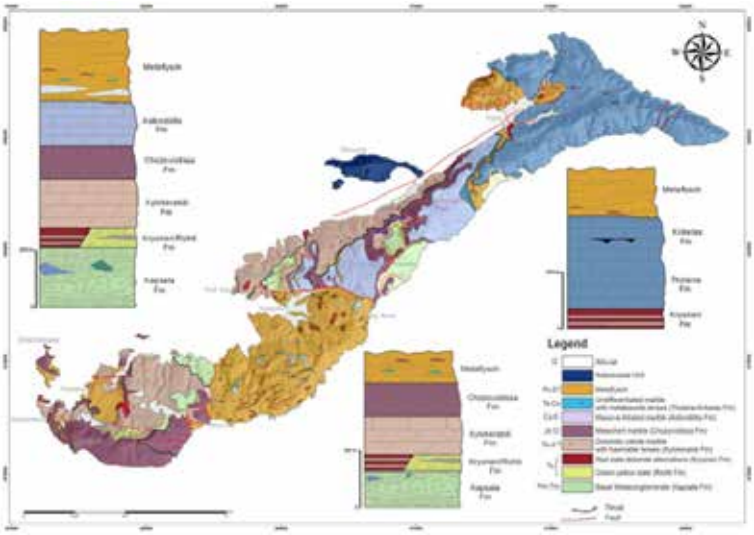

Figure 1. Geological map of Amorgos Island and lithostratigraphic columns of southwestern, central, and northeastern Amorgos (adapted from Laskari et al., 2022)

Data

For the objectives outlined, satellite imagery from the NASA Landsat 8/9 satellites was selected as the primary dataset source, based on accessibility, spatial resolution, spectral range, and enhancement capabilities even though Sentinel-2 imagery could have been used as well.

For this study, one Landsat 8 image acquired on May 27, 2022(Level 2 data product: "LC08_L2SP_181034_20220527_20220603_02_T1"), has been used. This image included layers such as surface reflectance (SR), surface temperature (ST), intermediate ST bands, angle coefficient files, and quality assessment (QA) bands.

Method

Satellite data pre-processing was conducted in QGIS 3.22.1 using the Semi-Automatic Classification Plugin (SCP). Pansharpening was applied through the GDAL toolbox with Nearest Neighbor (NN) resampling. Dimensional reduction was performed using Principal Component Analysis (PCA) with PC1 selected for analysis. The final processed image had dimensions of 2067×1253 pixels, and a 15×15-meter pixel size. The image was segmented into 400×400-pixel tiles.

For automated tectonic lineament extraction, a Python-based algorithm called GeoLine was developed. Image import and georeferencing were handled using the GDAL library. Edge detection was performed with Canny algorithm. Vectorization was achieved through the Probabilistic Hough Transform (PHT), extracting edges as vector lines while refining parameters such as minimum length and angular tolerance (Fig. 2). The generating shapefiles were merged in QGIS, and a rose diagram was created using the Line Direction Histogram plugin.

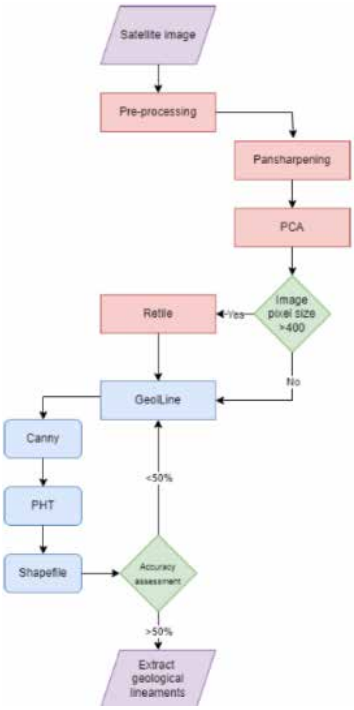

Figure 2. Methodology's Flowchart.

Results And Discussion

This study evaluated the accuracy and relevance of the extracted geological lineaments by comparing them with published geological datasets. Five image sets were generated using different parameter configurations for the Canny and PHT algorithms.

Validation was conducted by comparing the extracted lineaments with datasets from Laskari et al. (2022) and the Hellenic Society of Geology and Mineral Exploration (H.S.G.M.E.) (Fig 3.). Additionally, the results were assessed against PCI Geomatica 9.1 software (Salui, 2018), where seven image sets were generated using different parameter configurations.

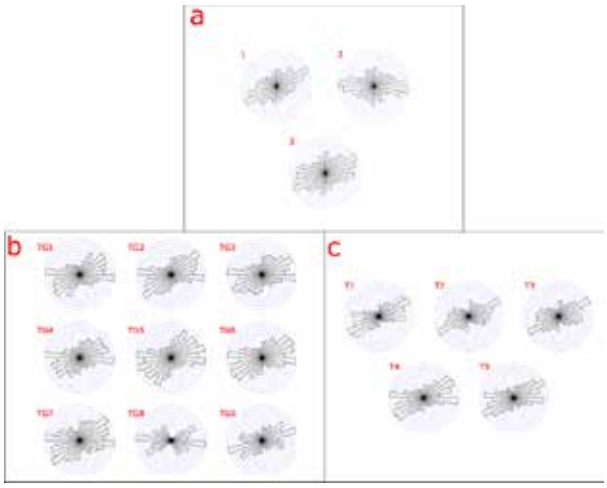

Figure 3. Rose diagrams of lineaments: (a) Ground truth data (1: Laskari et al., 2022; 2: H.S.G.M.E.; 3: combination of 1 & 2), (b) Geomatica Line algorithm, seven datasets with different parameters, (c) GeoLine algorithm, five datasets with different parameters.

Correlation analysis using the LineComparison plugin revealed an overall low correlation due to the limited distribution of control data. However, focused comparisons in specific regions around the control data consistently exceeded 33%. Notably, both Geomatica and GeoLine achieved correlation rates of up to 53%, with the T4 and TG7 datasets displaying the highest correlation percentages (Fig. 4).

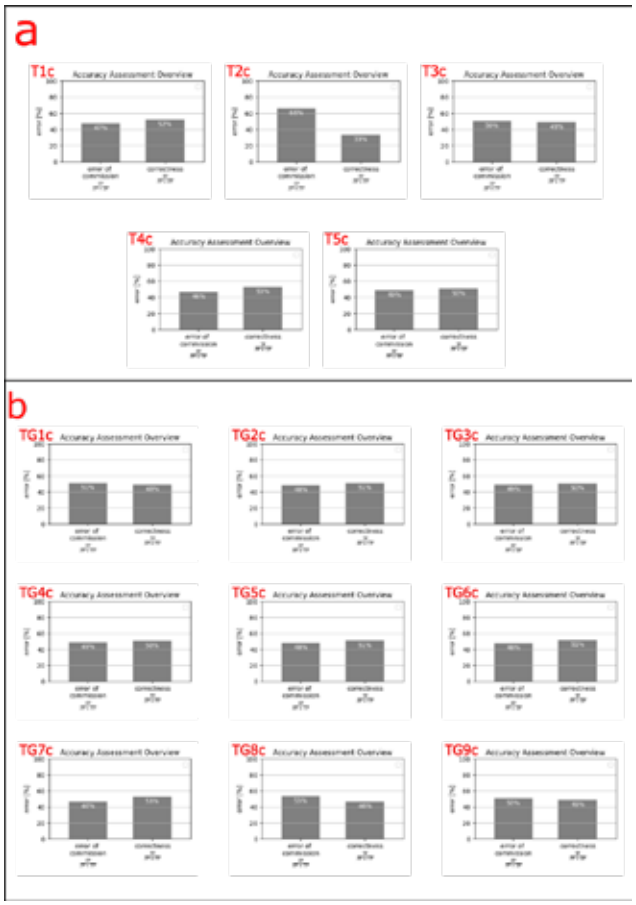

Figure 4. Accuracy assessment in demarcated zone with a) GeoLine dataset, and b) Geomatica dataset.

Although the results are promising, there is still room for improvement in terms of precision, accuracy, and usability. Future efforts will focus on two key areas.

First, enhancing result efficiency by refining GeoLine to improve post-lineament extraction capabilities. This includes achieving better correlation between detected lineaments and generating more accurate polygonal chains. Expanding the methodology to incorporate a wider range of satellite data sources, such as SAR images for terrain relief and high-resolution multispectral imagery like WorldView-3, would further improve accuracy and applicability.

Second, improving usability by automating procedural steps and integrating them into a user-friendly QGIS plugin. This would make the methodology more accessible to researchers with limited programming skills. Developing an open-source plugin would simplify data input and lineament extraction, streamlining workflows and broadening access for geoscientists.

These advancements would greatly enhance both the effectiveness and accessibility of the GeoLine algorithm, establishing it as a more valuable tool for geological research.

Conclusions

This study demonstrates the efficiency and accuracy of the developed methodology in extracting geological lineaments from satellite imagery, by showing a significant correlation with existing geological data. GeoLine shows strong potential for large-scale geological surveys, further refinement is needed to minimize noise and enhance accuracy in complex geological settings. By offering a reproducible and efficient methodology, this research contributes to the growing body of knowledge in the field of automated geological mapping.

Major and trace element analysis on geological samples using WD-XRF on pressed pellets

I. Gerontidou[1], A. Koroneos [1]

(1) Department of Mineralogy-Petrology-Economic Geology, Faculty of Geology, Aristotle University of Thessaloniki, Thessaloniki, Greece, ioangero@geo.auth.gr.

The sample preparation protocol and the analytical method of elemental analysis using WD-XRF Supermini200 from Rigaku Holdings Corporation, are presented. The use of pressed pellets, traditionally employed for trace element analysis, is examined and proposed for major element analysis as well.

Introduction

Wavelength Dispersive X-ray Fluorescence (WD-XRF) spectrometry has been the cornerstone of elemental analysis for geological samples. It is a non-destructive analytical technique that provides high accuracy and precision, when measuring the composition of both light and heavy elements (Beckhoff et al., 2007; Rainer, 2016). Measuring major elements is quite a challenge because light elements emit weaker fluorescent energies. This problem was approached with the use of fused beads because they offer optimal homogeneity within the sample and a smooth surface for the primary X-ray to hit, minimizing energy scattering and absorption effects (Beckhoff et al., 2007). That's why major element XRF analysis has been, almost exclusively, done on fused glass beads. However, sample fusion is costly, requiring the purchase and maintenance of a fusion machine and Pt-Au ware. Moreover, it is time-intensive due to multiple stages of preheating, prefusion, fusion and air cooling.

In this study, the use of pressed pellets for major element analysis is examined, by creating and calibrating an empirical hybrid quantitative method using certified reference materials. The use of pressed pellets is the most cost effective and time saving sample preparation method. The core of this research is the comparison of certified reference material values with their obtained results using the proposed method. Along with the major elements, the commonly used trace elements in geological research are calibrated into the method, broadening its utility.

Sample preparation

The most important part of calibrating a new analytical method is to maintain a consistent sample preparation protocol (Marguí & Queralt, 2024). The reliability of the results is always dependent on proper sample handling. For this reason, thorough care is taken to keep the lab-ware clean and to work in a laboratory environment with limited dust, ensuring minimal contamination from the surroundings.

Geological samples, due to their inhomogeneity, cannot be analyzed directly as a solid. Instead, the rocks are first crushed using a steel jaw breaker, downsizing them to an approximately 2cm fracture size. The next and most crucial step is pulverizing the rocks to a fine powder. To evaluate the use of pressed pellets over fused beads, it is vital to achieve sample homogeneity. Pulverization is also the most prone step to contamination, which is the reason many researchers have investigated its effects (Thompson & Bankston, 1970; Hickson, 1986; Roser et al., 2003; Mojtahed et al., 2006; Saikia et al., 2009; Takamasa & Nakai, 2009; Morikawa, 2014; Yamasaki, 2018).

Among the available options, using tungsten carbide (WC) pulverizing mill bowl is the most time-efficient choice, and essential for quartz-bearing siliceous rocks. However, it can affect the elemental composition of the sample. Morikawa (2014) presents the contamination of a SiO_2 sample, with W, Cu, Co, Ni and Fe, Yamasaki (2018) and Saikia et al. (2009) confirm the Co and W contamination of volcanic rocks and a quartz sample respectively and Mojtahed et al. (2006) suggests the added impurity of W, Co, C, Ti, Ni, Ta. Those studies point out the drastic effects of the pulverization duration. Morikawa (2014) displays the impurities present at 3, 5 and 10 minutes, Saikia et al. (2009) at 5 minutes, whereas Yamasaki (2018) indicates Co (~10 ppm) and W (up to 100 ppm) contamination at 40 sec and lastly, Roser et al. (2003) confirm the Co and W contamination at 30sec pulverizing time using tungsten carbide mill.

To avoid any contamination mentioned above, the proposed protocol follows strictly the under 10 second duration time in WC pulverizer, preferably at 5 seconds. Another measure taken to ensure the purity of the sample is following the technique of prewash, where a small portion of the sample is grinded and discarded, before continuing with the rest of the sample. For the last step of pulverization, to ensure the fine grain size (smaller than 50μm), the sample is grinded on a manual agate mortar. The agate mortar has been proven to add limited contamination (Takamasa & Nakai, 2009).

The typical procedure for pelletizing geological samples is followed. The sample must be mixed with a reagent to behave

as a binder, guaranteeing the cohesion of the pressed solid disc. These reagents improve uniformity, durability, and increase the density of the pellet, creating a consistent surface to analyze. This study's protocol uses CEROX from FLUXANA GmbH & Co. KG, as a binder, which is known as Hoechst wax ($C_{38}H_{76}N_2O_2$). It is very low on impurities and resistant to X-rays. It is mixed with the sample on a 1:4 ratio (Rainer, 2016), more specifically 2 grams of the binder are mixed with 8 grams of the sample. In the case that the sample has very high relative density, the portions are increased accordingly to achieve infinite thickness (Marguí & Queralt, 2024) of the pressed pellet. X-rays can penetrate the sample up to a few millimeters that's why the pellet must be thick enough (>0.5 cm) for the penetration to not go further to the back of the pellet. The mixture of sample-binder is then inserted into the automatic Retsch 200 mixer mill for homogenization. After testing, the most optimal mixing is achieved at 15 minutes by fluctuating the speed of the mixer, turning it from low to high. This lets the particles mix more efficiently than letting the mixer work on high for the whole period. In the end, the palletization is completed with the Specac 15-ton Hydraulic press with the 40 mm pressing dies. XRF machines are sensitive to dust, so to make sure the pellet won't break inside the instrument, the durability of the pellets is tested with the drop test. The drop test involves the free fall of the pellet from 15 cm distance from a flat surface. The pellets that pass the fall test, show a homogeneous surface without colored spots that would indicate the differentiation within the solid, and have a smooth flat surface, are ready for analysis. The maintenance of the pressing dies is important to achieve the desired smooth flat surface.

Part of the sample preparation is also the calculation of loss on ignition (LOI). Geological samples contain volatiles like CO_2 (e.g. in calcite) and crystalline water (bound H_2O^+ found in OH-bearing minerals like amphiboles or micas). These elements cannot be analyzed with XRF. Modern XRF analytical methods can estimate the LOI without the need of pre-calculation. However, for better accuracy it is recommended to calculate LOI beforehand, by exposing the samples in high temperatures and measuring mass loss (Brouwer, 2003). Approximately 2 grams of the fully dried sample is inserted into a fully dried heat-resistant ceramic capsule and then placed in a high temperature furnace. This protocol suggests first heating the samples at 150°C for 15 minutes and then at 1050°C for 120 minutes, so that the temperature is gradually going up. At 1000°C there is complete removal of volatiles (Lechler & Desilets, 1987). After cooling down, the capsules are weighed to calculate the mass loss. The final goal of this procedure is to calculate the volatile content of the sample so that the LOI % value can be in the sample's final composition to be normalized to 100%. It is highlighted that the samples and crucibles are fully dried before the heating, so that moisture water (H_2O^-) is not confused with bound water (H_2O^+) at the LOI value.

Instrument specifications

The Superimini200 is a benchtop Wavelength Dispersive X-ray Fluorescence (WD-XRF) spectrometer from Rigaku. It is equipped with a Pd anode X-ray tube, operating at 200W power. The X-ray beam is filtered using a Zr filter. The system utilizes two primary crystals: LiF(200) and PET, coupled with two detectors: a flow proportional counter and a scintillation counter. It has a broad elemental detection range from O to U. For analysis on solids, the system operates under vacuum. The instrument requires a P10 gas mixture (10% Ar - 90% CH_4) as its primary consumable. To ensure optimal performance and consistent analytical results, the laboratory environment temperature must be kept below 28°C. The fluctuation in laboratory temperature has been observed to affect drastically the quality of the results, so the importance of maintaining a constant temperature of 20-25°C is highlighted.

Analytical method

The Supermini200 operates using the ZSX Guidance software, which is user-friendly and provides extensive control over the calibration and data analysis. For this study, the analytical method was developed using nineteen certified reference materials (CRMs) from FLUXANA. These standards were carefully selected to cover a wide compositional range, ensuring that the calculated results for unknown samples fall within the calibration range. Specifically, the analytical method achieves optimal precision when the unknown sample's composition lies between the highest standard composition (Point A) and the lowest standard composition (Point B) for each element. Since this analytical method was meant for geological samples, silica content is a useful indicator, so it was essential to cover a large range. The standards that were picked cover the silica range from 35.69% to 73.42%.

The method quantifies major elements in their oxide forms, including SiO_2, Al_2O_3, K_2O, Na_2O, MgO, CaO, TiO_2, MnO, Fe_2O_3, P_2O_5, and SO_3 in percent (%), as well as the trace elements Rb, Sr, Ba, Zr, V, Cr, Co, Ni, Cu, Zn, Pb, Sc, Y, Ga, and Nb in ppm.

The analytical method is classified as a standardized method, more specifically as an empirical analytical method. Its basis is the calibration curve, which is represented graphically from the relationship between the standards' certified analytical values (x axis) and their X-ray fluorescent intensities (y axis). This correlation then is used to obtain the content of the unknown sample by projecting the unknown sample's X-ray intensity on the graph (Brouwer, 2003).

The method includes the «optimizing measuring conditions» (OMC), which determines the measurement conditions for each element. This step is prior to the measurement of the standards and hence the calibration. It is critical because it affects all the next steps, and it would be very time-consuming to go back to adjusting this step after completing the method. For the OMC, standards are first measured with the highest and the lowest content for each element to take scans. The OMC is divided into four parts, determining the peak position, selecting background points position, setting counting time and adjusting the pulse height analyzer (PHA) window. The peak position (2-theta degrees) is unique for each element, there is a theoretical value, but this can vary depending on the laboratory conditions. Background noise from scattered X-rays was negligible for major elements, therefore background points weren't needed. Background points were selected for all the trace elements, with most requiring two points to form linear background (BG) coefficients, except from Co and Sc where three points were selected, forming quadratic BG coefficients. Effective management of measuring time is crucial so that accurate results are achieved without unnecessary delays. Insufficient measuring time can lead to poor precision, while excessive measurement can reduce the efficiency of the method. The measuring times allocated for each element were: 40 seconds (sec) for the peaks of major elements and 40-140 sec for the trace elements, depending on their complexity. For example, 139 sec were chosen for Ba, a challenging element to measure because of its overlap with Ti, whereas 40 sec were sufficient for Ni. Each background point is measured for 10 to 33 sec. The total analysis time is calculated to be 34 minutes per sample. PHA window was widened for all elements to include their entire signal.

Another important part of the analytical method creation is drift correction. Over time, instrument aging, temperature fluctuations and changes in environmental conditions affect the X-ray intensities. To overtake these variations and maintain result stability, drift correction materials are measured on the day the method is created, and the results are stored in the software for the instrument to use during subsequent measurements and adjust accordingly. It works as a monitor to bring the method back to its calibrated state. In this study, the Alpha-Beta drift correction method was applied, using high and low concentration standards for as many elements as possible. Specifically, BR SQ1N and BR SQ3N glass discs from Bruker Corporation were used for Si, Al, K, Na, Mg, Ca, Ti, Mn, Sr, Ba, Zr, Zn and Pb. It is essential to update the drift correction library, before and after any maintenance service of the instrument.

Three corrections were made. First, a mixing ratio correction (0.25) was applied for the binder, using a 1:4 binder-to-sample ratio to account for the dilution effect of the binder on the sample's X-ray fluorescent intensity. Lastly, overlap and matrix corrections were chosen for elements whose peaks overlap or show absorption/enhancement respectively. The analytical element lines with their correction lines are displayed on Table 1.

Table 1. Element lines with their correction line(s)

Element line	Si-KA	Al-KA	K -KA	Ca-KA	Mn-KA	Fe-KA	P -KA	S -KA
Correcting line(s)	Al-KA	Ca-KA Si-KA	Fe-KA	K -KA	Cr-KA	Mn-KA Co-KA Si-KA	Zr-KA Ca-KA	Ti-KA Pb-LA
Element line	Rb-KA	Sr-KA	Ba-LA	Zr-KA	V -KA	Cr-KA	Co-KA	Ni-KA
Correcting line(s)	Sr-KA Al-KA	Ca-KA Rb-KA	Sc-KA Cu-KA Ti-KA	Sr-KA Y -KA	Ti-KA Ba-LA Cr-KA	V -KA	Fe-KA Ni-KA	Y -KA Rb-KA
Element line	Cu-KA	Pb-LA	Sc-KA	Y -KA	Ga-KA	Nb-KA		
Correcting line(s)	Sr-KA	Si-KA Zr-KA	Ca-KA Ti-KA	Rb-KA	Al-KA	Zr-KA V -KA		

The empirical method was converted to Fundamental Parameters (FP) method to achieve greater accuracy (Rousseau, 2013). The empirical method, while effective for calibration, relies heavily on the standards and appears problematic when a sample shows heterogeneity in the matrix. This means that for samples that don't contain a high variety of elements, the empirical method is sufficient to quantify them, with the best accuracy. In the case of rocks where a lot of elements are present and there is a heterogeneous matrix (complex mineral assemblance) there is a misfit (Beckhoff et al., 2007). For a purely empirical method to work well for rocks, an extremely large number of standards would be needed, which is not possible to use. With the conversion of the empirical method to FP, theoretical equations are introduced to correct matrix effects (Rousseau, 2006; Kawai et al., 2019), rather than relying solely on empirical data, but still using them. This way, analysis of samples outside of the exact compositional range of the calibration standards is possible. This hybrid method proved to be more accurate than the purely empirical methods that were developed.

To ensure the ongoing validity of the analytical method, the software provides the ability to input a check sample. This

check sample is used as a consistent reference analyzed every time before a batch of unknown samples is analyzed. It has known composition and standard deviation values, which are predefined within the software. This way, the system automatically flags results that deviate beyond acceptable limits (high and low). It's best to also test the sample preparation process by making new pressed pellets occasionally of the same check sample's powder.

Validation – Accuracy and precision

The validation of an analytical method is a significant step after the calibration, this method was validated in-house (Boqué et al., 2002). For this study, six certified reference materials were used for the validation of the method to cover a wide range of silica content, from 42.38% to 73.42% (CRM values). This is so the validation covers a wide range of concentrations (Boqué et al., 2002) for geological samples. These samples are listed in Table 2 with their basic information.

Table 2. Certified reference materials used for the validation of the method.

No.	FX part number	Manufacturer	Manufacturer's code	Application
1	FI000042	GSJ	JP-1	peridotite
2	FI007834	GSJ	JB-2a	basalt
3	FI000048	GSJ	JSy-1	syenite
4	FI007152	GSJ	JA-1	andesite
5	FI000097	GSJ	DC71302	trachyte
6	FI007981	GSJ	GM	granite

Accuracy and precision are two key properties that determine the quality of the analytical method. Accuracy reflects how close the calculated result is to the true or correct value, while precision indicates the reproducibility of the results (Ragland, 1989).

To assess precision, Ragland (1989) proposes duplicate analyses on five samples, for each major element to calculate the percent deviation or coefficient of variation (V) from equation 1 (Tab. 3). V is perceived as a measure of error or precision. For this study triplicate analyses were carried out on six samples (Tab. 2). Before calculating V, the results per element must be standardized to be comparable. To do that, the average $\bar{x}$ (for each sample) and the grand mean $\bar{x}_G$ (average from all samples) are calculated to find the factor f from equation 2 (Tab. 3). Then, to standardize the results, each calculated value is multiplied with f, equation 3 (Tab. 3). Standard deviation (s) is calculated from the standardized results; hence V is calculated from the standardized results (equation 1 from Tab. 3).

Table 3. Equations used for precision and accuracy measures. Modified from Ragland (1989).

$V = 100s/\bar{x}_G$	equation 1
$f = \bar{x}_G / \bar{x}$	equation 2
f * element %	equation 3
$x^2 = \Sigma[(O-R)^2/R]$	equation 4

For the main major elements Al_2O_3, TiO_2, Fe_2O_3, MgO, CaO, Na_2O, K_2O, Ragland (1989) indicates that V should be < 3-4 % per oxide, whereas for SiO_2 V should be < 2 %. For this study, Al_2O_3, TiO_2, Fe_2O_3, MnO, MgO, CaO, Na_2O, K_2O have V ranging from 0.9 % to 3.9 % and SiO_2 has V = 0.068 %. For P_2O_5 and S_2O_3 V is 4.3 % and 4.9 % respectively, these elements are not approached by Ragland (1989), this V value is accepted because of the small content of P and S in these rocks and the difficulty of quantifying them.

To evaluate accuracy, Ragland (1989) describes the procedure of comparing the certified reference material value and the obtained concentrations for elements in one or more standards. He highlights the importance of these samples not being part of the regression calculations for the calibration curve. As an estimate of accuracy, he uses Chi-Squared (x^2) from equation 4 (Tab. 3), where "O" is the obtained value and "R" is the reference material value. The x^2 is calculated for each single comparison standard for the sum "Σ" of the major elements. This study's major elements had x^2 values ranging from 0.006 to 0.13. Ragland (1989) considers acceptable values for major elements with x^2 < 0.10-0.15.

For better presentation of the results, major and trace elements are projected with their obtained (y-axis) and certified reference material (x-axis) values in figures 1 and 2 respectively. On figures 1 and 2, the equations of the linear regression lines in the form of y = bx + a and the coefficient of determination R squared (R^2) are displayed. The quantity R^2 represents the variation of the data, a value near 1 indicates a good fit, whereas a value near 0 indicates a poor fit (Ross, 2010).

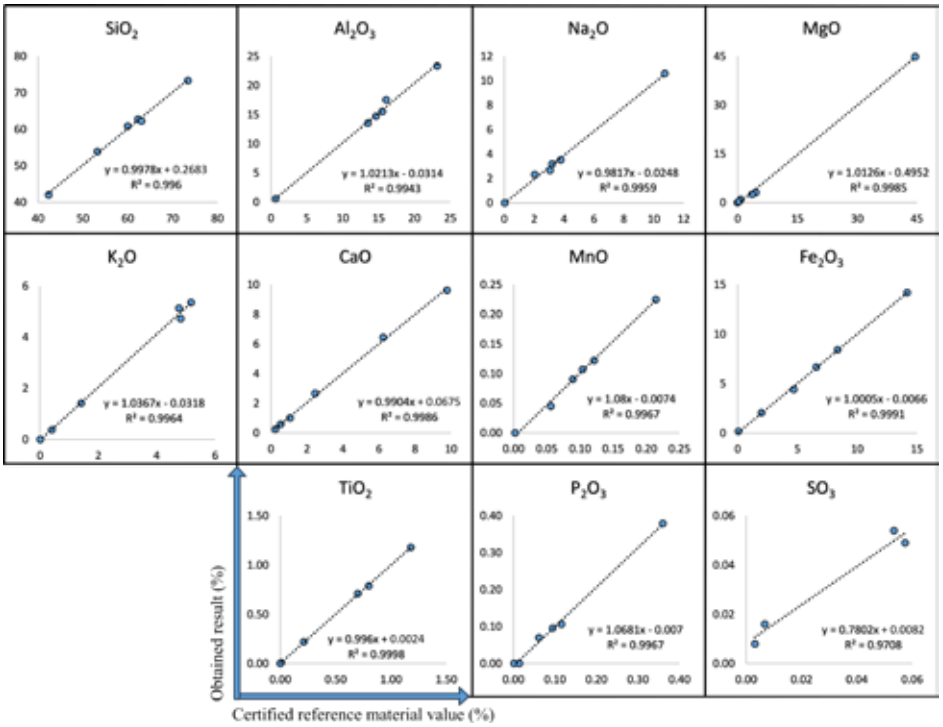

Figure 1. Certified reference material vs obtained result values for the major elements

The results for the major elements showed a coefficient of determination (R^2) higher than 0.99 for the major elements (Fig. 1), except for SO_3 yielding an R^2=0.97, which is considered a challenging element with very low content in the rocks studied. These results show excellent fit ($R^2 > 0.95$). This reflects a strong linear relationship between the obtained and the certified reference values.

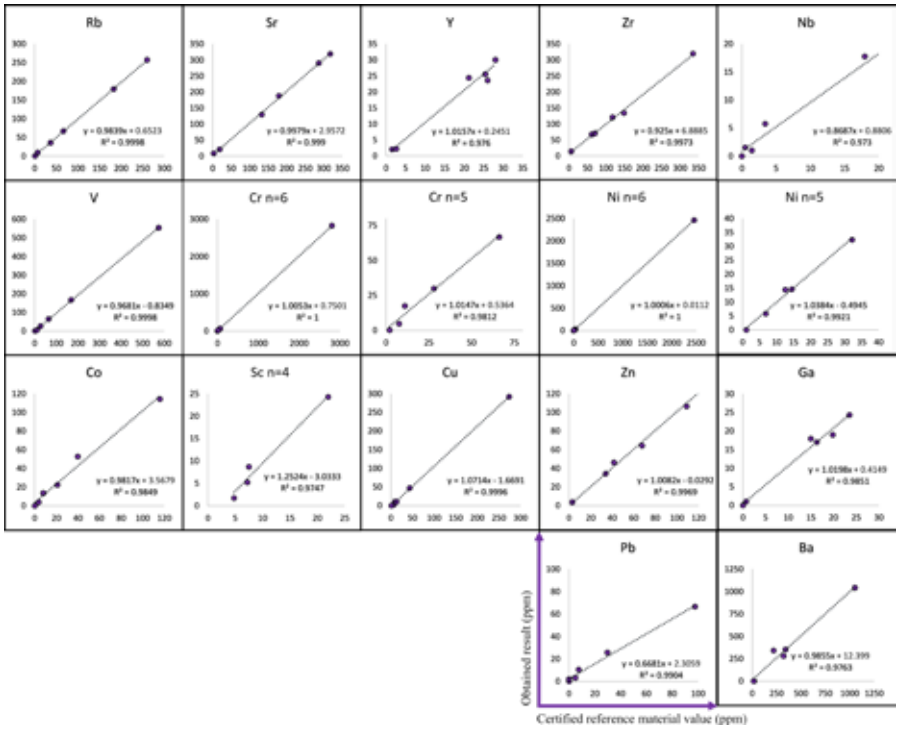

Figure 2. Certified reference material vs obtained result values for the trace elements.

The results for trace elements (Fig. 2) showed a correlation factor R^2 >0.99 for Rb, Sr, Zr, V, Ni, Cu, Zn, Pb and R^2>0.97 for Y, Nb, Cr, Co, Sc, Ga, Ba. For Cr and Ni, two diagrams are presented for 6 of the samples (n=6) and 5 samples (n=5), respectively, as one sample had an extremely high content that skewed the. To accurately test correlation between the samples, they must have comparable contents without extreme outliers. For Sc, 4 samples are plotted on the diagram (n=4) because the other two standards lacked certified values.

Limit of detection and limit of quantification for major elements.

Another important aspect of the analytical method set up is the determination of the limit of detection (LOD) and limit of quantification (LOQ). These values ensure the method's capability to reliably detect and quantify elements across the user's preferred concentration range (Shrivastava & Gupta, 2011). The LOD describes the lowest concentration of an element that can be detected but not necessarily quantified. The LOQ is the minimum concentration that can be quantified with acceptable precision and accuracy. For major elements the LOD and LOQ are calculated using equation i and equation ii respectively, with "s" as the standard deviation and "b" as the slope of the calibration curve (Tab. 4).

Table 4. Equations for LOD and LOQ calculation from Shrivastava & Gupta (2011)

LOD = 3s/b	equation i
LOQ = 10s/b	equation ii

For this study, the standard deviation (s) for each major element was calculated based on the average of the obtained results for the sample with the lowest concentration and its certified value (CRM). The slope (b) was derived from the equation y=bx+a, as determined from the regression lines presented in Fig. 1 and Fig. 2. The LOD and LOQ calculations, along with the obtained and CRM values, as well as the s and b for each oxide, are presented in Table 5.

The low LOD and LOQ values for major elements confirm the sensitivity of the method.

Table 5. LOD and LOQ values for major elements

Oxide	obtained value %	CRM value %	s	b	LOD %	LOQ %
SiO_2	42.30	42.38	0.0566	0.9978	0.170	0.567

P_2O_5	0.10	0.10	0.0007	1.0681	0.002	0.007
SO_3	0.02	0.01	0.0066	0.7802	0.025	0.084

Conclusions

Major element analysis has traditionally been done on fused glass beads, however in this study, major element analysis, in addition to trace elements, has been calibrated on pressed pellets. The accuracy and precision of the method were verified through multiple analyses on certified materials to ensure the reproducibility and results close to their true values. Major element analysis on pressed pellets has also been examined by Yamasaki et al., (2023) with a purely standardized method, who reported correlation results ranging from 0.9525 to 0.9989, thus proposing it for semi-quantitative analysis. The correlation results of the examined method range from 0.9943 to 0.9998 for the same ten main major elements (SiO_2, Al_2O_3, K_2O, Na_2O, MgO, CaO, TiO_2, MnO, Fe_2O_3, P_2O_5). The conversion of a purely empirical standardized method to a fundamental parameters method, could be the cause of the increased accuracy of this study's results. This quantitative analytical method was developed through the process of «trial and error», where adjustments were made based on observed errors until the desired accuracy was achieved. Important factors in creating such a method are sample preparation and corrections application. It is worth noting that this analytical method has been employed for two years at Aristotle University of Thessaloniki, in both undergraduate and postgraduate research. To ensure reliability, drift correction is conducted weekly, and the check sample is analyzed daily ensuring that any variations in instrument performance are corrected, and the results remain consistent and accurate over time.

The Art of Stone in Grevena-Kozani UGGp: Community-led Conservation Efforts

Ghikas D.[1], Batsi A.[1]
(1) Grevena-Kozani UGGp, Kozani, Greece, geowonders@gmail.com

Introduction / Background

Grevena-Kozani UNESCO Global Geopark

Grevena-Kozani UGGp is located in West Macedonia and covers an area of 2.486km2. The territory joined the UNESCO Global Geoparks Network in 2021 and was the 6th geopark in Greece. UNESCO Global Geoparks (UGGp) are single, unified geographical areas where sites and landscapes of international geological significance are managed with a holistic concept of protection, education and sustainable development. A UNESCO Global Geopark uses its geological heritage, in connection with all other aspects of the area's natural and cultural heritage, to enhance awareness and understanding of key issues facing society, such as using our earth's resources sustainably, mitigating the effects of climate change and reducing natural hazard-related risks. At present, there are 213 UNESCO Global Geoparks in 48 countries (unesco.org).

Geologic Background

The territory boasts exceptional geodiversity, spanning the boundary between the internal and external structural zones of the Hellenides (Ferriere *et al.,* 2013). The geopark includes a large swathe of the Mesohellenic Basin (MHB), a Late-Eocene to Late-Miocene intermontane basin (Doutsos *et al*., 1994) filled with mostly siliciclastic turbidite sequences and shelf originally deposited in the Tethys Ocean, until thrusting of the Hellenide orogeny and post-orogenic extensional tectonics completed the structural evolution of this piggyback basin (Vamvaka, 2009 and references therein).

The MHB is a source of high-quality stone for construction, particularly within the Pentalophos and Eptahori formations which contain many sandstone and siltstone units which are well lithified, fine grained, minimally deformed and have low permeability (Tyrologou *et al.,* 2023). Communities living on or adjacent to outcrops of these rocks took advantage of this resource and developed an industry and culture based on stonework.

The Stone Masters of West Macedonia

Communities which were historical centers of stonework and building are collectively known as Mastorohoria (Master Villages). The craftsmen or masters would build structures out of locally available, high-quality stone and other natural materials. A building gang, or *boulouki,* composed of highly skilled masters, variously specialized technicians and artisans, and low-level workers, would depart from their village to a job site and remain there for many months, until the completion of the project (Poravos, 2023). Many mastorohoria are located within Grevena-Kozani UGGp, principally in the townships of Voio and Grevena, and many more communities and areas of the geopark feature stone architecture including homes, churches and bridges built by these masters.

The 20th century saw a precipitous decline of the Mastorohoria, as industrial building materials flooded the market and economic centers shifted elsewhere. Young males migrated away from the area, and remaining craftsmen did not document their knowledge. Today hardly any skilled workers exist, and many of the historic structures of this territory are in a state of decay, and their future is uncertain as their proper restoration depends on increasingly scarce qualifications. Improper or anachronistic renovations risk exacerbating the collapse of already fragile structures (Lianos, 2012) as well as obscuring their historic and aesthetic value.

In recent years, there has been a renewed interest in reviving the craft of stone building, as the region of West Macedonia has begun to invest in tourism and sustainability. For these efforts to be successful, the technical know-how of the original masters is of vital importance, and every means must be taken to preserve what knowledge remains. Additionally, the recognition of geoheritage, or the linking of geologic science with human society (Rassios and Grieco, 2021), is necessary for the region to be able to sustainably realize the touristic potential of its tangible and intangible cultural heritage.

Recent Community-led Conservation Efforts

In 2024, there were several developments in the revitilization of traditional stone architecture. Grevena-Kozani UGGp was able to contribute to these events and we are confident of long-term partnerships with the people and organizations who are working in this direction.

Announcement: School of Traditional Stoneworking, Pentalophos Voio

In May 2024, an assembly was held in the village of Pentalophos, Voio Township, at which the Minister of Culture, Ms. Lina Mendoni, together with professors from the National Metsovio Polytechnic University of Athens and Utah Valley University, announced the upcoming establishment of a School of Stone and Traditional Building Forms, to be based in the village of Pentalophos. From 21-27 October, these two schools held a field study course in Pentalophos, although the geopark was not able to participate in that event.

1st Traditional Stone Workshop, Kyparissi Grevenon

In August 2024, the 1st Workshop in Traditional Building, Art and Customs of the Craftsman Villages took place in the village of Kyparissi, the first workshop of its kind in the Township of Grevena. The 4-day event was a collaboration between the Community Association of Kyparissi, the Aristotelian University of Thessaloniki (AUTh), and a qualified stone master, Mr. Athanasios Poravos. Registered participants numbered about 30, coming from around the country, and had various backgrounds relating to architecture, engineering and history. Mr. Poravos guided the group through techniques for building a dry-stone wall, in the courtyard of the old stone schoolhouse of the village (now a museum). Participants received hands-on training in cutting, shaping and laying stones from Mr. Poravos, one of the few remaining First Masters in mainland Greece. In addition to the practical sessions, participants had lessons on various aspects of the stoneworking traditions of the region, including the history of vernacular architecture, as well as construction considerations including siting, framing, mortaring and repairing traditional stone structures. In the evenings, the group toured the villages of Kyparissi and Kalloni to examine their traditional building practices and current structural problems, and to learn the history of the area. Dr. Constantinos Katakalos (Dept. of Civil Engineering, AUTh) instructed participants on methods and materials for diagnosing, retrofitting and renovating traditional structures. Geopark staff guided the group through the geologic foundations of the Mastorohoria, with a tour of nearby outcrops and a classroom lesson and discussion on the geologic history of the territory.

Cultural practices related to stone working were also on display throughout the workshop, as local cultural societies, musicians, amateur artists and theater groups reenacted the emotional departure of workers from their communities and their arrival at seasonal building sites. Participants also learned words from *Koudaritika* (Stone Talk), the argo or secret language of the craftsmen, who wished not to be understood by their Ottoman rulers (Poravos, 2023). Events for the public included staged reenactments of some of the customs which marked both the annual departure of the workers from their villages, and the completion of a project. In the village of Sydendro, a village which was largely built by the craftsmen of the Mastorohoria, workshop participants and local authorities reenacted the tradition of *Bahcisia* (Tipping) whereby workers would climb onto the roof of a house which was nearly finished, erect a scaffolding and wooden cross, and pay hyperbolic (and somewhat ironic) compliments to the owner of the building and his family, in exchange for gifts. This custom has been submitted to UNESCO for recognition as Intangible Cultural Heritage.

Figure 1. Left: historical photograph of a *boulouki*. Right: reenactment of the *Bachcisia*.

8th Workshop on Traditional Building, Pentalophos Voio

In September 2024, Dr. Constantinos Katakalos (Dept. of Civil Engineering, AUTh) led the 8th Workshop on Traditional Building in the village of Pentalophos. Geopark staff were invited speakers and field experts to give the participants, who numbered about 25, geologic and geoheritage context for their studies. They had the opportunity, for most participants their first, to examine outcrops of Pentalophos sandstone and learn about its formation, age, properties

and what criteria should be used in assessing the quality of the stone as building material. They also learned how the landscape and climate influenced the local environment and culture, and received general information about the geopark and its activities. Local stone craftsmen (masters) were also present as honored guests, and at the conclusion of the workshop, participants received certificates of completion in a ceremony, officiated by the Pentalophos stone masters.

Conclusions

The distinctive vernacular architecture of the Mastorohoria, shaped by the local geologic history, is part of the unique character of the region. As West Macedonia strives to diversify its economy and stanch emigration, there is renewed and growing interest in reviving the craftsman traditions. This imperative will only grow as the stone structures of the territory will face continual need for maintenance. Grevena-Kozani UGGp is dedicated to the preservation of its historic stone structures, the continuance of its intangible cultural heritage, and the spread of knowledge about geoheritage—the indivisible bonds between geology and humanity.

Acknowledgements

The authors wish to thank A. Poravos, K. Katakolos, M. Stephanidou, and Z. Karanikou for sharing your knowledge. The communities of Pentalophos, Kyparissi, Kalloni and Sydendro for hosting these events. The municipal and regional authorities of Grevena and Kozani for welcoming the participants and supporting the geopark in its ongoing efforts for West Macedonia.

EXTENDED ABSTRACT 095

Paleoecological imprints of pteropod assemblages and their response to sapropel S1 conditions in the eastern Mediterranean Sea

Giamali C.[1], Kontakiotis G.[2], Antonarakou A.[2]

(1) The Goulandris Natural History Museum, Kifissia, Greece, ch.giamali@gnhm.gr, (2) National and Kapodistrian University of Athens, Faculty of Geology and Geoenvironment, Department of Historical Geology and Paleontology, Panepistimiopolis, Zografou, 15784, Athens, Greece

Research Highlights

Environmental factors during the sapropel S1 interval, affect pteropod assemblages in a way that the development of a precise eco-biostratigraphic scheme for the eastern Mediterranean Sea, seems feasible to accomplish.

Introduction

Pteropods are widespread and abundant in the global ocean and entirely adapted to a pelagic life cycle. They are considered valuable tool in paleoceanographic and paleoclimatic reconstructions due to their sensitivity in the environmental changes (Wall-Palmer *et al.*, 2014). Within the Mediterranean Sea, the preservation of pteropod shells is excellent because of the relatively shallow water, high bottom water temperatures, and the limited number of mud feeders (Herman, 1971). A considerable number of studies present the late Quaternary pteropod assemblages and their distribution pattern in the western and/or central Mediterranean basin (Buccheri *et al.*, 2002; Herman, 1971; Wall-Palmer *et al.*, 2014). In the eastern sector and particularly the Aegean Sea the only available data are that extracted from the gravity cores AEX-15, AEX-23, KIM-2A (Giamali *et al.*, 2019; 2020). These three cores constitute the only high-resolution records that depict their pattern during the deposition of the most recent sapropel S1. In the current work, we focus on understanding the response of the pteropod fauna in environmental changes during the sapropel S1 deposition. To do so, correlations with the distributional patterns of planktic foraminifera were also made. This preliminary attempt may lead to a future establishment of eco-biostratigraphic zonation based on pteropod assemblages.

Material & Methods

For the needs of our study, we used the data published by Giamali *et al.*, (2019; 2021), from two gravity cores, one in the north Aegean Sea, AEX-15, and one in the south Aegean Sea, KIM-2A (Fig. 1). In these cores, a total of 13 species of Euthecosomata (*Heliconoides inflatus, Limacina trochiformis, Limacina bulimoides, Limacina retroversa, Creseis acicula, Creseis sp., Boasia chierchiae, Hyalocyclis striata, Styliola subula, Clio pyramidata* s.l., *Clio cuspidata, Diacria trispinosa, Cavolinia* spp.) were identified. Here, we focus on the species that present a notable distributional pattern and were encountered in both cores in the interval from 10.0 ka to 5.0 ka. These are *H. inflatus, L. trochiformis, C. acicula, C. pyramidata,* and *D. trispinosa.* Furthermore, a correlation was made with planktonic foraminifera species that are common within the sapropel S1 (Cassford *et al.*, 2002; Kontakiotis, 2016). Sapropel layers in AEX-15 spans from 9.6 ka to 6.1 ka (with the interval between 7.0 ka and 6.1 ka being the oxidized part) and in KIM-2A from 9.4 ka to 6.4 ka with the sapropel interruption (S1i) placed at 7.8 ka to 6.8 ka. Comparison of these two cores is challenging and demanding as it includes two regions with different hydrographic characteristics and climate contrasts between more humid conditions in the north and semiarid conditions in the south and (Lykousis *et al.*, 2002). Moreover, data availability differs between the cores, due to higher resolution sampling of AEX-15 core. However, the downcore variation of the fauna enables an initial recognition of the imprints left by environmental changes on the pteropod distribution.

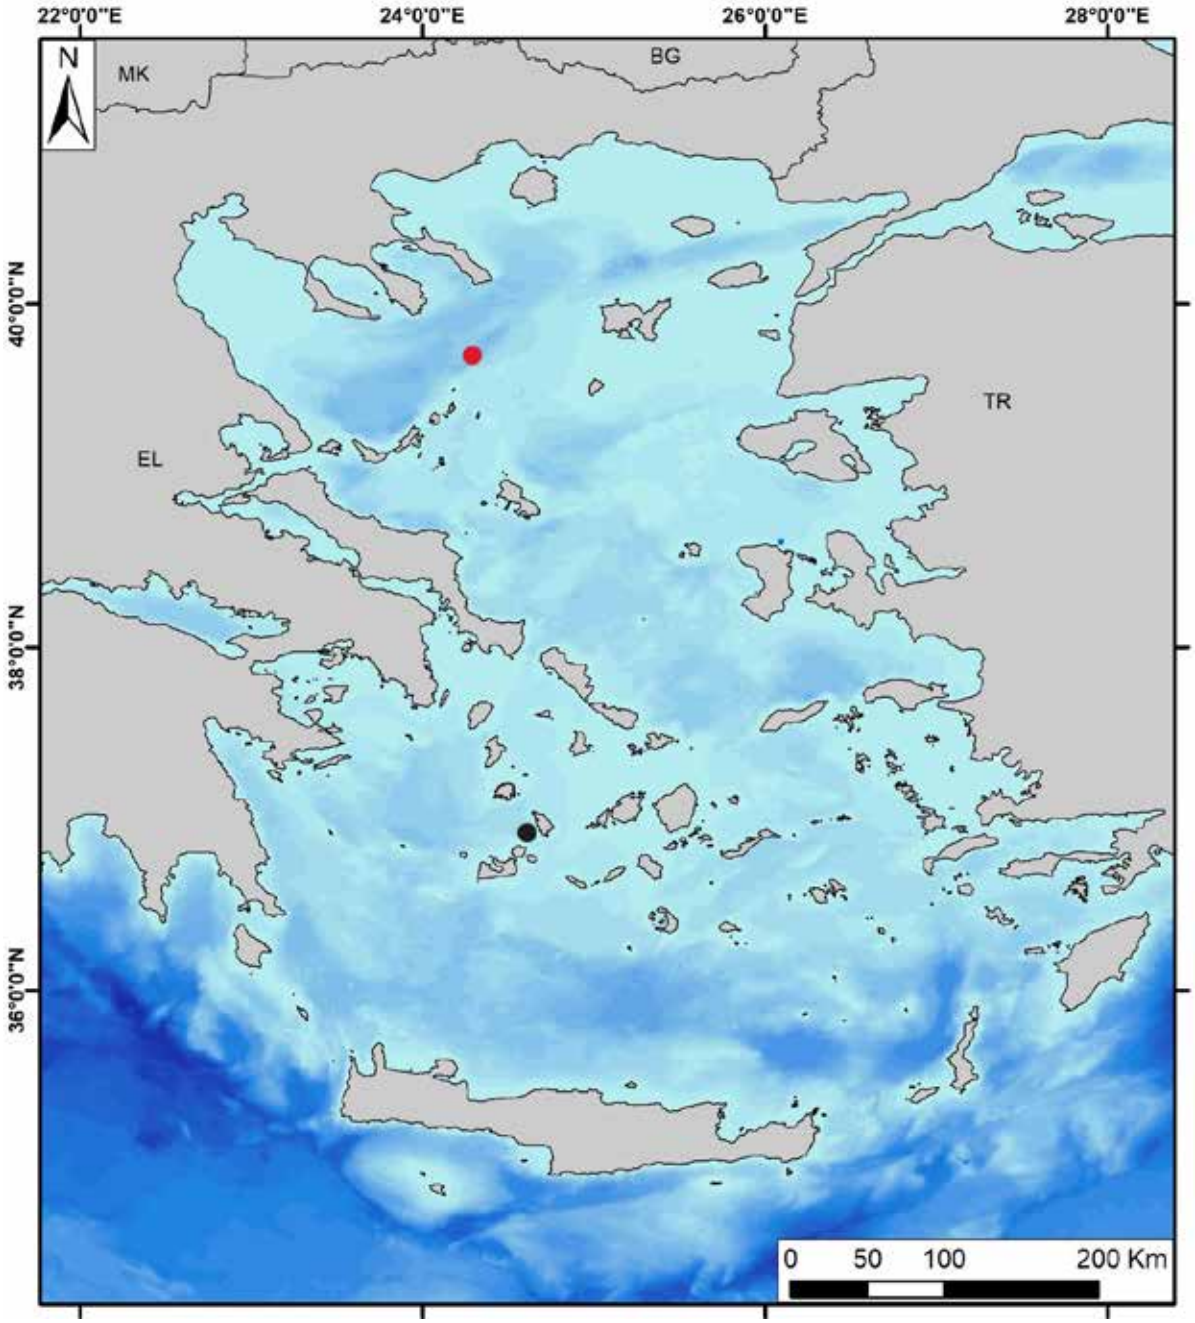

Figure 1. The Aegean Sea and the location of the two gravity cores; AEX-15 with red dot (39°39.900′N, 24°15.369′E; 1242 m water depth, length 178 cm) and KIM-2A with black dot (36°95.4640′N, 24°06.3540′E; 640 m water depth, length 200 cm). Map available via GIS, bathymetry is after (Ioc, 2003) country names are given by © EuroGeographics for the administrative boundaries (Eurostat).

Results & Discussion

As the distributional pattern of the plankton fauna is presented exhaustively in Giamali *et al*., (2019, 2020), herein we focus on the paleoecological aspects that are reflected in the downcore variation of specific pteropod species (Fig. 2). During the sapropel S1 deposition, an increase in temperature and humidity has been documented in all marine records in the eastern Mediterranean region (Giamali *et al*., 2019; Kontakiotis, 2016). This paleoclimate change coincides with the Holocene summer precession-related insolation maximum in the Northern Hemisphere (Laskar *et al*., 2004), and the monsoon intensification that resulted in a widespread increase in humidity over the entire Mediterranean region as well as the concomitant increase of freshwater inputs mainly to the eastern Mediterranean (Rohling, 1994; Rossignol-Strick, 1983).

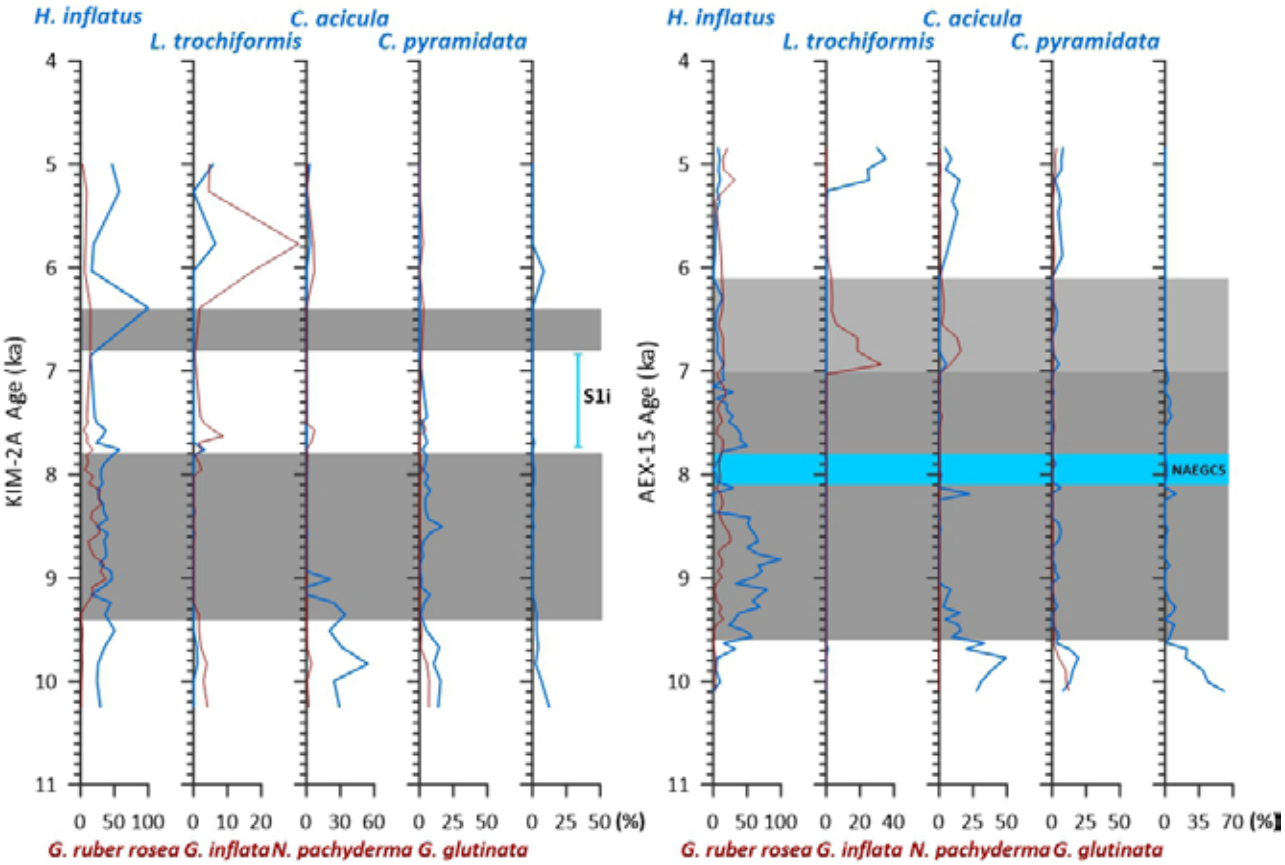

Figure 2. Downcore variations of selected pteropod and planktonic foraminifera species. Blue line corresponds to pteropods, dark red line to planktonic foraminifera. Gray bands correspond to the sapropel S1a and S1b in the core KIM-2A. Gray and light gray bands correspond to the sapropel S1 and its oxidized part in the core AEX-15. S1i interval is depicted in core KIM-2A, and the cooling event NAEGC5 in core AEX-15.

The warm-water mesopelagic *H. inflatus,* presents high percentages during the S1 deposition followed by a notable reduction during the S1i interval in core KIM-2A, and during the cooling event NAEGC5 (Giamali *et al*., 2019). The distribution pattern of this species can be correlated well with that of the warm indicator *Globigerinoides ruber rosea*. Both species can provide a complete overview of the water column as the former lives at a depth ranging from 200-1000 m, whereas the latter is considered as indicative of warm surface waters (Pujol and Vergnaud-Grazzini, 1995). Though *H. inflatus*, seems to reflect better the temperature fluctuations. The epipelagic *L. trochiformis,* is associated with the mixed layer in the upper water column thriving in upwelling conditions (Bé and Gilmer, 1977). Such ecological preferences explain its absence from the S1 interval (Fig. 2). It can be correlated to *Globoconella inflata* which reflects deep seasonal mixing conditions (Hemleben *et al.*, 1989), such as those dominated during the S1i interval characterized by the breakdown of the stratification (Kontakiotis, 2016; Geraga *et al.,* 2010). It is notable that *L. trochiformis* bounds the S1a layer in the core KIM-2A and the termination of S1 layer in core AEX-15 (at 7.0 ka), suggesting the prevalence of homogenization/overturn conditions in the upper water column.
Creseis acicula is a warm-water, euryhaline species that has the shallowest depth habitat amongst all epipelagic pteropods (Liu *et al*., 2022). This specific habitat most probably led to its outbreak as high percentages during the last 0.7 – 1.5 ka before the onset, and the first 0.3 ka of the sapropel S1 are observed (Fig. 2). This pattern may mark both the rising temperature and the increase of freshwater input in the Mediterranean Sea that may increase the ingestion and assimilation rates of the species for algal food (Liu *et al.,* 2022). Its reduction afterwards may mark the change in environmental conditions or an increase in competitors and/or predators (Dai *et al*., 2020).
The mesopelagic species *C. pyramidata* and *D. trispinosa* on the contrary are less tolerant in high temperatures and in salinity fluctuations, and prefer a well-ventilated water column (Buccheri *et al.,* 2002; Giamali *et al*., 2020), which explains their low percentages during the S1 interval. Their abrupt decline is correlated with the onset of S1 deposition in both cores. A similar downcore record can be seen through the distributional pattern of the planktonic foraminifera *Globigerinita glutinata*.

Conclusions

Based on the faunal distribution of two gravity cores of north and south Aegean Sea, the biotic response of specific pteropod species in environmental changes during the sapropel S1 deposition was made. In particular, temperature, salinity, stratification and food availability are the factors that affect the distribution of the examined species. The observed data if enhanced by new records within and beyond the Aegean basin, can give more insights for the establishment of a precise regional eco-biostratigraphic scheme.

Acknowledgements

The gravity cores examined in this work, were collected during the "YPOTHER" project realized at the Hellenic Survey of Geology and Mineral Exploration in collaboration with the Institute of Oceanography of the Hellenic Centre for Marine Research (HCMR).

Introduction

Ophiolitic rocks are used extensively as engineering materials in applications such as road construction, concrete and railway ballast (Rigopoulos *et al.*, 2010, Rigopoulos *et al.*, 2015, Petrounias *et al.*, 2016, Petrounias *et al.*, 2018, Giannakopoulou *et al.*, 2018). The suitability of aggregates for their applications is determined by evaluating their physical, physicochemical and mechanical properties, which are collectively known as engineering properties.

Nowadays, natural aggregate sources are depleting, and their mining impacts the environment adversely. In this direction, during the last decades, marine aggregates exploitation increases due to the high demand for material supply regarding construction industry (Velegrakis *et al.*, 2010). Also, marine aggregates play a crucial role in meeting the demand for construction materials, coastal protection, and beach replenishment. On average, in Europe, almost 60 million tonnes of marine aggregates are extracted from the sea used for construction and as a strategic material in supplying large scale coast defense and beach replenishment projects. The contribution of marine dredged sand and gravel resources as part of the wider portfolio of construction aggregate supply is growing in importance. Where local primary aggregates are constrained, either because resources are not geologically present or because existing resources have become depleted, alternative sources of supply have to be found. Economies of scale allow marine aggregate supplies to play an important role using a fleet of highly specialized dredgers to load sand and gravel from licensed areas located around the coast of England and Wales.

“The main use of marine aggregates is in the manufacture of concrete. Nearly 80% of the marine aggregates landed for construction purposes are used as concrete aggregate, increasing to nearly 90% in London and the south-east of England. By contrast 60% of land-won sand and gravel production and 16% of crushed rock is sold as concrete aggregate,” says the organization. Indeed, while the largest use of marine aggregates is in construction, they are also widely used for the production of asphalt and coated products; masonry and paving blocks; drainage and fill materials; leisure facilities; sports pitches; golf courses; equestrian facilities; horticulture products; steel manufacture and beach replenishment. So, it is not surprising that worldwide production is on the increase. Therefore, it is necessary to optimize the river sand consumption while, at the same time, increasing the use of alternate sources to replace them. There is a wide use of marine sand as fine aggregate material in cement mortar and concrete (Limeira *et al.*, 2012, Xiao *et al.*, 2017, Ganesan *et al.*, 2022).

Marine aggregate extraction is closely regulated to protect the environment. Expert studies are undertaken to help inform license decisions and permission will be refused if there is any concern about impacts on the coastline or any other environmental or economic interests.

The aim of this study is, on the one hand, to evaluate the engineering properties of the tested aggregates, whether overland or marine, and on the other hand, to conduct a comparative study between them in order to identify whether the properties of aggregates change from the area where it is currently possible to locate them.

Materials and Methods Geological Setting of aggregate samples

Ten block samples of ultramafic rocks (five overland and five marine blocks) from Gerania ophiolite complex were collected according to the EN 932-1 standard to evaluate their suitability as aggregates for construction applications (Figure 1).

Figure 1. (a,b) overland ultramafic aggregate rock samples from Gerania ophiolite complex, (c,d) marine ultramafic aggregate rock samples from Gerania ophiolite complex.

The Gerania Ophiolite Complex belongs to the Pelagonian geotectonic zone of the internal Hellenides. They comprise a Permian sedimentary and volcanic succession overlain by a series of carbonate rocks and lesser radiolarites (Clément, B.,1971, Bornovas, J,. 1981, Vacondios, I., 1997, Giannakopoulou *et al.*, 2018). This succession is tectonically overlain by an ophiolite sequence. The ophiolite is a NE-trending rhomb-shaped outcrop, with approximately 10 km in length and 5 km in width, representing an incomplete and dismembered ophiolite sequence. It is dominated by variably serpentinized and tectonized lherzolite, locally crosscut by thin pyroxenite dykes with subordinate harzburgite and dunite (Figure 2). These serpentinized peridotites are interrupted by gabbro dykes, some of which have been transformed into rodingites. An ophiolite mélange includes fragments of lavas, serpentinized peridotites, gabbros, oceanic sediments previously described as schist-chert formation, as well as an amphibolite metamorphic sole tectonically underlie the ophiolite.

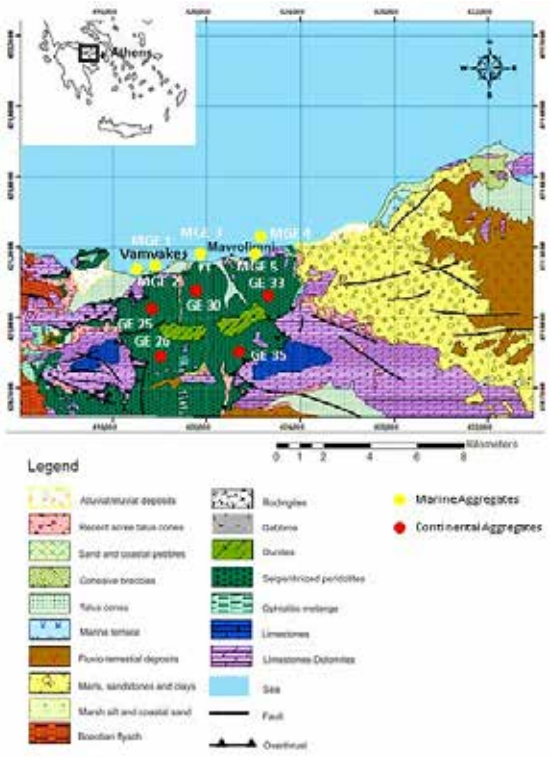

Figure 2. Geological map of the Gerania region (Giannakopoulou *et al.,* 2018), the rectangle in the inset shows the study area.

Analytical methods

All aggregate rock samples have petrographically been observed by variety of petrographic methods. The mineralogical and textural characteristics of the samples were studied in polished-thin sections using a polarizing optical microscope (Leitz Ortholux II POL-BK Ltd., Midland, ON, Canada), according to the EN-932-3 standard for the petrographic description of aggregates. The engineering properties of the tested aggregates were determined in the Research Laboratory of Minerals and Rocks, Department of Geology, University of Patras, Patra, Greece. Moisture content (w) was measured in accordance to the AASHTO T-255 standard, the Los Angeles (LA) test was carried out in accordance to the ASTM C-131 standard using the "B" gradation. The Uniaxial Compressive Strength (UCS) was determined from the average value of six cylindrical rock specimens for each sample with diameters ranging from 51 to 54 mm and their height/diameter ratios between two and three for each sample (ASTM D-2938). As for the geometrical properties of the tested aggregates, the flakiness index (I_F) and the elongation index (I_E) were performed according to the BS 812 Part 105.1 and 105.2 correspondingly.

Results and Discussion

Petrographic features

Peridotites from the Gerania ophiolite complex include lherzolite and harzburgite with low to moderate degrees of serpentinization and deformation even they are overland or marine. Lherzolite shows protogranular, porphyroclastic and locally cataclastic textures. Their primary minerals are olivine, orthopyroxene and clinopyroxene. Opaque minerals (mainly Al-spinel in light brown color) are present in small amounts. Porphyroclastic texture is characterized by large orthopyroxene, clinopyroxene and olivine clasts in a finegrained matrix made up of recrystallized olivine neoblasts. Serpentine is the main secondary mineral, which shows mostly mesh and locally ribbon textures. The effect of serpentinization also leads to the replacement of orthopyroxene from bastite. The secondary assemblage is completed by chlorite and actinolite. Also, a dense network of microcracks is observed. The harzburgite presents mainly porphyroclastic and locally cataclastic textures. Its primary assemblage includes olivine, orthopyroxene and rare clinopyroxene. Olivine appears as porphyroclasts, which present strong deformation, as well as small-sized unstrained neoblasts. Frequent replacement of orthopyroxene from olivine neoblasts is also observed. Al-spinel in light brown color and Cr-spinel characterized in red-brown color are present in small amounts, some of which display embayed margins and rims altered to secondary magnetite. A dense network of microcracks also occurs in the harzburgite. The serpentine comprises the most common secondary phase presenting ribbon texture; minor chlorite occurs as well. Regarding the tested aggregate samples (overland and marine), the only remarkable variation that appears is the degree of oxidation of the metallic minerals, which is likely due to the entry of seawater into the intercrystalline cracks, where it creates conditions for their extensive oxidation. The remaining secondary minerals do not appear to show any change in any environment they have been exposed to.

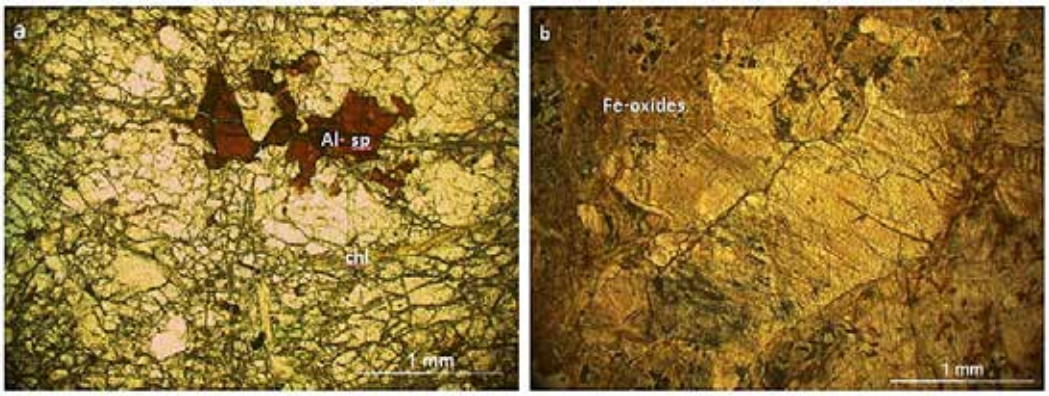

Figure 3. Photomicrographs of (a) overland lherzolite where chlorite is occurred and Al-spinel, (b) marine lherzolite which present high oxidation.

Engineering properties

The values of the engineering properties are summarized below in Table 1. In general, the results show that the overland and marine aggregates present similar physicomechanical characteristics. A small decrease in the mechanical strength of the marine lherzolites is observed compared to the overland ones. More specifically, it seems that the physical properties present a similar variation which may be attributed to the different degree of alteration.

This fact regarding the physical properties is also confirmed by the petrographic study which did not reveal significant differences. The same conclusion has also been conducted by the results of the geometric properties, where the more serpentinized are the aggregates the more elongated grains present. There is no significant difference among them depending on their origin (overland or marine).

Table 1. Engineering properties of the tested aggregate rocks (*GE: overland aggregates, MGE: marine aggregates, w: moisture content, I_F: Flakiness Index, I_E: Elongation Index, LA: Los Angeles, UCS: Uniaxial Compressive Strength).

Samples	Engineering Properties				
	W (%)	I_F (%)	I_E (%)	LA (%)	UCS (MPa)
GE25	0.78	22.54	34.17	15.90	79.0
GE26	0.91	33.90	32.33	19.6	66.0
GE30	0.92	26.84	34.16	16.60	75.0
GE33	0.08	16.25	30.16	20.90	69.1
GE35	0.69	25.15	24.51	23.90	76.0
MGE1	2.60	28.53	27.67	25.60	42.0
MGE2	2.30	29.56	31.25	24.35	49.0
MGE3	2.10	27.84	32.89	26.48	48.0
MGE4	0.90	29.95	34.52	27.00	54.0
MGE5	2.80	31.00	36.01	26.68	39.0

Regarding the mechanical properties UCS and L.A, a small reduction of the properties is shown in marine aggregates, which is probably due to the extensive oxidation of the secondary minerals where they can result in extensive intercrystalline microcracks that can act as surfaces of weakness and cause fractures. Several scientists have conducted similar conclusions when investigated the mechanical behavior of mafic rocks (Petrounias *et al.,* 2018). Giannakopoulou et al. 2018 considered that the increase of alteration such as serpentinization in ultramafic rocks strong influences the physical and mechanical properties of rocks. This happens because the soft and platy nature of serpentine constitutes a critical factor for the development of extensive porous areas, which are weak. The above result, although presented in all the examined samples, it should not be generalized because the mentioned variation may be result of the degree of serpentinization. However, the results of the present study are particularly encouraging as marine aggregates appear to be a quite valuable alternative way to replace overland aggregates.

Conclusions

The engineering characteristics of the tested marine peridotites are generally identical to the tested overland peridotites used as aggregates and hence these results are particularly encouraging for the replacement of the overland aggregates with the corresponding marine. However, it should be mentioned that a study like this in order to conduct a safer conclusion must combine the research results of many scientific fields such as engineering geology, applied petrography and marine geology.

EXTENDED ABSTRACT 097

Estimation of an empirical relationship for calculating quantities of demolished materials through three-dimensional visualization of buildings affected by the earthquake of June 12, 2017, in Vrisa, Lesvos.

Giannakou A., Soulakellis N., Zouros N., Kavroudakis D.
Affiliation : University of the Aegean, Department of Geography

Intoduction

Natural disasters, particularly earthquakes, can cause severe social, economic, and environmental disruptions. These include fatalities, injuries, infrastructure failures, and challenges related to waste management. Post-disaster debris management is critical due to its implications for public health, environmental preservation, and the efficiency of relief operations. Accurate estimation of the volume and composition of building debris is essential for effective waste management planning.

Objectives

This study aims to develop a rapid methodology for estimating construction and demolition waste C&DW quantities generated after natural disasters using geospatial data. Initially, an attempt will be made to estimate C&DW production rates based on footprint measurements for different building categories. These estimates can be used both for calculating the quantities of various waste streams according to the European Waste Catalogue classification system and for determining total waste quantities at both the building and area levels. Subsequently, using empirical data from demolished buildings, an effort will be made to construct a mathematical formula that calculates the quantities of construction waste in volume and weight units, utilizing independent variables (building characteristics).

Methods

Specifically, the study will investigate the impact of the number of floors and footprint area of buildings on the estimation of waste quantities resulting from collapses or demolitions of buildings severely affected by a natural disaster. These variables are chosen because empirical data for them can be easily and quickly collected with high accuracy through the use of geoinformatics systems, either before or after the occurrence of the disaster. The estimation of the mathematical model will be performed using the method of multiple linear regression, a widely used and powerful statistical tool for estimation based on empirical data. In this analysis, for the first time, detailed data are available at the building level for 182 structures following a catastrophic event, specifically the Vrisa earthquake of June 12, 2017 (6.3 Mw) analyzed at three different scales: area scale, street scale and building scale.

Map 1: Map of Area B1, Vrisa Settlement

Using 140 point clouds and 240 3D models obtained from terrestrial laser scanners and terrestrial photogrammetry, along with two orthophotos, two digital terrain models and a digital surface model generated by UAVs, a wealth of empirical data has been gathered at both area and building levels. This data facilitates the development of a model to calculate C&DW quantities following a disaster.

Figure 1. A section of the 3D model from July 25, 2017, generated from high-resolution images taken by unmanned aerialvehicles (UAVs), N. Soulakellis, S. Chatzistamatis, C. Vasilakos, G. Tataris, A. Papakonstantinou, D. Kavroudakis, K. Topouzelis, O. Roussou, Ch. Kalloniatis, E. E. Papadopoulou, K. Chaidas, P. Kalaitzis, (2018)

Results

As part of this study, an initial attempt was made to estimate the rates of demolition waste production in volume and weight per square meter of floor plan for various categories of buildings. In the study area, the most prevalent use of buildings consists of residences and warehouses, which is logical for a small traditional village on an island, such as Vrisa. Thus, it was deemed necessary to create a separate categorization of the buildings in these two uses based on the number of floors, the type of exterior masonry, and the method of roofing. These data can easily be derived using GIS, as well as through on-site visits to an affected area after a natural disaster. Four tables of weight and volume values of waste per square meter of floor area were compiled in total for different types and codes of construction waste, in accordance with the European Waste Catalogue, as well as overall for each building category. These values can be used for a quick calculation of potential quantities of waste from collapses and demolitions of buildings that may be damaged after a catastrophic event, as well as the total quantities of waste in an affected area. To summarize, buildings with storage use have an average of 2,470 kg/m² and 1.47 m³/m² of generated construction waste, while buildings with residential use have an average of 4,170 kg/m² and 2.40 m³/m² of generated construction waste.

In addition, using the processed data for 182 buildings in the B1 sector of Vrisa, four mathematical formulas were calculated for estimating construction waste and are presented below in a table format.

Table 1: Consolidated table of the four mathematical formulas with their variables and weights.

Equation of the form $Y = \beta_0 + \beta_1 * x_1 + \beta_2 * x_2$						
	Y	**β_0**	**β_1**	**x_1**	**β_2**	**x_2**
1.	Weight (kg)	-130242.6	48903.4	Building Height (m)	1332.6	Building floor area (m^2)
2.	Volume (m^3)	-58.85607	22.78869	Building Height (m)	0.74388	Building floor area (m^2)
3.	Weight (kg)	-147134.0	154491.7	Number of floors	1734.2	Building floor area (m^2)
4.	Volume (m^3)	-64.66171	70.11125	Number of floors	0.94282	Building floor area (m^2)

To examine the relationship between the variables, four multiple linear regression analyses were conducted, where the dependent variables were waste weight (kg) and waste volume (m³), while the independent variables included building height (m), floor area (m²), and the number of floors.

The results indicated that the fitted models were statistically significant, explaining a substantial proportion of the variance in the dependent variables.

1. Waste weight (kg) as the dependent variable with building height and floor area as independent variables
   - $F(2,179) = 320.30$, $R^2 = 0.782$, $p < 0.001$
   - Building height: $\beta = 48{,}903.4$, $t = 18.092$, $p < 0.001$
   - Floor area: $\beta = 1{,}332.6$, $t = 7.809$, $p < 0.001$
2. Waste volume (m^3) as the dependent variable with building height and floor area as independent variables
   - $F(2,179) = 528.5$, $R^2 = 0.8552$, $p < 0.001$
   - Building height: $\beta = 22.79$, $t = 22.16$, $p < 0.001$
   - Floor area: $\beta = 0.74$, $t = 11.46$, $p < 0.001$
3. Waste weight (kg) as the dependent variable with the number of floors and floor area as independent variables
   - $F(2,179) = 262.40$, $R^2 = 0.7457$, $p < 0.001$
   - Number of floors: $\beta = 154{,}491.7$, $t = 15.992$, $p < 0.001$
   - Floor area: $\beta = 1{,}734.2$, $t = 9.866$, $p < 0.001$
4. Waste volume (m^3) as the dependent variable with the number of floors and floor area as independent variables
   - $F(2,179) = 359.70$, $R^2 = 0.8008$, $p < 0.001$
   - Number of floors: $\beta = 70.11$, $t = 17.55$, $p < 0.001$
   - Floor area: $\beta = 0.94$, $t = 12.97$, $p < 0.001$.
   -

These findings confirm that building height, floor area, and the number of floors are strong predictive factors of waste volume and weight, with all β coefficients being statistically significant.
Subsequently, we created the necessary diagnostic plots to check the assumptions of the linear model regarding the residuals. From the first plot, we observe that the red line partially follows the horizontal dashed line, indicating that there do not appear to be issues with linearity. In the second plot, since the points follow the dashed line, the assumption of normality of the residuals is satisfied. In the third plot, the red line is almost flat, thus fulfilling the assumption of homoscedasticity. In the fourth plot, the solid red line remains close to the grey horizontal dashed line, and none of the points exhibit a Cook's distance greater than 0.5, indicating that there are no influential observations."

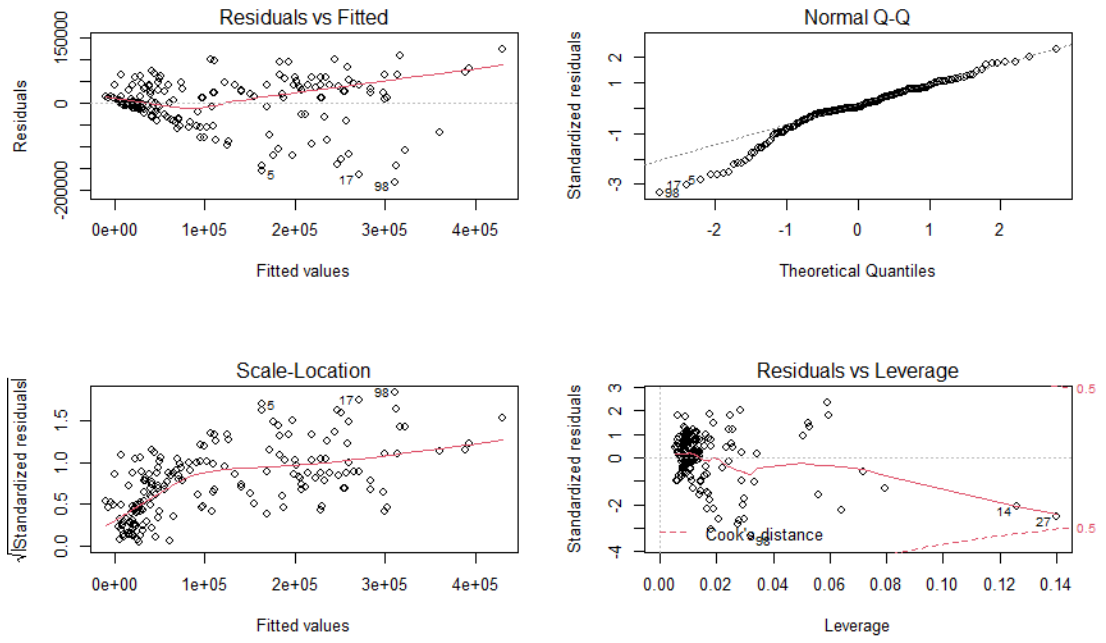

Figure 2. Linear model diagnostic plots

Additionally, an effort was made to study the impact of the number of floors of the buildings in sector B1 of the settlement of Vrisa for three different categories of floor area. Specifically, the study examines how the quantities of

waste in kg, m³, as well as in kg/m² and m³/m², vary on average in the cases of single-story buildings with a floor area ≤ 50 m², two-story buildings with a floor area ≤ 50 m², and three-story buildings with a floor area ≤ 50 m². A similar process is applied for floor areas E > 50 m² and E ≤ 100 m², as well as for E > 100 m². The results are based both on the initial data derived from geographic information systems [Chrysafis, 2018] and on the application of the empirical relationships developed within the framework of this thesis analysis.

Finally, comparison of the results was conducted between the use of the formula developed by the NTUA Chemical Engineering School which has been widely used since 2005 for the preparation of all Regional Solid Waste Management Plans in Greece and the empirical relationships of this thesis. Specifically, the estimation of waste weight using the NTUA formula shows a deviation of approximately 50% upwards compared to empirical relationships and the estimation of waste volume shows a deviation of approximately 60% upwards. This confirms the need for a model to calculate demolition waste quantities that take into account the unique morphological characteristics of an area (e.g., traditional settlements, stone-built structures, etc.) rather than relying solely on statistical data from the Hellenic Statistical Authority (ELSTAT) regarding the number of demolitions.

Conclusions

In conclusion, the availability and collection of empirical data is the most important and necessary step in establishing standardized methods for estimating construction waste, both at the local level and at the building level. The collection of data can precede a disaster and, therefore, facilitate political leadership in organizing immediate and effective recovery plans for areas threatened by various types of natural phenomena. According to the EU Protocol for the management of construction and demolition waste [European Commission, 2016], an inspection must be conducted prior to demolition projects for any material to be reused or recycled, as well as for any hazardous waste. The methodology developed in this study for determining waste generation rates per EWC category can significantly contribute to this inspection and aid in the systematic utilization of materials from debris for subsequent building reconstruction processes. The proposed models from our study can be used for future estimates of waste that may result from a potential natural disaster in various other areas that morphologically resemble the area of our study. Specifically, they can be applied to traditional settlements whose basic morphological characteristics include stone-built walls, wooden internal and external openings, internal partition walls made of bagdati (a type of traditional construction technique), wooden floors, etc. It is understood that they can also be used for predictions and estimates of other traditional settlements on the island of Lesbos, as well as settlements in the Aegean island complex with similar architecture. Our analysis was based on estimates from the available building stock rather than field measurements taken after the disaster occurred. Estimating quantities based on available building stock almost always provides a consistent amount of waste, whereas methods relying on field measurement data after an event can yield significantly fluctuating values.

The need to find a standardized empirical relationship for calculating construction waste with broad application in traditional settlements of Greece, with vulnerable building stock and unauthorized structural interventions, necessitates further research using more empirical data. One attempt is to use existing data for the entire area of Vrisa, so that our mathematical models can be reassessed and adjusted. Additionally, data could be obtained for other areas of the island of Lesbos using GIS methods, so that by knowing the available building stock, we can automatically estimate potential disaster waste quantities, as various natural hazards (earthquakes, floods, fires, etc.) threaten the existence of the island. Furthermore, measurements of construction waste quantities should be made after necessary demolitions by the waste management authorities (AEKK) within their environmental responsibility framework, so that a comparison and verification of the results from the application of the empirical relationships can be made. Finally, other or different variables could be used in the mathematical model so that, using the method of multiple linear regression, it can be determined whether they contribute and to what extent to the correct estimation of quantities, as well as to identify their interdependencies. Such variables could, for example, include the building coefficient, or even categorical variables, such as floor type, roof type etc.

Acknowledgements

I would like to express my gratitude to my supervising professor, Nikolaos Soulakellis, for the guidance he provided throughout the duration of this thesis. I would also like to extend my thanks to the other two members of the committee for their contribution to this thesis.

Introduction

The origin of metals in the environment can be both attributed to natural or to anthropogenic sources. The occurrence of mineralization in an area can affect the metals concentration in the geological background. Wastes from past or current mining and metallurgical activities can contribute to these concentrations through natural processes or through the disposal of the wastes encountered during these activities (Kabata-Pendias, 2011; Alloway, 2013). The research area of Palea Kavala in Northern Greece, is distinguished by the presence of diverse mineralizations rich in Pb, Zn, Fe, Mn, As, Cu, Au, and Ag. Mining and metallurgical activities have been conducted in the region in the antiquity and in the beginning of the 20th century, resulting in the disposal of large quantities of mining waste. The presence of Fe-oxides has been identified in the geological background of the Palea Kavala area. Although they can accumulate inorganic pollutants, no detailed study has been carried out concerning the composition of these oxides in the broader district. The main analytical technique applied for the detailed determination of elements accumulated in the oxides was the application of LA-ICP-MS. The advantage of this method in relation with other analytical techniques, is that it does not require the dissolution of the material to be analyzed and is fast. Additionally, its detection limits are very low and no loss of elements concentration could result, since it does not include many steps, which could cause contamination of the samples (Günther et al. 2000, Huelin et al. 2006). This ongoing study is considered as environmentally significant, since it will reveal locations with high concentrations of chemical elements that are often characterized as harmful for the local community.

Geological Setting

The study area belongs to the Pangeon unit, part of the Southern Rhodope Core Complex. The latter represents a large metamorphic core complex, which was exhumed along the Strymon detachment fault between upper Oligocene and middle Miocene. The lithology of the Pangeon unit includes Paleozoic-Mesozoic gneisses overlain by marbles with schist intercalations (Krohe and Mposkos, 2002; Brun and Sokoutis, 2007). These rocks were intruded by the Kavala (or Symvolon) pluton of Miocene age (22-21 Ma) (Kydonakis *et al.*, 2014). This pluton is an I-type intrusion and mainly consists of amphibole-biotite granodiorite with subordinate amounts of tonalite, diorite, monzogranite, and monzodiorite. Alluvial sediments of a Quaternary age consisting of clays, sands and gravels overlie the crystalline rocks in the western part of the studied area and form the Philippi basin (Figure 1).

Approximately 150 major and minor base- and precious metal occurrences, mostly weathered and oxidized, are spread in an area of about 100 km^2. These metal occurrences have a magmatic-hydrothermal origin and are found within the Kavala pluton, as well as in the surrounding metamorphic rocks. Five different metal assemblages, including Fe-Mn-(Pb-Zn-Ag), Fe-Mn-Au, Fe-As-Au, Fe-Cu-Au and Bi-Te-(Pb-Sb-Au), exhibit a zonal distribution around the magmatic intrusion and contain complicated primary and secondary metallic mineral paragenesis. Primary minerals consist of pyrite, arsenopyrite, chalcopyrite, galena, sphalerite, tetrahedrite-tennantite, with subordinate pyrrhotite, bismuthinite, petzite, lillianite, proustite, pyrargyrite, argentite, cosalite, tetradymite, jalpaite, stephanite and native gold and silver. The secondary minerals comprise mainly goethite, lepidocrocite, hematite, covellite, chalcocite, malachite, smithsonite, cerussite, mimetite, siderite, arseniosiderite, scorodite, jarosite, pyrolusite, manganite, manganosite, cryptomelane, todorocite, nsutite (Vavelidis *et al.*, 1997; Fornadel *et al.*, 2011).

Considerable underground and surface mining activities took place during Classical to Roman periods for gold or lead–silver, and during the 20th century (1904-1914) for iron, manganese, zinc and lead. In the vicinity of the mines, large piles of mining wastes, mainly from the recent activities, are spread along the rivers and the streams. The wastes are eroded and significant quantities of the metals are diffused in the aquatic environment of the river drainage systems and are transported downhill, in the Phlippi basin (Giouri et al. 2013, 2016a,b, 2018; Giouri, 2020).

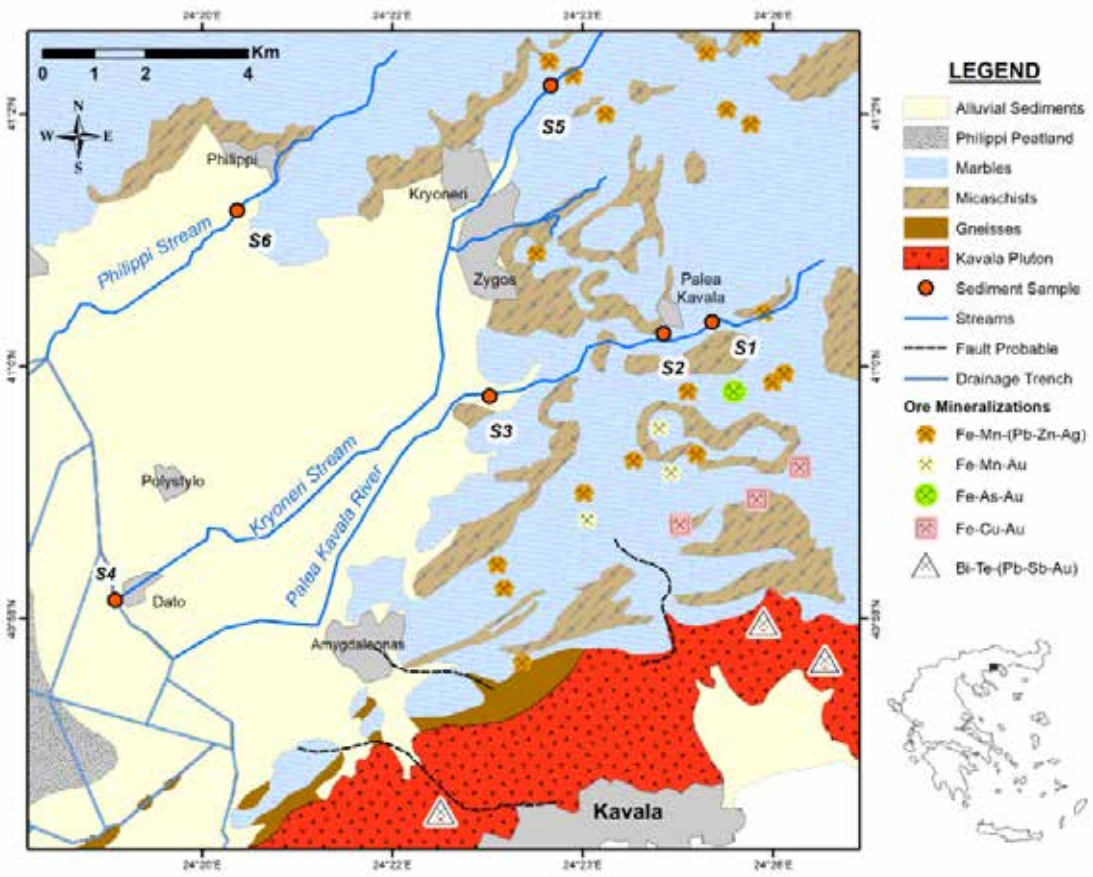

Figure 1. Geological map of the Kavala-Philippi area (modified after Kronberg, 1970 & Kronberg, Melidonis 1970), including the Palea Kavala river and the Kryoneri and Philippi streams. The sampling sites of the stream sediments are also shown.

Methods

Samples collection

Six sampling sites were strategically chosen for sediment collection, distributed across three branches of the main drainage system that traverse areas of ore mineralization and historic mining waste deposits. The site selection considered the expectation that closely situated locations would not exhibit significant variations in geochemical background. Despite the presence of numerous metal occurrences in the study area, their exact dimensions are undefined, and they lack a discernible geometric distribution. Consequently, metal dispersion throughout the region is irregular. Sediments were collected from the following locations: samples S1, S2, and S3 were obtained downstream of the Palea Kavala River, samples S4 and S5 from the Kryoneri Stream, and sample S6 from the Philippi Stream (Figure 1). The collection process involved using an acid-washed plastic shovel to minimize contamination, after which the samples were transferred into clean polyethylene bags. These bags were sealed immediately to preserve sample integrity and transported to the laboratory for further processing and analysis.

Samples preparation

The collected samples were dried at 60 ˚C in an oven, at the Department of Mineralogy-Petrology-Economic Geology of the School of Geology, Aristotle University of Thessaloniki (AUTH), in order to remove the adsorbed moisture. Then they were gently ground in an agate mortar, in order to be disaggregated. The dried and disaggregated samples were sieved through a 0.5 mm and a 0.18 mm sieve in order to obtain the in-between fraction of each sample for the polished sections. Samples were also sieved through a 0.063 mm sieve in order to obtain the fine grained fractions for further chemical analyses.

Samples analysis

In the present study, the fine grained fraction (<0.063 mm) was used for the determination of the mineralogical composition of sediments by the application of X-ray diffraction (XRD), at the Department of Mineralogy-Petrology-Economic Geology, AUTH, using a PHILIPS PW1820/00 X-ray diffractometer, which carry a PW1710 microprocessor. The operating conditions were 35 kV and 25 mA using Ni-filtered CuK radiation. The 2θ scanning range was between 3 and 63 degrees and the scanning speed was 1.2 deg/min. The sediments fraction between 0.5 and 0.18 mm of each sample has been studied under a stereoscopic

microscope in order to separate the Fe-oxide fraction. Subsequently, polished-thin sections were prepared and an initial identification of minerals was carried out by the use of a reflected-transmitted light polarizing microscope. The determination of both composition and morphology of the Fe-oxides, was conducted by the use of scanning electron microscopy (SEM) at the Faculty of Sciences, Aristotle University of Thessaloniki, by the use of a JEOL JSM-840A SEM equipped with an ISIS 300 OXFORD energy-dispersive spectrometer (EDS). The LA-ICP-MS was applied for the determination of the Fe-oxides chemical composition in ultra-trace level. The analyses were conducted at the Geological Institute of the Bulgarian Academy of Sciences in Sofia. Trace elements were measured using a PerkinElmer ELAN DRC-e ICP mass spectrometer coupled with a New Wave UP193-FX excimer laser ablation system, with ablation conducted in a helium medium. The system was optimized daily to ensure sensitivity, using a 35 μm spot size and an energy density of 5.0–5.2 J/cm². The analysis included a 100-second cycle (40 seconds for background, 60 seconds laser-on). Predefined areas in the sections avoided mineral inclusions, and repeated external standardization was performed with NIST SRM 610, USGS GSD-1G, and USGS Mass 1 standards. Data reduction utilized SILLS software (Guillong *et. al,* 2008), with Fe and contents determined by SEM-EDS as internal standards. Fluctuations in isotope intensity were evaluated to exclude contamination by other minerals.

Results

The mineralogical composition of the samples consists mostly of quartz, plagioclase, K-feldspar, mica, calcite, with minor amphiboles. Clay minerals such as chlorite, smectite and kaolinite were also determined (Figure 2a). By the use of a stereoscopic microscope, grains of ore minerals were separated out of the sediments, and randomly oriented samples were analyzed with XRD. These enriched samples consisted of hematite and goethite, along with mica, K-feldspar, quartz and clay minerals (Figure 2b).

The application of optical and scanning electron microscopy on the studied samples revealed that the sediments of the research area comprise ore minerals which are mainly Fe-oxides (Figures 3a,b, 4a,b, 5a,b). According to the results of the scanning electron microscopy (SEM-EDS) these Fe-oxides are mainly hematite and magnetite which are rich in As, Pb and/or Zn. Other identified minerals were goethite, pyrite, galena and titanite. This comes in agreement with the results revealed by Giouri *et al.* (2013, 2016a,b, 2018) and Giouri (2020) according to which most of the sediments in the studied area are enriched in metal(loids), which among others include As, Pb and Zn. More specifically, by the comparison of the mean elements concentrations in the sediments with the corresponding mean concentrations in the rocks of the studied area, it is demonstrated that the sediments are enriched 1.3 times in Fe, 8.7 times in As, 34.9 times in Pb and 4.4 times in Zn (Giouri, 2020). Hence, as concluded by both the bulk sediments geochemistry and the statistical analysis of the results, the enrichment of sediments in As, Pb and Zn is mainly attributed to the neighboring ore deposits.

The LA-ICP-MS further proved As, Pb and Zn accumulation and revealed specific groups of trace elements participating in the studied Fe-oxides (Figures 3c, 4c, 5c). The Fe-oxide from sample S6 contains the highest accumulation of trace elements, while sample S3 is the most depleted one. Based on the chemical composition of the analyzed oxides main accumulations of elements included As (<16,971.57 μg/g in S5), Cd (<10.90 μg/g in S5), Cr (<7,932.26 μg/g in S5), Co (<69.83 μg/g in S6), Cu (<342.02 μg/g in S5), Ni (<716.41 μg/g in S5), Pb (<4,314.55 μg/g in S5) and Zn (<4,180.71 μg/g in S5), as well as the critical and rare metals Ag (<197.30 μg/g in S5), Ce (<211.42 μg/g in S6), La (<440.91 μg/g in S5), Lu (<3.36 μg/g in S6), Th (<16.92 μg/g in S5), and U (<3.29 μg/g in S5, Figures 3c, 4c, 5c).

Figure 5. a. SEM back-scattered electron image of a Fe-oxide grain from sample S6. b. The same grain as seen under reflected light. c. Representative chemical analyses by means of LA-ICP-MS.

Although the mineralogical composition of the studied samples mainly consists of silicate minerals, the presence of chlorite, smectite, and kaolinite among the clay minerals indicates a complex sedimentary matrix (Figure 2a). In addition, the co-occurrence of pyrite and galena with Fe-oxides as indicated by SEM-EDS analysis suggests secondary oxidation processes, leading to the incorporation of trace elements such as As, Pb, and Zn within the oxide matrix.

The trace element contents revealed by LA-ICP-MS, especially for the elements As, Pb, Zn, Cr, and Cd, exceed common environmental thresholds, highlighting potential geochemical hazards (Kabata-Pendias, 2011). The ongoing research includes the co-evaluation of the semi-quantitative mineralogical compositions by XRD and the statistical analysis of LA-ICP-MS results in an effort to estimate the spatial distribution of potentially hazardous concentrations. For example, a 10% Fe-oxide content in contaminated sediment suggests a significant geochemical reservoir of toxic elements, that could be related to a maximum of ~1.7 g in As per kg of sediment (as of <16,971.57 µg/g in S5, Table 4). These advanced mineralogical and geochemical approach, if coupled with leaching studies may help determine whether these elements remain immobilized or may constitute an environmental risk, under natural or disturbed conditions.

Conclusions

The study highlights the significant influence of ore deposits on the geochemical background of the Palea Kavala area, emphasizing the role of Fe-oxides in stream sediments as environmental monitors due to their capacity to accumulate inorganic pollutants. Mineralogical analysis revealed the presence of major components like quartz, K-feldspar, mica, calcite, and clay minerals, with minor presence of amphibole, hematite, and goethite. Analytical techniques such as SEM-EDS, LA-ICP-MS, and XRD identified Fe-oxides as primary carriers of toxic metals, including As, Cd, Cr, Mn, Ni, Pb, Zn, and U. The geochemical variability among samples suggests that local redox conditions, mineralogical composition, and post-depositional alterations have played key roles in element mobility and retention. The strong association of As, Pb, and Zn with Fe-oxides raises concerns about their potential release into the environment under varying physicochemical conditions, emphasizing the need for further geochemical and environmental assessments. The findings underscore the environmental significance of Fe-oxides in tracing pollutant

pathways and their role in geochemical cycling. This comprehensive approach demonstrates how integrating multiple analytical methods provides robust insights into sediment composition and metal distribution. Future research could focus on the mobility and bioavailability of these metals to better assess their environmental impact.

Acknowledgements
Authors would like to thank Aristeidis G. Stamatiadis for the preparation of the polished sections, as well as the Geological Institute of the Bulgarian Academy of Sciences for facilitating the LA-ICP-MS analysis.

EXTENDED ABSTRACT 099

Investigating the interseismic coupling degree of the northern Apennines external Arc in Emilia Romagna region, (northern Italy).

S. Giuffrida[1-6], L. Anderlini[2], S. Graham[3], F. Carnemolla[1-6], F. Brighenti[4-6], G. de Guidi[1-6], F. Cannavò[5], R. Caputo[4-6]

The Emilia Romagna region, hosts part of the outermost sector of the northern Apennines. This domain is affected by a contractional stress dynamic results from the westward subduction of the Adriatic lithosphere and its flexural retreat. This process leads the formation of a thrusts and fold belt system, migrating toward east and north-east (Malinverno and Ryan, 1986; Fig. 1 a - b). The above-mentioned regional dynamics, determine a shortening deformation pattern, in the interseismic period, probably accommodated by various faults hidden below the Po-Plain, which represents the nowadays foredeep of the northern Apennines. In this work, we apply a kinematic Block Modeling approach (McCaffrey, 2002), to investigate which faults, striking across the Po Plain, is actively accommodating the recognized geodetic velocity field. We use several GNSS data available in these areas (Serpelloni et al., 2022), and exploit all the available fault parameters (e.g., position, strike, dip angle and locking depth) from previous studies and database, to verify the role of major fault segments in accommodating the given velocity field. Our solution shows that the outermost sector of the Northern Apennines, which includes the Mirandola fault and Ferrara Thrusts System, is characterized by contractional slip rates, at most equal to 1.5 mm/yr (dip-slip component), that reproduce the observed velocity field in the long-term (Fig. 2 a). These two above mentioned faults have been widely studied during the last years because of their capability of generating high magnitude earthquakes. An example is the 2012 seismic sequence, characterized by two mainshocks occurred on 20 May (Mw ~ 6) and 29 May (Mw ~ 5.8), (Lavecchia et al., 2012; Fig. 1 b).
Due to the complex seismotectonic history of the studied domain, we discretise the northern Apennines external Arc by means of a Triangular Dislocation Elements (TDEs) mesh to resolve the variability of the slip-deficit rate pattern on fault planes. (Fig. 2 a) According to Meade and Loveless (2009), we calculate the interseismic coupling degree as the ratio of the slip deficit and the long term slip derived from the relative motion of the bounding blocks (Fig 2 b). We therefore investigate each fraction of coupling increment to discern portions of fault planes characterized by a complex behaviour (e.g., aseismic creep vs elastic responses). Finaly, we detect at least three locked asperities, with which we propose a set of possible rupture scenarios and calculate the amount of seismic moment rate that the Emilia Romagna region is accumulating. The obtained seismic moment accumulation rate (3.21 x 1016 Nm/yr) is higher than the rate of the released seismic moment (2.2 x 1016 Nm/yr) in the last ~35 years. Assuming that all this energy (1.01 x 1016 Nm/yr) is released elastically, it would be the equivalent of an earthquake of Mw ~ 4.4, each year..

Introduction

Antimony (Sb) is consistently included in the European Union's (EU) list of Critical Raw Materials (CRM) since its establishment in 2011, due to its economic importance and the EU's supply reliance on imports from third countries (European Commission, 2023). Greece is one of the EU member states that host a significant number of antimony mineralization (both occurrences and deposits that were exploited in the past), located in central-eastern Macedonia, western Thrace, the eastern Aegean Sea, and the Pelion peninsula (Stergiou *et al.*, 2022,2023; Kanellopoulos *et al.*, 2024). Antimony mineralization at Pelion has never been the subject of systematic research, especially compared to other Greek antimony mineralization. The aim of this study is to determine the mineralogical and geochemical characteristics of the antimony mineralization at the Mantemia and Moni Panagias sites, North Pelion, in an attempt to determine the conditions of ore deposition.

Regional Geology

The Pelion peninsula consists of a HP-LT metasedimentary sequence (e.g., mica schists) of Permian-Cretaceous age, which can be subdivided into two units (i.e. the North Pelion unit and the South Pelion unit) based on dissimilarities regarding their lithology, stratigraphy and provenance (Hinshaw *et al.*, 2024). The metamorphic rocks of North Pelion overlie the Permo-Carboniferous and Neoproterozoic Pelagonian basement and exhibit similar provenance history to the Cycladic Blueschist Unit (CBU) (Hinshaw *et al.*, 2024). Magmatic intrusions of Tertiary age and porphyritic texture occur throughout the North Pelion unit, crosscutting the metamorphic rocks (IGME, 1987). Antimony mineralization occurs in the "Alikopetra" area of N. Pelion, in proximity to the contact of the HP-LT metamorphic rocks of the North Pelion unit and the marbles of the Pelagonian basement.

Methods

Sixteen (16) samples were collected from two Sb-mineralization sites, namely the "Mantemia" and "Moni Panagias", in the broad "Alikopetra" area. The mineralogical content of the samples was determined using optical microscopy, X-ray Diffraction analysis (XRD), and Scanning Electron Microscopy combined with Energy-dispersive X-ray Spectroscopy (SEM-EDS). Geochemical analyses included X-ray Fluorescence Spectroscopy (XRF) and Inductively Coupled Plasma Mass Spectrometry (ICP-MS). The analyses were conducted at the laboratories of the Hellenic Survey of Geology and Mineral Exploration (HSGME).

Results and Discussion

The antimony mineralization at the "Mantemia" site occurs in the form of stibnite lenses within the marble, ranging in size between 2-15 cm (Fig. 2A). The ore assemblage consists of stibnite, pyrite, sphalerite and Sb-Pb sulfosalts, accompanied by the secondary Sb minerals valentinite, a mineral of the roméite group, stibiconite and senarmontite (Fig. 2B, C). Five different species of Sb-Pb sulfosalts were identified, namely zinkenite, fülöppite, plagionite, robinsonite and boulangerite (Fig. 3). Sphalerite exhibits low Fe concentrations (up to 1.65 wt.%). Pyrite has a high As content, reaching up to 10 wt% and being mostly incorporated in the rims of the crystals. Geochemical analysis yielded concentrations up to 29 wt.% Sb, 6.13 wt.% Fe, 6100 ppm Zn, 3550 ppm As, 2400 ppm Pb, 300 ppm Cu, 40 ppm Sn, 167 ppm Ga, 67 ppm Ta, 3 ppm Te and 2 ppm Ag in the ore. The hydrothermal alteration of the host-rock consists of quartz, carbonate minerals (calcite, dolomite), and muscovite.

The antimony ore at "Moni Panagias" occurs in thin and discontinuous quartz veins (Fig. 2D). The ore assemblage at this site appears more diverse, consisting of stibnite, pyrite, sphalerite, arsenopyrite, cinnabar, Bi-Pb-Cu±Ag sulfosalts, (Bi-tennantite, coloradoite and tetradymite, accompanied by the same secondary Sb minerals as in "Mantemia" (Fig. 2E, F). Iron content in sphalerite reaches 2.32 wt.%, while As content in arsenic pyrite reaches 4.98 wt.%. The geochemical composition of the "Moni Panagias" ore consists of 9.10 wt.% Sb, 2.41 wt.% Fe, 7200 ppm Zn, 2240 ppm As, 160 ppm Cu, 2 ppm Ag and 2 ppm Te. The "Moni Panagias" mineralization exhibits a depletion in Pb (up to 210 ppm), Sn (up to 10

ppm), Ga (up to 7 ppm) and Ta (up to 6 ppm), and an enrichment in Bi (up to 30 ppm) compared to the “Mantemia ore”. The mineral composition of the hydrothermal alteration remains similar to “Mantemia”; however, the quartz participation is significantly higher in this location.

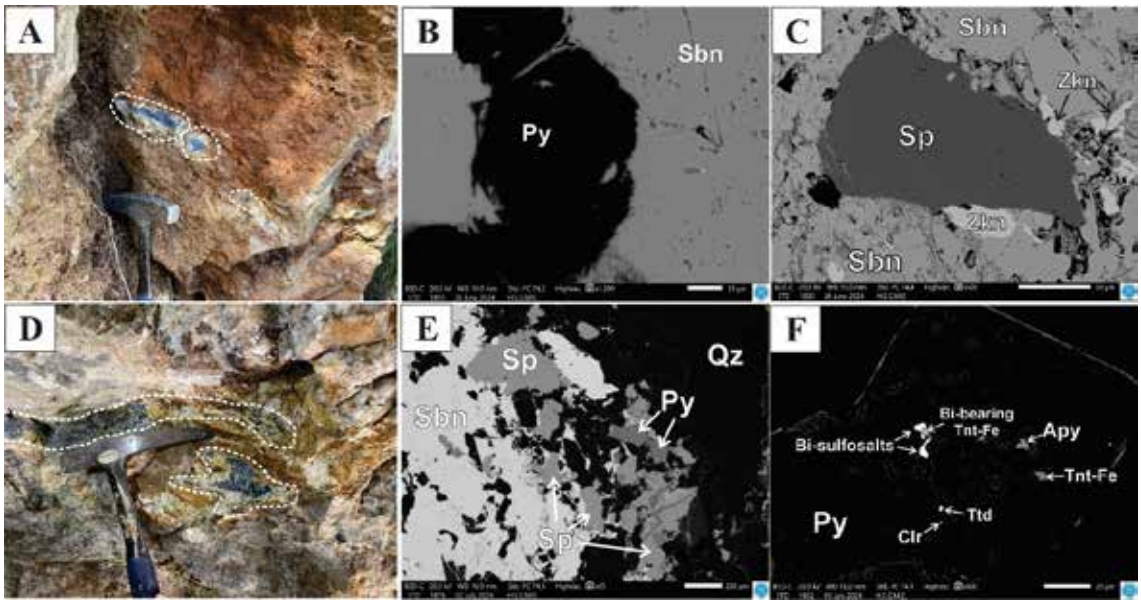

Fig. 2. (A) In-situ antimony mineralization at the “Mantemia” site, (B) Backscattered electron image (BSE) of pyrite and stibnite crystals from the “Mantemia” ore, (C) BSE of sphalerite, zinkenite and stibnite crystals from the “Mantemia” ore, (D) In-situ antimony mineralization at the “Moni Panagias” site, (E) BSE of stibnite, sphalerite, pyrite and quartz from the “Moni Panagias” ore (F) BSE of mineral inclusions inside a pyrite crystal, consisting of Bi-Pb-Cu±Ag sulfosalts, (Bi-)tennantite, arsenopyrite, coloradoite and tetradymite. Abbreviations (according to IMA–CNMNC 2021): Py=pyrite, Sbn=stibnite, Sp=sphalerite, Zkn=zinkenite, Qz=quartz, Tnt=tennantite, Apy=arsenopyrite, Clr=coloradoite, Ttd=tetradymite.

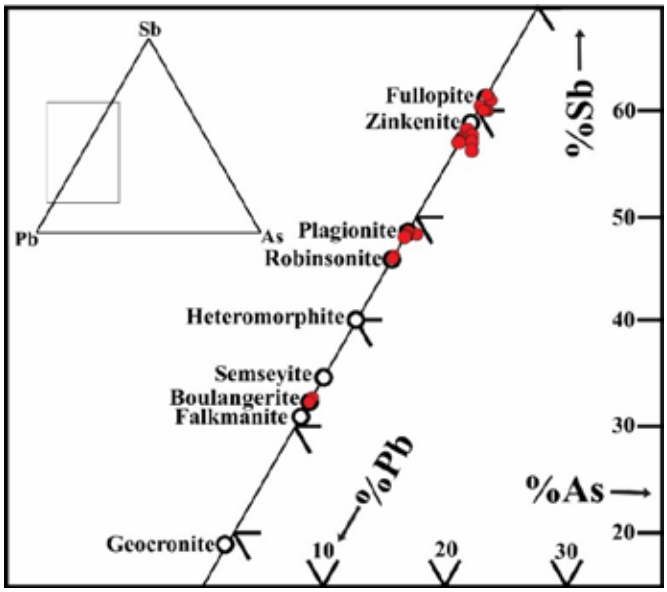

Fig. 3. Composition of Sb-Pb sulfosalts from “Mantemia” plotted on a Sb-Pb-As ternary diagram.

Conclusions

The antimony mineralization in Pelion exhibits characteristics of an epithermal mineralization, formed due to hydrothermal activity, under relatively low temperatures and intermediate to low-sulfidation fluid states. The differences

identified between the two mineralization sites can be attributed to variations of physicochemical conditions during the precipitation of the ore, such as lower fluid sulfidation states and temperatures during the precipitation of the “Moni Panagias” ore (probably due to increased neutralization and/or sulfur consumption), compared to those at “Mantemia” ores.

(2) Aristotle University of Thessaloniki, Thessaloniki, Greece, kpapaza@geo.auth.gr

Introduction

During February-March 2025, a seismic swarm occurred near the Santorini-Anydros-Amorgos area, with thousands of earthquakes being recorded with a maximum magnitude of **M**5.2. Hundreds of earthquakes with magnitudes larger than 3 were recorded and felt by inhabitants of Santorini and neighboring islands, to a tentative self-evacuation of Santorini and the declaration of emergency state by the Hellenic government. In light of these events, we rapidly responded to the ongoing crisis by designing and deploying a new seismic array in Santorini (SantoArray). The collaboration between the Aristotle University of Thessaloniki (Greece) and the Institute of Geophysics, Polish Academy of Sciences (Poland) facilitated the preparation, shipment, deployment, maintenance, and data analysis of 7 SmartSolo units and 117 DATA-CUBE instruments. The network operated continuously for approximately 3 weeks (28 February – 23 March 2025) without instrumentation losses, resulting in a plethora of data recorded by the deployed large-N network. We present detailed information on this newly deployed temporary seismic network along with a preliminary example of data analysis.

Over the last decades, the proliferation of equipment for large-N seismic experiments has provided unique opportunities for extensive investigations aiming at resolving the Earth's finer structure and towards a better understanding of seismicity. In the case of Santorini, numerous nodal experiments (e.g., PROTEUS; Hooft et al., 2019; Chatzis et al., 2022) have provided local and fine-scale tomographic images of the crust and uppermost mantle (e.g., Dimitriadis et al., 2010, Hooft et al., 2019; Heath et al., 2019; McVey et al., 2022; Autumn et al., 2025; Huftstetler et al., 2025) with the aim of improving our understanding of the deeper structure of the volcanic plumbing system, as well as the geophysical and geological characteristics of the near-surface structure. The presented SantoArray experiment expands over Santorini, Kammeni and Thirasia islands, providing a unique opportunity to better resolve the islands' shallow structure using land stations.

SantoArray

The SantoArray comprises of continuous records from all permanent (broadband and wide-band; red squares in Figure 1) stations in Santorini operating under the Hellenic Unified Seismic Network (H.U.S.N., Evangelidis et al., 2021), augmented with temporarily deployed nodal stations (117 DATA-CUBE 3-C & 7 SmartSolo 3-C instruments) in two deployment phases (I and II), with distinct instrument configurations and geometries. Phase I (28 February – 11 March, Figure 1a) involved the installation of 7 SmartSolo 5Hz IGU-16HR-3C sensors (blue triangles in Figure 1a) and 117 DATA-CUBE digitizers equipped with 4.5Hz 3-component sensors, set in two different instrument gain configurations (minimum-"low" and maximum-"high" possible) deployed as follows: 50 co-located low- and high-gain sensor sites (grey triangles in Figure 1a), 10 high-gain sensors (white triangles in Figure 1a) and 7 low-gain sensors (black triangles in Figure 1a), with a ~1.3 km average inter-station spacing. Phase II (11-23 March; Figure 1b) was initiated due to instrument battery replacing needs and comprises of the same total instrument number. However, during Phase II we have set all sensors configuration to the maximum possible gain (white triangles in Figure 1b), while sensors co-located at "double" (low- and high-gain) sites and near permanent station locations (grey and several black triangles of Figure 1a) were relocated and distributed throughout Santorini to improve the inter-station spacing to about ~600m. We successfully retrieved all stations and downloaded above 95% of the expected continuous time series for future analyses.

Data examples

Figure 2 presents a preliminary analysis of two local earthquakes that occurred in the vicinity of Anydros (08/03/2025 **M**3.7, Figure 2a) and Kyparissia (09/03/2025 **M**4.7, Figure 2b) recorded during first phase of the SantoArray experiment operation (Phase I). For both events, P- and S-wave phases were manually picked, and P-wave arrival times were calculated relative to the origin time of each event. Then, a simple topographic correction was applied to account for the rapidly changing topography in Santorini, incorporating the mean P and S velocities presented by

Chatzis et al. (2022). A smooth 2D kriging interpolation was applied to the observations to enhance the visualization of spatial wave propagation. The preliminary observations verify the adequate data quality for earthquakes occurring in both near (Anydros sequence example), and large distances (Kiparissia earthquake) from Santorini, and highlight areas of loose formations (sparse time contours in Figure 2b) and near the bedrock (dense time contours in Figure 2b).

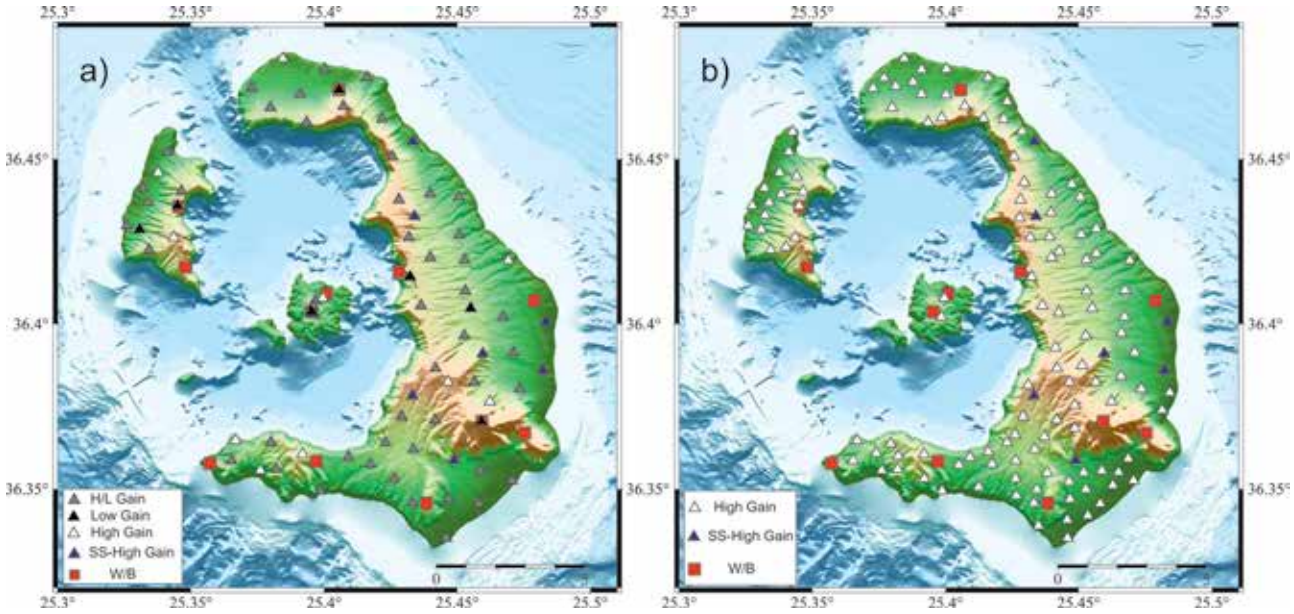

Figure 1. Sensor distribution of the newly deployed SantoArray temporary network. Red squares show permanent Wide-band and Broadband stations from the Hellenic Unified Seismic Network. Blue triangles show deployment locations of the 7 SmartSolo sensors and otherwise colored triangles show the 117 DATA-CUBE sensors. a) SantoArray Phase I, b) SantoArray Phase II.

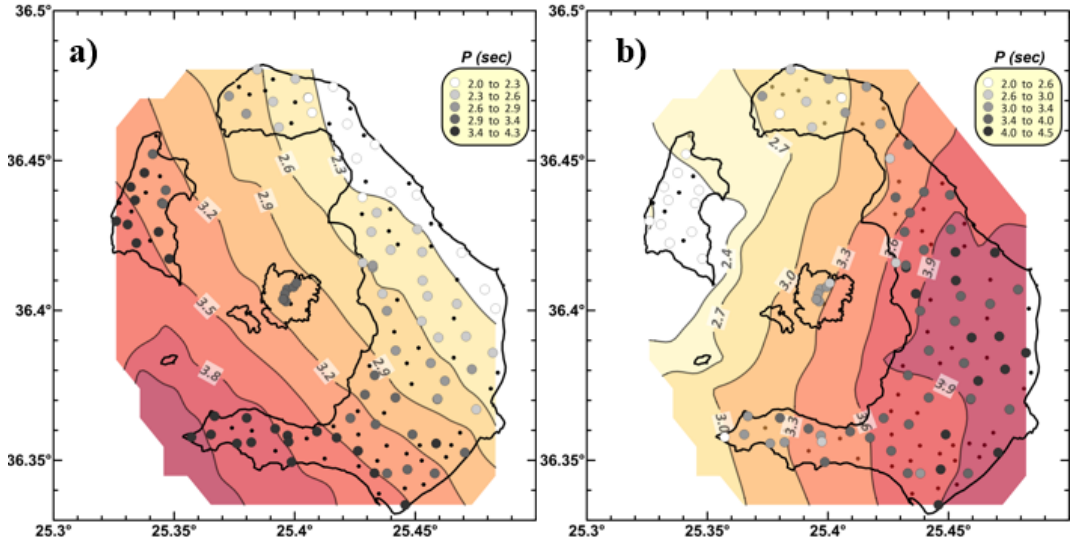

Figure 2. Example of P-wave arrivals from two local earthquakes recorded by SantoArray. Travel-times (colored circles) were calculated for the vertical component measured from the earthquake origin time and corrected for topography. Black dots show locations of SantoArray Phase II stations that were asynchronously deployed and did not record the earthquakes presented here. Smoothed 2-D kriging traveltime contours are plotted in the background. a) the 08/03/2025 M3.7 Anydros earthquake the 08/03/2025 M4.7 Kiparissia earthquake. Traveltimes presented are relative to arbitrary times [00:13:55 for (a) and 20:56:00 for (b)].

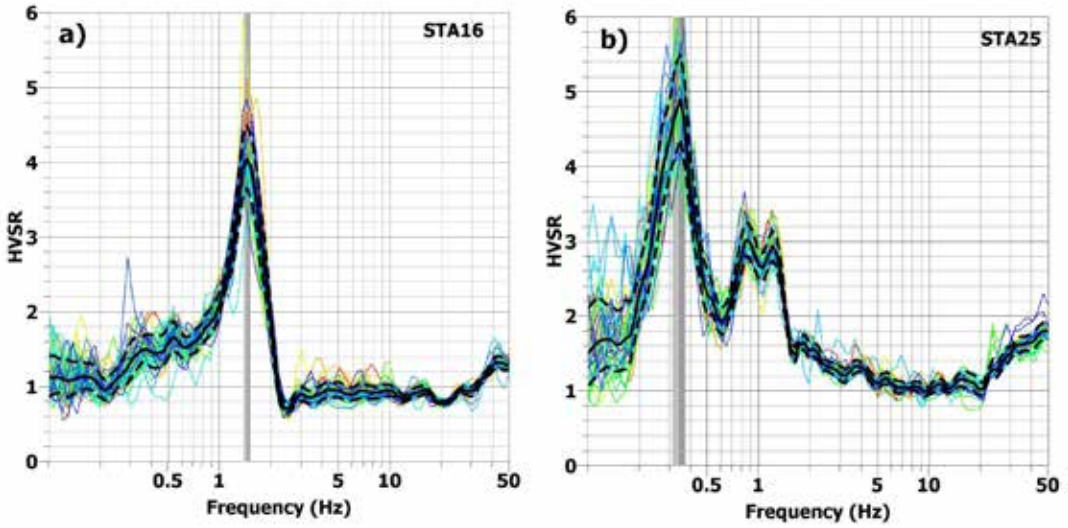

Figure 3. Typical examples of HVSR curves. a) HVSR curve from a site close to the outcrop basement, where a prominent peak is observed at the f_0=1.5 Hz due to impedance contrast between pyroclastic deposits and the underlying metamorphic basement. b) HVSR curve from a site with a very low frequency peak at f_0=0.35 Hz, indicating very deep volcanics above the basement, as well as a secondary frequency peak at f_1~1 Hz, due to shallower impedance contrast within the volcanic layers. The frequency peak is presented in vertical grey line.

In Figure 3, we present two examples of HVSR (Nakamura 1989) curves obtained from single-station 3-component ambient noise measurement at two sites located closer (Fig.3a) and farther (Fig.3b) from the basement outcrop. A sharp fundamental frequency peak is observed in both plot, in agreement with earlier findings (e.g. Chatzis et al., 2022). Moreover, the fundamental frequency, f_0, shifts from ~1.5Hz to 0.35Hz as we move further away from the basement, verifying that the HVSR dataset can be employed to identify the presence of shallow and deep volcanic layers above the metamorphic basement, based on existing and future calibrations of the bedrock depth against the fundamental frequency.

Conclusions

The deployment and operation of SantoArray was completed successfully. The rapid emergency response to the earthquake swarm crisis and the instrument and data retrieval rates underscores the ability of future large-N seismic experiments of similar nature in Greece. The recorded earthquakes presented here provide high quality data encouraging future analysis for several purposes, e.g. earthquake relocation, body-wave tomography, sire-response analysis, etc. Moreover, the hybrid geometry of the network will also allow us to use the recorded ambient noise records for several purposes, such as HVSR and noise autocorrelation, or to compute and use thousands of inter-station pairs for ambient noise cross-correlation tomography, yielding tomographic images of Santorini with unprecedented resolution. Additional inter-disciplinary and collaborative approaches are planned to be realized with the SantoArray data, towards a better understanding of Santorini's seismic structure, the earthquake swarm and the volcano structure and behavior.

Acknowledgement

We are thankful to the people from both institutes who have worked these last few months towards making this experiment happen. We would also like to thank the technicians of the IRIS local technical company who participated in the field work, Manolis Pitsikalis, Ioanna Vamvakouri and other anonymous volunteers for providing local support, as well as the Institute for the Study and Monitoring of Santorini Volcano (ISMOSAV) for covering part of the installation costs.

Introduction

The early 2025 earthquake swarm between Santorini and Amorgos, in the southern part of the Aegean Sea, triggered an immediate mobilization of the authorities and operational structures of the Civil Protection system in Greece, with a primary focus on increased preparedness actions for an imminent strong earthquake. Among other significant actions, a specially developed web platform was made available for all users (mysafetyplan.gov.gr), for locating designated assembly points in case of an earthquake. These locations were selected by the Independent Department of Civil Protection of the Municipalities, though the methodology used for their selection and the factors considered in the decision-making process were not explicitly defined.

The Aegean Sea, like the broader Eastern Mediterranean region, is characterized by high tsunami hazard (Shaw *et al.* 2008; Sørensen *et al.*, 2012; Papadopoulos and Fokaefs, 2005; Karkani *et al.*, 2022; Gogou *et al.*, 2023). In addition to historical records, three seismic events in the past 70 years have triggered tsunamis with considerable impact on the coastal areas, including those triggered by the 1956 Amorgos earthquake (Galanopoulos, 1956; Ambraseys, 1960; Papadopoulos and Pavlides, 1992; Okal *et al.*, 2009; Leclerc F. *et al.*, 2024), the 2017 Kos earthquake (Lekkas *et al.*, 2018) and the 2020 Samos earthquake (Triantafyllou *et al.*, 2021; Dogan *et al.*, 2021). Furthermore, the study area belongs to the tsunamigenic zone of Cyclades, which is characterized by moderate tsunamigenic potential (Papadopoulos and Fokaefs, 2005; Gogou *et al.*, 2023).

The high tsunami exposure in the region is related to the increasing urbanization on the islands over the past few decades and, most notably, to the continuous expansion of tourism in coastal zones. Moreover, the ongoing climate crisis, which has led to steadily rising temperatures throughout the year (Copernicus Climate Change Service, 2025), has enabled the tourism development in coastal areas even during winter season (Bank of Greece, 2025). This fact has resulted in the extension of the tourist season in Greece, consequently increasing exposure and vulnerability to several natural hazards, including tsunami.

The present study assesses the suitability of designated assembly points in case of an event triggers a tsunami in the southern part of the Aegean Sea. The research methodology was applied to the coastal areas of islands within the Cyclades complex, located close to the activated area surrounding Anydros Islet.

Methodology

Mapping and quantifying tsunami hazard remains a significant challenge, as predicting the occurrence, magnitude, and extent of damage from a tsunami is inherently complex and difficult to model. The wide array of potential causes, combined with the numerous possible source areas, renders it nearly impossible to provide a fully accurate and deterministic risk assessment.

Even in regions with rich tsunami inventory, the potential for a larger, more impactful event persists, despite the exclusion of certain combinations of source and magnitude through prior analysis. This is especially true for areas that are susceptible to tsunamis triggered by any of the primary tsunami-triggering mechanisms (earthquakes, volcanic eruptions, and coastal and offshore landslides) or by their combination, as applicable to the study area.

Based on the literature on tsunami impacts in coastal areas, both within the study area and globally, along with the unique morphological features of the southern part of the Aegean Sea and the exposure and vulnerability of the coasts to potential tsunamis, the delineation of tsunami risk zones of the studied coastal areas was implemented.

When the run-up increases, the tsunami risk usually increases as well, since the inundation covers a larger area. However, there are certain factors that can reduce the risk, even when the run-up is high. These factors include urban and morphological characteristics of the affected area, including natural barriers (such as coastlines with steep slopes, sandy beaches, or wetlands), as well as constructions and infrastructure that avoid contact with sea level.
The used run-up values were obtained from a combination of data from past events (Gogou *et al.*, 2018) and contributed to the effective tsunami risk zoning, which comprises the following six zones characterized by different run-up values (Table 1):

- **Zone 1 with run-up up to 3 m**: These run-up values have been reported during tsunami generation in the southern part of the Aegean Sea, based on the available historical data. They represent the minimum recorded values in the area. However, they are characterized by high occurrence probability. Furthermore, this zone is the most vulnerable and exposed to tsunami impact as it lies along the coastal front. Considering that this zone is where most of the constructions, infrastructure, and the most intense human activity are developed, the Zone 1 is defined as the direct-high risk zone, presented with red colour in Table 1 and Figure 1.
- **Zone 2 with run-up ranging from 3 to 5 m**: This zone is located farther inland compared to the previous zone, making it more distant from the coastal front. It includes run-up values recorded and reported from the majority of the islands of the central and southern part of the Aegean Sea, which were affected by the 1956 Amorgos tsunami. This area is also considered highly vulnerable to tsunami inundation and impact. The Zone 2 is defined as the high risk zone, presented with orange colour in Table 1 and Figure 1.
- **Zone 3 with run-up ranging from 5 to 10 m**: This zone also includes run-up values from the 1956 tsunami. At least five areas in Amorgos, Folegandros and Astypalaea Islands experienced such inundation or larger based on Okal *et al*. (2009). The Zone 3 is defined as the moderate risk zone, presented with yellow colour in Table 1 and Figure 1.
- **Zone 4 with run-up ranging from 10 to 20 m**: In the 1956 tsunami, the highest recorded run-up reached 20 m along the southern coastline of Amorgos Island (Okal et al., 2009). The Zone 4 is defined as the low risk zone presented with light green colour in Table 1 and Figure 1.
- **Zone 5 with run-up ranging from 20 to 30 m**: . This zone includes run-up values that exceed the maximum identified and published run-up in the southern Aegean islands from the 1956 tsunami, which is 20 meters in the southern part of Amorgos. The Zone 5 is defined as the very low risk zone presented with dark green colour in Table 1 and Figure 1.
- Zone **6 with run-up larger than 30 m**: This zone is considered to have a low probability of tsunami impact due to volcanic eruptions along the South Aegean Volcanic Arc based on historical evidence. However, extreme events cannot be entirely ruled out. Similar tsunami events caused by volcanic activity, such as the 1883 Krakatau eruption, have produced run-ups of up to 42 meters (Charles W. et al., 1994). This zone can be considered safe under most scenarios due to the rarity of the phenomenon. This zone is located farther inland compared to the previous zone and has no colour indication in Table 1 and Figure 1.

The proposed zoning for the coastal areas of the southern Aegean islands is presented in Table 1.

Table 1. The Tsunami Risk Zones for the Central Aegean area.

Zone	Max Run-Up (m)	Past events	Tsunami Risk
1	< 3 m	Common events (tsunamis with lowest run-up)	Direct-high
2	3-5	Recorded values from 1956 Amorgos tsunami	High
3	5-10	Recorded values from 1956 Amorgos tsunami	Moderate
4	10-20	Maximum run-up from 1956 Amorgos tsunami	Low
5	20-30	Seabed deformation or largest landslide	Very low
6	> 30	Rare extreme events (volcanic eruptions)	Considered safe under most scenarios

Using a Geographic Information System (GIS), the delineation of tsunami risk zones was conducted based on the local contours of selected islands in the south Aegean and subsequently overlaid with recent satellite imagery. Then,

the thematic layer of the assembly points for earthquake-related emergencies were also added and evaluated based on the tsunami risk zones. This methodological approach enabled the identification of (i) the specific tsunami risk zones in which the designated assembly points are located, and (ii) the corresponding level of tsunami hazard exposure associated with each site.

The aforementioned methodology was applied along the entire coastline of Ios, Folegandros, Naxos, Irakleia, Schoinousa, Ano Koufonisi, Kato Koufonisi, Amorgos, Santorini, and Anafi Islands. These islands were selected due to their short distance from the seismically activated area in early 2025 and the increased probability of being affected by a potential tsunami, which could be triggered in the case of a larger seismic event either by sea-bed displacement or by coastal and submarine landslides.

Results

This section comprises the results of the applied methodology to four locations within the study area: Perissa area in Santorini, Katapola settlement in Amorgos, Chora town in Naxos, and the Ios port (Figure 1). These sites were selected because they are characterized by significant population densities, comprising both residents and visitors, as well as the presence of critical infrastructure essential during emergencies triggered by natural hazards, particularly earthquakes and related geohazards.

In Santorini, the designated assembly points are situated at considerable distances from the coastline. For example, the southeastern assembly point is located approximately 3,100 meters from the coastal settlement of Perivolos and 3,200 meters from Perissa. While such locations may be suitable for seismic safety, they are impractical as immediate, pedestrian-accessible assembly points in the event of a tsunami. In Naxos, many of the designated assembly points fall within the direct-high risk zone (red zone). In Ios, the sole designated assembly point for the port area is located within the inundation zone, even under 0–3 m run-up. This renders the location unsuitable for tsunami evacuation.

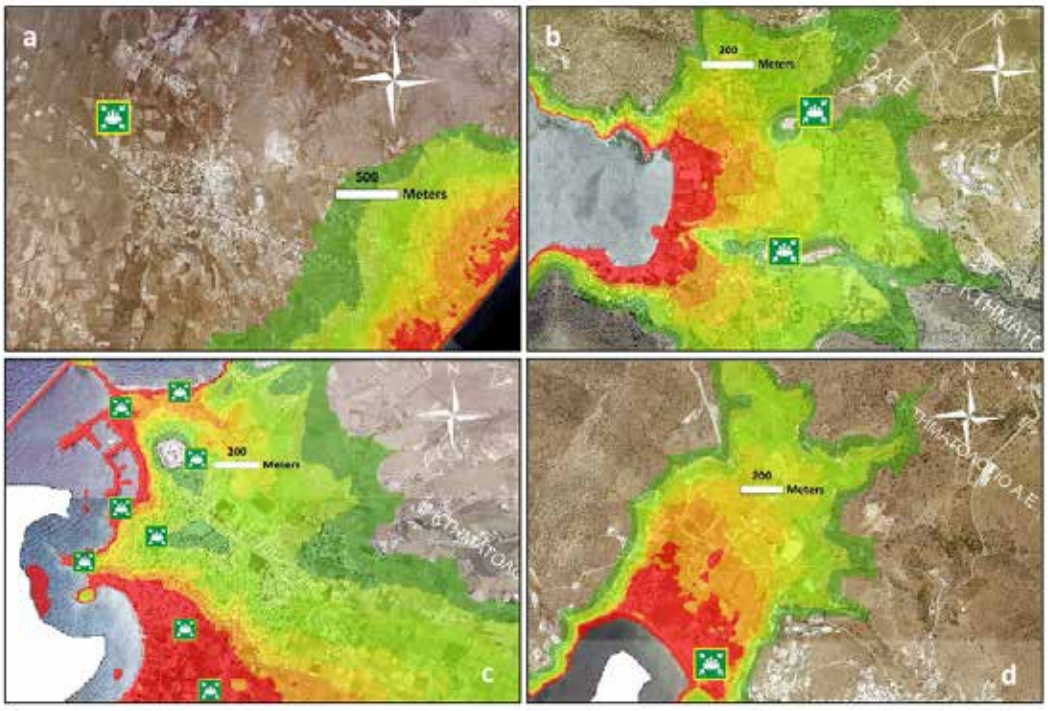

Figure 1. Maps illustrating the results of the applied methodology in selected coastal areas of the Cyclades island complex: (a) Perivolos – Perissa in Santorini. This assembly point is located at a considerable distance from the coastal zone, making it safe from the adverse effects of a potential tsunami, but unsuitable for immediate sheltering of the affected people, who will have to cover many kilometers to reach the site. (b) Katapola in Amorgos. The assembly points have been correctly selected, as they are located both in the safe zone and close to the residential area. (c) Chora town in Naxos. Most of the selected assembly points are considered unsuitable, as the majority is located either along the coastal front or within the direct-high and high risk zones. (d) Ios Port. The designated assembly point is considered unsuitable due to its location within the direct-high risk zone.

This approach enables the integration of additional thematic layers, such as key urban planning characteristics, including land use, road network, and public spaces, into the assessment process. Such integration supports the development of targeted actions aimed at enhancing safety and accessibility, including the updating and optimization of assembly points and the delineation of safe evacuation routes.
A representative application of the aforementioned methodology was conducted within the present study in the area of the port of Ios. The assembly point proposed in the frame of this study (indicated by the blue symbol in Figure 2), is situated on a hillside between the port facilities and Gialos beach and selected to serve the eastern shoreline of the port bay. The site is positioned approximately 15 m above sea level and lies just 130 m from the coastline. Based on the aforementioned zoning, it is classified within a low tsunami risk zone. As such, it may be considered a safe location in the event of tsunami scenarios of equal or lesser intensity than the 1956 Amorgos tsunami, compared to the rejected assembly point located within the port area and in the direct-high risk zone (Figure 2).

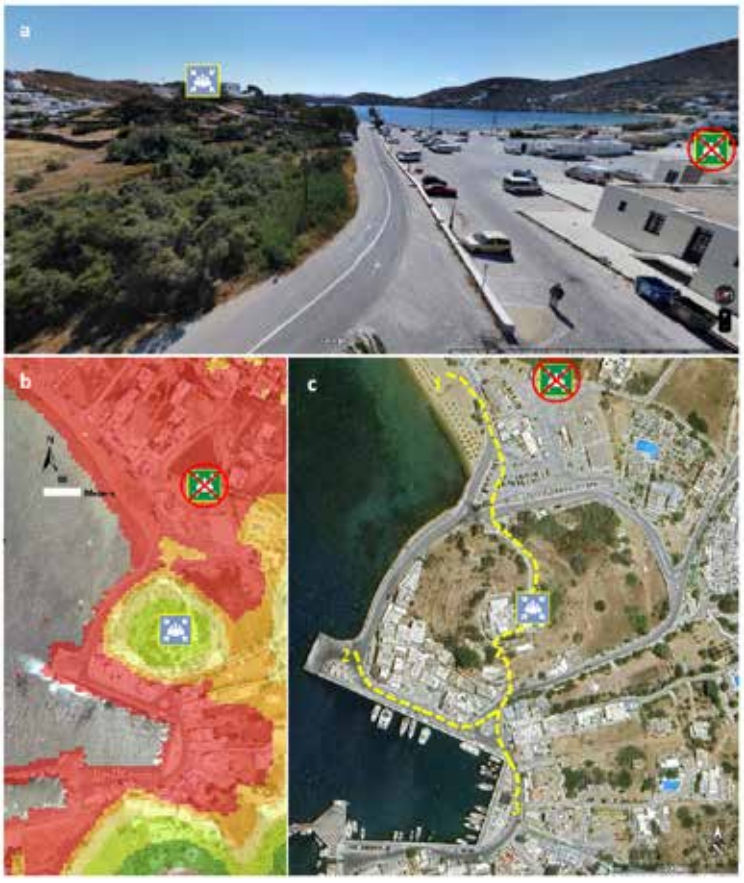

Figure 2. (a) View of the area showing both the rejected assembly point included in the web platform and the new assembly point proposed in the frame of the present study. (b) The old point is located within the direct-high risk zone, while the new point lies within the low risk zone. (c) Delineation of evacuation routes from three important locations to the proposed assembly point in case of an emergency.

The primary accessibility characteristics of the newly designated assembly point in Ios Port (indicated by the blue symbol in Figure 2) are summarized as follows:

- From a representative location within the coastal settlement (Coordinates: 36.726458, 25.274483): approximately 400 meters, with an estimated average arrival time of 6 minutes.
- From Gialos Beach (point 1 in Figure 2): approximately 240 meters, with an estimated average arrival time of 4 minutes.
- From the main port pier (point 2 in Figure 2), the location used for large passenger vessel docking and embarkation/disembarkation: approximately 250 meters, with an average arrival time of 3 minutes.
- From the central area of the marina pier (point 3 in Figure 2): approximately 200 meters, with an estimated average arrival time of 2 minutes.

These distances and times reflect the site's high accessibility from key coastal activity zones, supporting its suitability as an emergency evacuation point.

Conclusions

With the exception of a few cases (e.g., Amorgos), where designated assembly points have been appropriately selected and offer sufficient protection in the event of a tsunami, the majority of sites proposed by local municipalities and currently listed on the aforementioned web platform of assembly points are assessed as inadequate for tsunami response and require urgent reassessment.

In Santorini, additional strategically positioned assembly points should be designated specifically for vulnerable coastal zones. In Naxos, due to the high density of the urban fabric in Chora town, it is essential to reassess current assembly points and develop accessible, well-defined evacuation routes that can be safely followed during emergencies.

With particular focus to the area of the bay where the port of the Ios island is located, , the present study proposes a more appropriate emergency assembly point. Based on calculated distances and estimated pedestrian travel times, the newly proposed site demonstrates an adequate level of protection from tsunami inundation. However, for these evacuation routes to function effectively, targeted urban planning interventions are necessary, such as creating direct, unobstructed paths to safe zones, avoiding bottlenecks, low-lying flood zones, and congested areas, as well as selecting designated multi-modal paths, walkable for pedestrians, accessible for vehicles and people with disabilities, among other actions. Additionally, at least two more assembly points should be established: one for the western section of the bay and another for the southeastern zone.

To mitigate tsunami risk in the study area, several key actions are recommended. These include the systematic reassessment and, where necessary, revision of designated evacuation and assembly points, as well as the clear delineation of tsunami evacuation zones. It is essential to design and mark evacuation routes that are both accessible and efficient, ensuring they can be safely used by all individuals, including individuals with disabilities. Regular operational exercises should be conducted with the active participation of residents and authorities at the central, regional, and local levels, to ensure preparedness and coordination in the event of a tsunami. Furthermore, continuous scientific monitoring of regional seismic and volcanic activity is necessary, as well as the submarine mapping, alongside enhancements to the tsunami early warning system and the supporting sensor network. Finally, public awareness and education initiatives should be implemented, targeting local populations, visitors, and vulnerable groups, in order to foster a culture of preparedness and resilience.

Acknowledgements

The main author would like to express sincere gratitude to the pioneering scientists whose invaluable data and, most importantly, their passion, served as an inspiration to continue working towards making this world safer. Prof. E. Lekkas and Dr. G.A. Papadopoulos are acknowledged for their continuous guidance and encouragement.

EXTENDED ABSTRACT 103

Palaeoenvironmental Interpretation and Soft Sediment Deformation of the Ionian Basin Lower Jurassic Formations in Astakos (Western Greece)

Golfinopoulos V.[1], Piper J.W.D.[2], Zelilidis A.[1], Pe-Piper G.[3], Papadopoulou P.[1], Bourli N.[1], Iliopoulos G.[1]

(1) University of Patras, Department of Geology, Patras, Greece, gkolfinopoulosv@ac.upatras.gr (2) Dalhousie University, Department of Oceanography Halifax, Canada (3) Saint Mary's University, Department of Geology, Halifax, Canada

Introduction

The Ammonitico Rosso (AR) Formation (Fm) is one of the best-known lithofacies of the Tethys Ocean's history due to its peculiar lithological features (Cecca et al. 1992). During the Early Jurassic, the opening of the Tethys Ocean begun, influenced by intense faulting which led to the development of both shallow marine platforms and deep-sea basins (Bernoulli and Renz, 1970). Extensional stress led to the development of the Ionian Basin (Bernoulli and Renz, 1970; Zelilidis et al., 2015). Intrabasinal differentiations resulted in submarine highs with minimal sediment deposition and continuous deposition in local depressions (Bernoulli and Renz, 1970).

Benthic foraminifera and ostracods are valuable tools for palaeoenvironmental reconstructions (Ansari et al., 2022 and reference therein;). Especially for the Jurassic, they could be useful for the age determinations of the studied formations as well. Thus, a variety of studies on Lower – Middle Jurassic ostracods and benthic foraminifera have been conducted in the Neo-Tethys region. Despite extensive research on Jurassic foraminifera and ostracods in the Tethys Ocean, there is a notable absence of such studies in Greece, except for a few studies on Jurassic benthic foraminifera using thin sections. Nevertheless, the systematic study of ostracods through the study of thin sections is not possible.

Landslides that produce mass-transport deposits occur in loosely consolidated soft sediments in both subaerial and submarine environments (Ferrill et al. 2023). Synsedimentary deformation structures (synsedimentary faults, folds, slide planes, dewatering structures, etc.) are widely distributed in the syn-rift formations of the Ionian Basin of Greece (Golfinopoulos et al. 2025 and reference therein).

The study area is located in the region of Western Greece, in the regional district of Aitoloakarnania, approximately 8 km northwest of Astakos town and 10 km southeast of Mytikas village. In this area, Jurassic and Cretaceous formations of the External Ionian Basin are exposed in coastal sections, road cuts, and sparsely vegetated mountain slopes.

Objectives

The main objectives of this study are: i) to document the first stereoscopic record of Jurassic benthic foraminifera and ostracods in Greece, ii) to reconstruct the palaeoenvironment and determine the age of the AR and Posidonia beds Fms in the Ionian Basin, iii) to unravel the internal structure of AR Fm, which includes several horizons of synsedimentary deformation and iv) to present the revised geological map of the studied area as part of this project.

Methods

In the field, detailed bed-by-bed logs were measured, and then the corresponding lithostratigraphic columns were produced. Fieldwork also included measurements, descriptions, and reconstruction of the studied stratigraphy, bearing in mind the local tectonic activity. A total of 52 rock samples and 8 sediment samples were collected from eight sequences. Thirty of the most characteristic rock samples were thin sectioned for microfacies analysis. Microfacies analysis was conducted using Folk's (Folk, 1959) and Dunham's (Dunham, 1962) classifications. Additionally, the revised Wilson model (Wilson, 1975), which defines 26 standard microfacies (SMF) types that are associated with 10 standard facies zones (FZ), was employed. For all sediments samples, micropalaeontological analysis was carried out. The strongly deformed horizons were recorded in detail, including their thickness, deformation axis, their relation to the underlying and overlying horizons, and the bedding planes' dip and direction. Additionally, the characteristics and kinematics of the faults were recorded and analyzed in relation to the depositional processes.

Results

The Jurassic to Cretaceous formations of the External Ionian sub-basin were studied, focusing on the AR Fm, as it appears fully developed in the study area. Specifically, in this area, the following formations are exposed (from the

base to the top): Pantokrator limestones, Sinies limestones, Lower Posidonia beds, AR, limestones with filaments, and Vigla limestones Fms. The base of the succession consists of massive- to thick-bedded white limestones (Pantokrator Fm, Sequence 1). These are overlain by thin- to medium-bedded siliceous limestones (Sinies Fm) which locally contain ichnofossils, stylolites, and occasional chert nodules (Sequences 2-5). Conformably, on the latter, alternations of laminated green-brown pelites with laminated marly limestones were recognized (possible Posidonia beds, Sequence 6, the beginning of Sequence 7). Above them, alternations of red pelites and calcilutites with grey and red nodular limestones were observed (AR Fm, Sequence 7). In the red pelites, grey nodular limestones, and red nodular limestones, ammonites and ichnofossils were observed. The upper stratigraphic part of this formation consists of pink-beige limestones (Limestones with filaments Fm, the beginning of Sequence 8). These strata are laminated to medium-bedded. In the upper part of the studied section, thin- to thick-bedded beige siliceous limestones with chert nodules and chert bands (Vigla limestone Fm, Sequence 8) are present. Notably, within this upper formation, brown shales containing very small polymetallic nodules were recorded (Golfinopoulos et al. 2025, Figure 1).

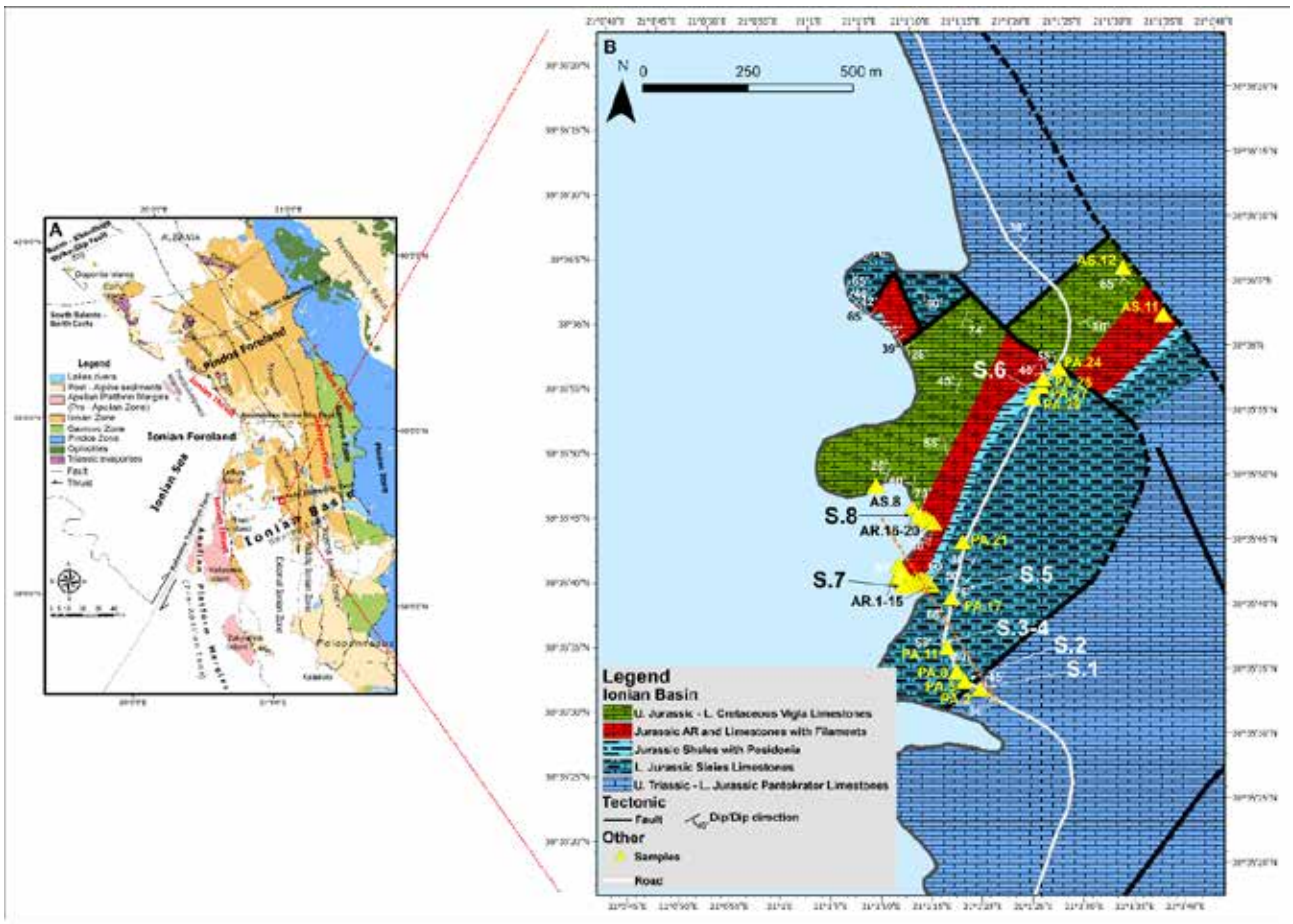

Figure 1: A) Simplified geological map of the External Hellenides in NW Greece, modified from (Zelilidis et al. 2015), where the red box indicates the study area. B) Geological map of the study area. Codes with letter "S" represent the locations of the sequences referred to in the text (modified from Golfinopoulos et al. 2025).

The microfacies analysis of 30 studied thin sections from Sequences 1 - 8 showed two different depositional environments, toe of slope (FZ 3) and platform-margin reefs (FZ 5), corresponding to two different standard microfacies types. Each MF corresponds to a different SMF type. Specifically, MF 1 is classified as biosparite/ boundstone (SMF 7), while MF 2 includes micrites, fossiliferous micrites, and both sparse and packed biomicrites/ wackestones and packstones (SMF 3, SMF 3-RAD, SMF 3-CALP, SMF 3-FIL). The biofacies analysis revealed among others (radiolaria, filaments, benthic and planktonic foraminifera), the existence of planktonic foraminifera of the genus *Globuligerina* in Sequences 5, 6, 7 and 8. The samples of Sequence 5 belong to the upper part of Sinies limestone Fm, based on their lithological features and their relationship to the overlying formations, they appear to have been deposited during the Late Pliensbachian. If verified, this claim would shift the first appearance of

planktonic foraminifera from the Toarcian to the Pliensbachian (Golfinopoulos et al. 2025).
In total 8 sediment samples from Sequences 6-7 were micropalaeontologically studied as well. Two of the samples were barren, while all the other samples contained sufficient numbers of benthic foraminifera tests and ostracod valves. A few fish teeth and sea urchin spines were recorded as well. In total, 15 benthic foraminifera species belonging to 7 families, namely Ichthyolariidae, Vaginulinidae, Lagenidae, Nodosariidae, Polymorphinidae, Spirillinidae and Saccamminidae, were determined. Regarding the ostracod assemblages, at least 10 species belonging to 3 families (Polycopidae, Healdiidae and Bairdiidae), were determined as well. Most of the studied material is moderately to very badly preserved, thus making some of the determinations difficult. Ostracod molds of oval to ellipsoidal shape have been retrieved. Their shape points to a suborder other than Metacopina and Podocopina, whose shape is more sub-triangular. A significant number of the determined in this study benthic foraminifera (Ichthyolariidae, Vaginulinidae, Polymorphinidae and Saccamminidae) and ostracods (Polycopidae and Healdiidae) are characteristic for the Lower Jurassic (Pliensbachian – Toarcian) assemblages of the Tethys Ocean.
In Sequence 7 synsedimentary deformation structures have been developed. The succession of this Sequence begins with greenish-grey shales, quite distinct from the overlying red and white limestones and shales of the AR Fm. The base of the unit is not exposed, whereas at beach level, the top is marked by a few centimetres of greenish deformed fissile shale, conformably overlain by AR-type limestone. Along the strike, in the cliff face, the contact appears rather irregular. As the internal details of this unit are not well exposed, it is simply termed the Lower Unit. It is probably either a complex slide or a debris-flow deposit with rafted blocks of bedded limestone, but the possibility that the unit is in situ and suffered some internal deformation from the overlying slide cannot be excluded. The base of the AR Fm shows considerable synsedimentary deformation. The lowest shale unit has a recumbent fold closure. It is overlain by discontinuous decimeter-scale boudins of micritic limestone enclosed in rubbly AR limestones and shale, with a ghost stratigraphy about 1 m thick. This is overlain by 30 cm of apparently undeformed reddish marl and several meters of alternating nodular limestones and reddish shales with discontinuities between packets of limestone beds, thus creating a series of oblique, bedding-parallel slabs of alternating limestone and shale. In places, limestone beds terminate or are boudinaged, and shales are deformed. The proportion of limestone increases upward. This limestone is overlain by a 2 m thick, polymictic limestone, matrix-supported conglomerate interpreted as a debris-flow deposit, termed debrite 1. Debrite 1 is overlain by about 1 m of reddish shales with discontinuous thin limestone beds. Overlying bedded limestones show brittle deformation into metre-scale tilted blocks, apparently as part of the slide mass. Interbedded with the AR limestones is at least one graded calcirudite to calcarenite turbidite. Debrite 2 overlies the tilted blocks and is about 1 m thick. It is redder in colour than debrites 1 and 3 and is also matrix-supported. Debrite 3 is poorly sorted, with large subangular blocks, supported by a matrix of sand-sized limestone clasts and red mud. The top of debrite 3 is overlain by 30 cm of seemingly undeformed red shale and then an AR limestone section that in its upper part is deformed into a large open fold (Figure 2). The fold is unconformably overlain by about 1 m of bedded limestones with rapid lateral thinning, suggesting that it is also a block within the overall slide. These bedded limestones are overlain by an 1 m bed of sorted conglomerate with an erosional contact with the underlying limestones. The conglomerate consists of rounded limestone pebbles, with the upper part of the bed comprising fine pebbles and granules. Above this conglomerate is a succession of red-grey bedded calcarenites (Golfinopoulos et al. 2025).

Figure 2: Representative view of sequence 7, where the three debrites (1-3) are developing.

Conclusions

During this study, 8 sedimentary sequences in the Astakos area have been studied. Detailed sedimentological, tectonic, and biostratigraphic analyses of both carbonate and clastic sediments have been conducted. Therefore, the following findings have been reported:

- This work presents the first stereoscopic record of Jurassic ostracods and benthic foraminifera in Greece.
- There are indications that some *Globuligerina* tests occurred earlier than previously known; their first appearance probably occurred during the Pliensbachian.
- Lower Posidonia Beds and Ammonitico Rosso Formations were deposited in the shelf and transported in deeper environments during the Pliensbachian to Toarcian.
- The studied sedimentary sequence, though, comprises an allochthonous submarine slide deposit, consisting of four imbricate slices capped by debrites (except the upper one) rather than four discrete slides. Upwards, a conglomerate with reworked limestone clasts has been deposited as a result of a single turbidite. The sequence closes with sediments of the limestone with filaments and Lower Posidonia bed Fms.
- The autochthonous AR Fm depositional setting fits well with a carbonate ramp, on which turbidity currents with a transport distance of several kilometres would have developed from a watery debris flow formed by headwall collapse
- The discovery of the AR Fm slide has a profound effect on the reported sedimentation rates for the area, which until now have not taken under consideration the duplication of the layers, and which thus must be significantly lower.
-

Acknowledgements

This work was supported by the “Andreas Mentzelopoulos Scholarships for the University of Patras” [grant number: 33720000], awarded to Vasilis Golfinopoulos, a PhD student. Special thanks go to the members of the Palaeontology and Stratigraphy Laboratory at the University of Patras, including Marianthi Tzortzi, Irena Pappa, and Maria Groumpou, for their essential support during the fieldwork.

EXTENDED ABSTRACT 104

A decade of data: Updating the Hellenic Macroseismic Database for historical earthquakes

Goutsos, G.[1], Sakkas, G.[1,2], Sakellariou, N.[3], Kouskouna, V.[1]

Introduction

The Hellenic Macroseismic Database for historical earthquakes (HMDB.UoA, Kouskouna and Sakkas 2013) was developed at the Laboratory of Seismology of the University of Athens in 2013 within the framework of NERIES and SHARE projects, as a contributor to the Archive of Historical Earthquake Data inventory of Europe. Since then, new studies presenting additional macroseismic intensities from historical earthquakes have been published. Our aim is to update this database with the new Macroseismic Data Points (MDPs) and present its latest version. In addition, amendments regarding the parameters PlaceID, PlaceName and coordinates were introduced in order to better constrain the identity of localities and their multiple names within the centuries. Thus, a separate column containing the latest name of the locality is added, as well as one for comments related to the amendments. We anticipate enhancing the database with earthquakes from the early 20th century in the near future.

Before the update

The first version of HMDB.UoA consists of four tables (Kouskouna and Sakkas, 2013):

The *Earthquake Catalogue table* containing the core information on the available earthquakes such as origin time and date, focal depth, epicentral area, geographical coordinates of the epicentre, maximum observed intensity and epicentral intensity, equivalent moment magnitude, number of available macroseismic data points as well as additional data on methods for estimating magnitude, preferred epicentre and magnitude and errors (Table 1).

Table 1. Example of the Earthquake catalogue table in Excel sheet format.

The *Macroseismic Intensity Data Points* table (Kouskouna and Sakkas, 2013, Tables 2, 4) is the catalogue of available macroseismic data per earthquake. It contains available information on macroseismic data points (MDPs) such as the various available names of the localities, place identifier for seismic history (Locati and Cassera, 2010), locality geographical coordinates, assigned macroseismic intensities, reliability of data, source of data and is directly connected to the earthquake catalogue as well as the sources table (*Studies* table).

The *Reference Places table* (Table 3) containing reference places used as basic input for the online map. It is an independent table, not related to the other tables. Information of this table include the name of locality and the geographical coordinates, country, geographical area that the reference location belongs, availability of the reference location to shown on the map depending on the zoom level.

The *Studies* table (Table 4) contains the necessary information of the sources (original macroseismic studies) of the database. This information includes name of authors, editors, title of the study, original language of the study and links to the studies.

Table 2. Example of the *Macroseismic Intensity Data Points* table in Excel sheet format

Inspections to detect problems

Checks were made to investigate whether the existing MDPs in the respective table needed to be improved. This was achieved by introducing appropriate functions (if, ifand), which identify any points which need amendment, such as:

- localities with the same name (PlaceName) but different identification key (PlaceID)
- localities with the same PlaceID for different PlaceSc (Place Special case: isolated building, multiple settlement…)
- localities with the different name (PlaceName) but same geographical coordinates
- localities with the same identification key (PlaceID) for different localities
- localities with the same identification key (PlaceID) for different coordinates

These points were marked with different colors (Figure 5). It was observed that certain cells present more than one color. All appropriate corrections were made to these cells

Steps followed

Five new columns were added to the mdp_cat table

- OldPlaceNamesEn (containing the old names in English)
- OldPlaceNamesGr (containing the old names in Greek)
- LatestPlaceNameGr (containing the latest names in Greek)
- LatestPlaceNameEn (containing the latest names in English)
- Comments (containing the comments for any changes made to this mdp)

The format of StudyCode column was changed from 5 letters and 3 digits to 4 letters and 4 digits.

Finally, all coordinates were checked on all coordinates and adjustments were made, where necessary (Tables 5, 6 and Figure 1).

Updating / adding "new" earthquakes

After the automation procedure, the existing database may be considered enriched and corrected. Moreover, we started to enrich this database with new data, either adding MDPs from recent studies in existing earthquakes, or introducing new earthquakes (Tables 7,8 and Figure 2). Thanks to the automation, this process was achieved without difficulty.

Figure 2. The epicentral areas of the "new" earthquakes (from Table 8)

Future objectives

New data inserted in the database, need previous thorough checks in terms of compatibility with the database format. More importantly, for each earthquake a macroseismic review is necessary to identify the most accurate and reliable source, as well as to double-check the available information from multiple sources in both terms of localities naming, geographical coordinates and avoid duplications that may lead to false data and, consequently, to unreliable results. On the other hand, newer earthquakes may include more data and be easier to calculate reliable equivalent moment magnitudes and epicentral

areas.

We aim to upload the updated database file at the webpage http://macroseismology.geol.uoa.gr/, as described by (Kouskouna and Sakkas 2013) using MIDOP (Locati and Cassera 2010) and also to incorporate early 20th century earthquakes and their MDPs, as it is common knowledge that the parameters determination of earthquakes continued to be based on macroseismic data for a few decades after the turn of the century. However, instrumental data begin to be more and more available and offer an opportunity to apply calibration methods using both macroseismic and instrumental data for improved parameters determination.

EXTENDED ABSTRACT 105

Seeking for dependencies of the high frequency "kappa" parameter of earthquake spectrum on weather/climate conditions

Grendas I.[1], Roumelioti Z.[1]

(1) Department of Geology, University of Patras, Patras, Greece, grendasioannis@gmail.com

Abstract

We investigate the seasonal variability of the κ_0 parameter, which describes the near-surface high-frequency attenuation of seismic waves. We analyze data from the ARGONET vertical array of accelerometers in Cephalonia, Greece, focusing on comparisons of high-frequency spectral decay between the surface station CK0 and the borehole bedrock station CK83. The study uses the ARGONET database records from July 2015 to October 2022. Results using two different approaches agree on a significant variation of κ_0 at CK0, with lower values in summer (dry period for Cephalonia) and higher values in winter (rainy period). This suggests that weather/climate related factors, such as soil moisture and temperature, influence near-surface attenuation, at least as expressed through the value of κ_0. This result challenges the assumption of a static value for κ_0 often made in site characterization for seismic hazard assessment.

Background

Kappa, κ, is used to quantify the attenuation of high-frequency seismic waves as they travel through the Earth's crust and near-surface materials. First introduced by Anderson and Hough (1984), it is determined from the slope of the high-frequency decay in the Fourier Amplitude Spectrum (FAS) of acceleration, typically using earthquake ground motion records. It is often analyzed in one component that reflects the attenuation occurring along the seismic ray path due to anelastic and scattering processes in the crust and one that quantifies the near-surface attenuation due to the shallow geological conditions, particularly in sedimentary layers.

The component of κ related to site-specific near-surface attenuation, widely called the kappa-zero, κ_0, is a crucial parameter in engineering seismology (e.g., Boore and Joyner, 1997; Ktenidou et al., 2014; Douglas et al., 2020). It enhances the accuracy of ground motion models in predicting high-frequency spectral amplitudes and is directly utilized in developing design spectra and ground motion simulations. By incorporating κ_0, engineers can better estimate seismic demands on structures, especially those sensitive to high-frequency vibrations. That is why it has been considered vital for critical facilities, such as nuclear power plants, where accurate characterization of high-frequency ground motion components is essential.

While κ has been widely adopted by both the seismological and civil engineering communities, several challenges and criticisms have emerged regarding its application. Estimating κ involves subjective decisions, such as selecting the frequency range for analysis and assuming linearity in the spectral decay. This can lead to variability and inconsistencies, which are further amplified by a lack of standardized methodologies in the parameter's computation and data with insufficient high-frequency content (e.g., Ktenidou et al., 2014). Furthermore, κ reflects a combination of attenuation processes, including scattering, anelastic absorption, site amplification effects and even soil-structure interaction and similar effects emerging from sensor installation practices (e.g., Parolai and Bindi, 2004; Hollender et al., 2020). Disentangling these contributions can be difficult and complicates the interpretation of the parameter under discussion. Another recently proposed process that may affect the spectral region where κ is measured is soil-atmosphere interaction, which suggests a seasonal variation in κ (e.g., Roumelioti et al., 2020; Grendas et al., 2025).

Objectives

This study aims to investigate the seasonal variability of κ_0 using data from the ARGONET vertical array, a special infrastructure for site effect studies on Cephalonia Island, Greece. The objective is to use this well-studied site to extract valuable insights about the possible contribution of weather/climate into the complex nature of near-surface, high-frequency attenuation.

Data and Initial Processing

The ARGONET infrastructure includes, among other components, a vertical array of accelerometers located in the sedimentary valley of Koutavos, south-southeast of Argostoli, the capital of the island of Cephalonia in western Greece. Details of the infrastructure can be found in Theodoulidis et al. (2018). In this study, we only use data from the surface and deepest sensor of the vertical array, code-named CK0 and CK83, respectively. CK0 is installed inside a light wooden construction on a relatively soft site. Average shear-wave velocity, $V_{S,}$ for the upper 30 m depth (VS_{30}) according to the V_S values from different methods (cross-hole, down-hole, seismic interferometry) reported in Cushing et al., (2020), is in the range 201-262 m/s. CK83, on the other hand, installed at a depth of 83 m, is reported to be in the limestone bedrock (Theodoulidis et al., 2018). For the purposes of this study, this station is used as a "reference" station, both in the classical sense of engineering seismology (i.e., absence of

significant site effects), but also in the sense that it is very unlikely to be significantly affected by short-term ground-atmosphere interactions (Roumelioti et al., 2020; Grendas et al., 2025).

Since its launch in 2015, ARGONET has been in continuous recording mode. Earthquake records that include CK83 acceleration time histories with a Peak Ground Acceleration (PGA) ³2mg are processed and organized in the ARGONET database, which is openly available online (https://argonet-kefalonia.org/data/argonet_data/). In this work, we process the horizontal records at CK0 and CK83 stations of 964 earthquakes epicentered in the wider area of Western Greece and occurring from July 2015 to October 2022.

The horizontal acceleration waveforms were first processed for standard corrections and S-wave window selection. The various steps of this processing are not presented here for reasons of space, but are described in detail in Grendas et al. (2021). Briefly, we selected S-wave windows of variable duration, depending on the earthquake-receiver distance and the earthquake magnitude. These S-wave windows were Fast Fourier Transformed (FFT) and smoothed following Konno and Ohmachi (1998) (with the parameter b of the method set to 50). Spectra were first generated for each horizontal component separately, and then combined (square root of the sum of squares) to compute a single horizontal spectrum per station and earthquake.

Computation of κ and κ_0

Kappa values were computed for each horizontal FAS, A(f), based on a linear fit of its amplitudes in the high-frequency spectral region in between user-defined frequencies f_e and f_{end}, following the original work of Anderson and Hough (1984) and the equation:

$$A(f)=A_0 \exp^{(-\pi\cdot\kappa\cdot f)} \qquad (f>f_e) \qquad [1]$$

in which A_0 corresponds to the plateau of spectral amplitudes at $f<f_e$. Figure 1 shows the computation of κ schematically. In addition to the examined earthquake spectrum (in blue), the corresponding Fourier spectrum of a noise window preceding the earthquake signal is shown (in red). The part of the earthquake spectrum used in the analysis is required to be above a certain multiple of the noise spectrum. Figure 1 shows an example of a multiple of 3. In this work, we set a stricter minimum signal-to-noise level of 5.

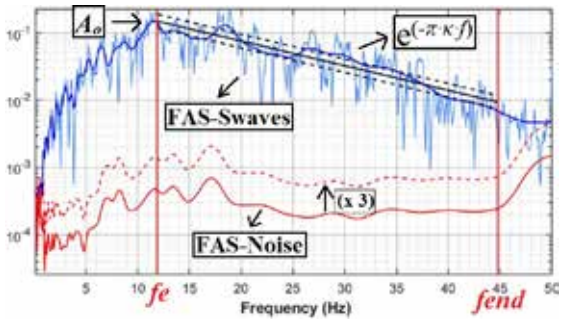

Figure 1. The Fourier Amplitude Spectra (FAS) of the S-wave earthquake motion (light blue line), its smoothed version (bold blue line), and the corresponding smoothed FAS of the noise before the arrival of the P-wave (bold red line). The red dashed line marks the 3-fold noise FAS level as an example of the minimum threshold for the earthquake signal to be considered reliable (Signal-to-Noise Ratio, SNR³3). Black lines show the least-squares regression of log(FAS) values in the frequency range from f_e to f_{end}, ±1 standard deviation (STD) of the mean.

We computed κ values for four different fixed frequency ranges, i.e., 6-25 Hz, 6-35 Hz, 10-25 Hz, and 10-35 Hz. The results for each of the two stations and each frequency range studied are plotted against epicentral distance in Figure 2. By linear regression of the distributions in Figure 2, it is possible to separate the "path" and the epicentral distance independent ("site" or/and "source" considered) terms of kappa. The mean values for the second term of kappa or κ_0, i.e., the values of κ corresponding to zero epicentral distance are reported in Figure 2 and Table 1. We restricted the linear regressions to data corresponding to epicentral distances £60 km, partly because data points were sparse at larger distances and partly because around 60 km there is an obvious change in the regional attenuation that could not be fit by a single line. We also kept the slope of the linear fit, based on the regression of the entire set of ARGONET data (i.e., all stations of the vertical array, not shown in this paper), fixed so as to reasonably assume exactly the same path attenuation factor for the two stations studied, since they are both located at the same epicentral distance.

Results in both Figure 2 and Table 1 show a larger variability of κ values at CK0 compared to CK83. They also highlight that mean κ_0 values are, as expected, larger at the "soft" CK0 stations and much smaller in the "soft rock" CK83 station. Another rather expected result is the dependence of κ and consequently of the κ_0 values on the frequency range used in the analysis, further highlighting the problem in understanding κ in the absence of standardized analysis practices.

Computation of $\Delta\kappa_0$

The exclusive site-specific character of κ_0 has been a subject of debate (e.g., Ktenidou et al., 2014 and references therein). Most studies support it (e.g., Cotton et al., 2006; Drouet et al., 2010; Ktenidou et al., 2013; Ktenidou et al., 2015). However, others also argue for a dependence on the seismic source (e.g., Tsai and Chen, 2000; Purvance and Anderson, 2003; Kilb et al., 2012), a component that would be difficult to isolate based on classical linear regression analysis on the κ measurements of a single site. To overcome this difficulty and secure that we have effectively removed any possible source effects, instead of using κ or κ_0 we used one site as target and one as reference and we computed their κ differences, Δκ. Δκ is equivalent to $\Delta\kappa_0$ under the realistic assumption that the wavefield at both examined stations experiences the same along-path attenuation.

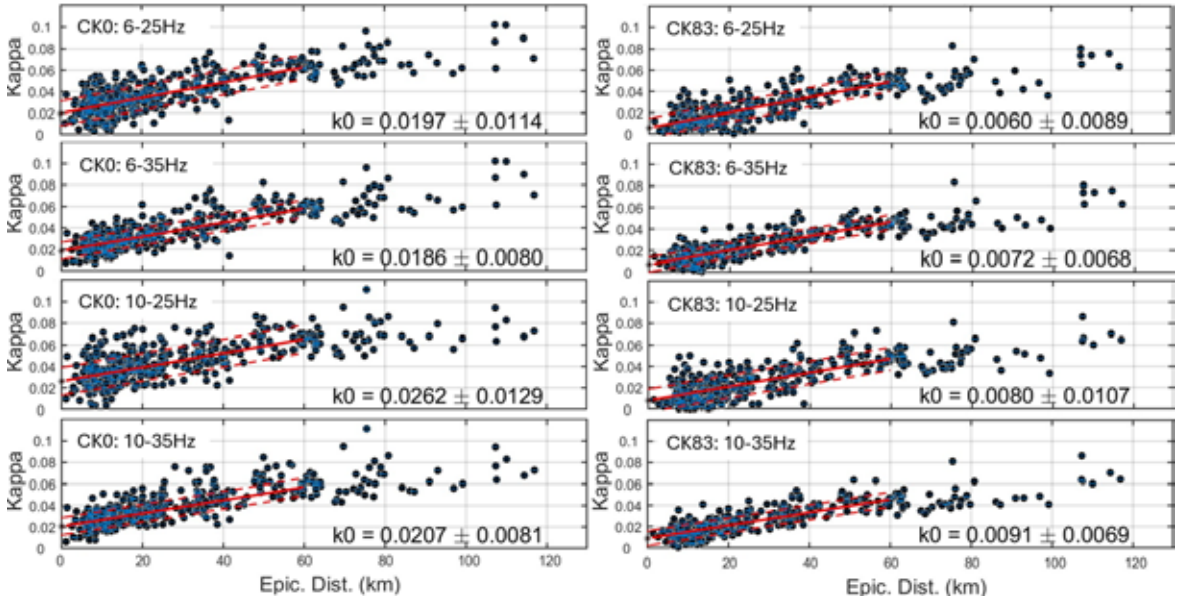

Figure 2. κ values computed from the earthquake records at stations CK0 (left) and CK83(right) considering four different frequency ranges (noted on top left of each subplot). The slope of the linear regression has been kept constant considering all ARGONET data. Mean κ_0 values (κ at zero distance) and the ± 1 STD are also noted in each subplot.

Table 1. Computed κ_0 and $\Delta\kappa_0$ mean values and their standard deviations (σ) for four examined frequency ranges. $\Delta\kappa_0$ results are shown for both applied methods described in the text. Columns named "SV model range" list the quantity "maximum seasonal model amplitude - minimum seasonal model amplitude" for each examined case.

	CK0		CK83		$\Delta\kappa_0$ Method1			$\Delta\kappa_0$ Method2		
f_e-f_{end} (Hz)	κ_0 (ms)	$\sigma\kappa_0$ / κ_0 (ms)	κ_0 (ms)	$\sigma\kappa_0$ / κ_0 (ms)	$\Delta\kappa_0$ (ms)	$\sigma\Delta\kappa_0$ / $\Delta\kappa_0$ (ms)	SV model range	$\Delta\kappa_0$ (ms)	$\sigma\Delta\kappa_0$ / $\Delta\kappa_0$ (ms)	Sv model range
6-25	19.7	11.4	6.0	8.9	18	6	7	17.4	0.8	6.5
6-35	18.6	8.0	7.2	6.8	14	6	5	14.4	0.5	4.3
10-25	26.2	12.9	8.0	10.7	20	10	10	20.6	1.1	9.6
10-35	20.7	8.1	9.1	6.9	15	10	6	14.4	0.7	4.5

In our case, CK0 is the target site and we examine its high-frequency shaking characteristics with respect to the borehole station CK83 using two different methods: In "Method 1", we used pairs of κ values from CK0 and CK83 stations to estimate $\Delta\kappa=\kappa_{(CK0)}-\kappa_{(CK83)}$ and equivalently $\Delta\kappa_0$. In "Method 2", we measured $\Delta\kappa_0$ directly on Standard Spectral Ratios (SSRs) of CK0 with respect to CK83. The two approaches will be presented in more detail in the following.

The computation of $\Delta\kappa_0$ from the κ values of CK0 and CK83 is straightforward and resulting values are plotted in Figures 3a and 4. For examining possible variations of $\Delta\kappa_0$ with seasons (Seasonal Variation, SV), we considered a "pseudo-waveform" $\Delta\kappa_0$(day), where "day" is derived from date considering as starting point the 1st of January of each year. We analyzed this pseudo-waveform for its frequency content via FFT. We computed FAS only for periods T_{SV}^h, corresponding to 365/h for h=1 and h=2, seeking for possible variations with a return period of the order of a year or half a year and aiming to a smooth model of the phenomenon, if proven significant. The seasonal variation of $\Delta\kappa_0$ ($\Delta\kappa_h(SV)$), was finally modeled as the sum of the 2,

discrete period (T_{SV}^h) cosine wavelets, based on the corresponding scaled FAS Amplitude, $\Upsilon(T_{SV}^h)$, and adopted phase, $\varphi(T_{SV}^h)$ (in degrees),as in:

$$\Delta\kappa_h(SV) = \Upsilon(T_{SV}^h) \cdot \cos\left\{\left(2 \cdot \pi / T_{SV}^h\right) \cdot [\text{Date} - \varphi(T_{SV}^h)]\right\} \quad [2]$$

Figure 3a shows as an example the starting data and resulting model (red dots and cyan lines in Figure 3a) for the frequency range 6-25Hz and the corresponding result of the FFT analysis (Figure 3b). The starting data and final models for the seasonal variation of $\Delta\kappa_0$ for all four tested frequency ranges are presented in Figure 4. If there is a time pattern in $\Delta\kappa_0$, a clear peak is expected to be observed in plots like the example plot in Figure 3b. In the specific example of Figure 3b, a prominent peak is seen at the examined period of 1 year, suggesting a yearly repeating change in $\Delta\kappa_0$.

In general, Figure 3 shows a clear time variation of $\Delta\kappa_0$ measurements, with lower $\Delta\kappa_0$ during summer and highest during winter. The proposed model for this variation also predicts the lowest $\Delta\kappa_0$ values during the first third of July and the highest values during the first third of January of each year. These results were consistent for all four examined frequency ranges and any differences were restricted to the order of a few days.

The modelled seasonal variation of the high-frequency ground motion amplitudes at CK0 with respect to those in CK83 can be characterized as significant, since its range (maximum seasonal model amplitude - minimum seasonal model amplitude) is of the order of 1 standard deviation of the mean $\Delta\kappa_0$ from data (Table 1, $\sigma\Delta\kappa_0\Delta\kappa_0$, Columns 7, 8). This means that the proposed model, if used to "correct" the observed data examined in this study, could lower the variability in κ_0 or $\Delta\kappa_0$ measurements and lead to more robust computations of the mean κ_0. The performance of the seasonal variation model of $\Delta\kappa_0$ shows some dependence on the frequency interval adopted in the analysis, but in all cases explains much of the variability of the examined parameter (Table 1).

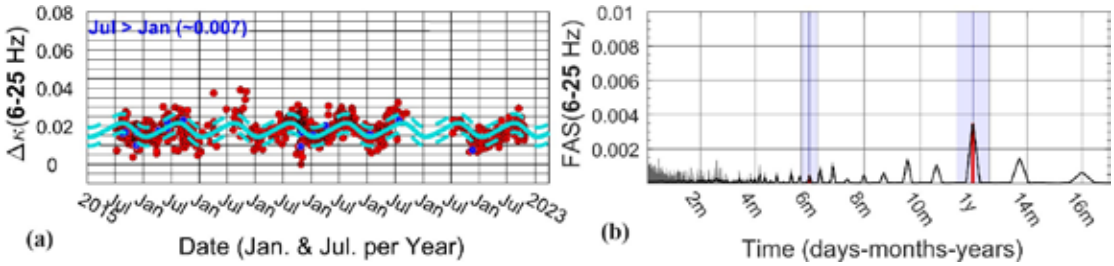

Figure 3. Variation of $\Delta\kappa_0$ with date a) data points of individual $\Delta\kappa_0$ measurements for the frequency range 6-25Hz and superimposed model of the seasonal variation of $\Delta\kappa_0$ ± 1 standard deviation (STD) of the mean model (cyan curves), b) Fourier Amplitude Spectrum (FAS) of the pseudo-waveform $\Delta\kappa_0$(day) considered. Shaded areas mark the areas of the investigated return periods of the phenomenon (i.e, at 1 year and 6 months). The difference between the lower and higher $\Delta\kappa_0$ values predicted by the proposed model are noted in the top left of a).

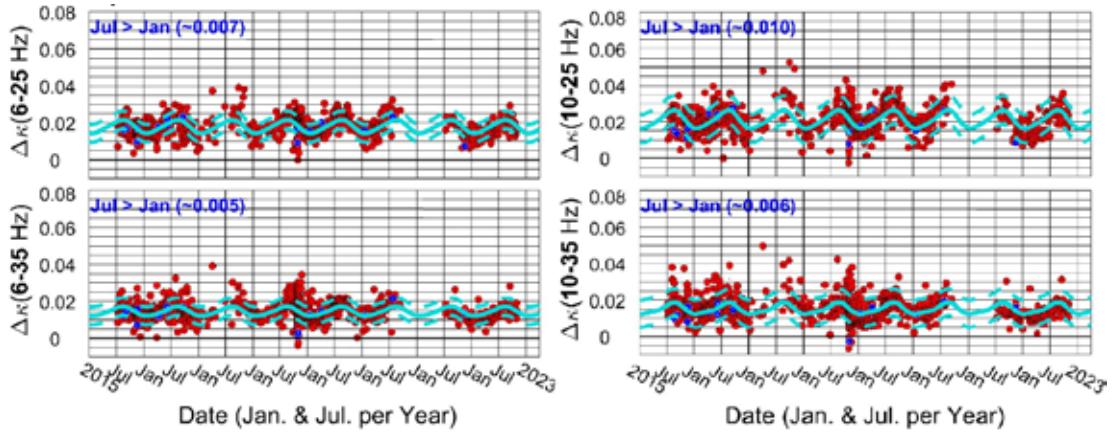

Figure 4. $\Delta\kappa_0$ values based on the κ_0 measurements at CK0 and CK83 stations ($\kappa_{(CK0)}$-$\kappa_{(CK83)}$) for the 4 examined frequency ranges. The modeled seasonal variation of $\Delta\kappa_0$ and its Standard Deviation (STD), are shown in cyan solid and dashed lines, respectively. The highest value of the seasonal $\Delta\kappa_0$ model is predicted to occur in July and the lowest in January of each year. The difference between the lowest and highest predicted $\Delta\kappa_0$, is written in the top left of each subplot.

The alternative approach to compute $\Delta\kappa_0$ (our "Method 2") is to measure it directly on Standard Spectral Ratios (SSRs) of CK0 with respect to CK83. By dividing the FAS of CK0 to those of CK83 and considering that the interstation distance is much smaller compared to any epicentral distance in the examined dataset, we assume that source and path effects are effectively removed (Borcherdt, 1970), including the path-dependent component of κ. In the high-frequency part of the SSR, the spectral division mainly includes the division of the factors $\exp(-\pi\kappa_{(CK0)}f)/\exp(-\pi\kappa_{(CK83)}f)$. The path-dependent component of κ is considered the same for both the surface and borehole station and is eliminated and what remains is the difference $\kappa_{0(CK0)}-\kappa_{0(CK83)}$, i.e., the quantity under study.
SSRs for the horizontal component of the ARGONET dataset have already been computed by Grendas et al. (2025). Herein, we use these published seasonal varying ratios to perform linear regression on their high-frequency parts and more specifically within the same four frequency ranges examined earlier ("Method 2"). The resulting $\Delta\kappa_0$ values are depicted in Figure 5, along with SSRs colored according to the date of their occurrence. Warm colors correspond to dry, summer months and cold colors to winter months and it is evident that the differences in the high-frequency signal of CK0 with respect to CK83 increases during winter and diminishes during the summer.
Linear regressions to compute the mean $\Delta\kappa_0$ and its values during the identified "extreme" seasonal variation periods (i.e., July-August and January-February) have been performed directly on the SSRs of Figure 5. Pertinent results are shown in each subplot, considering the four examined frequency ranges. The linear fits for the two extreme seasonal variation periods are also shown. $\Delta\kappa_0$ values and their STDs are also listed in Table 1, under "Method 2".
By comparing the linear fits in Figure 5, it becomes evident how the seasonal variation can largely affect the computation of $\Delta\kappa_0$ (and directly of κ and κ_0), at least at the specific site examined in this study. Datasets with a biased concentration of summer recordings would provide much larger values of κ_0 compared to non-biased or inversely biased datasets. The effect seems to be more significant when the examined frequency range terminates at frequencies largely affected by seasonal variations. In Figure 5, for example, the left subplots including analysis up to 25Hz present much larger discrepancies between the two "extremes" with respect to subplots to the right where the analysis is extended well beyond the frequency range mostly affected by seasonal variation. All these observations raise another "red flag" when the engineering and seismological communities face the necessity to harmonize κ measurements for comparisons.
Overall, the results of the two methods for computing $\Delta\kappa_0$ are similar and this is demonstrated by the comparison of values reported in Table 1.

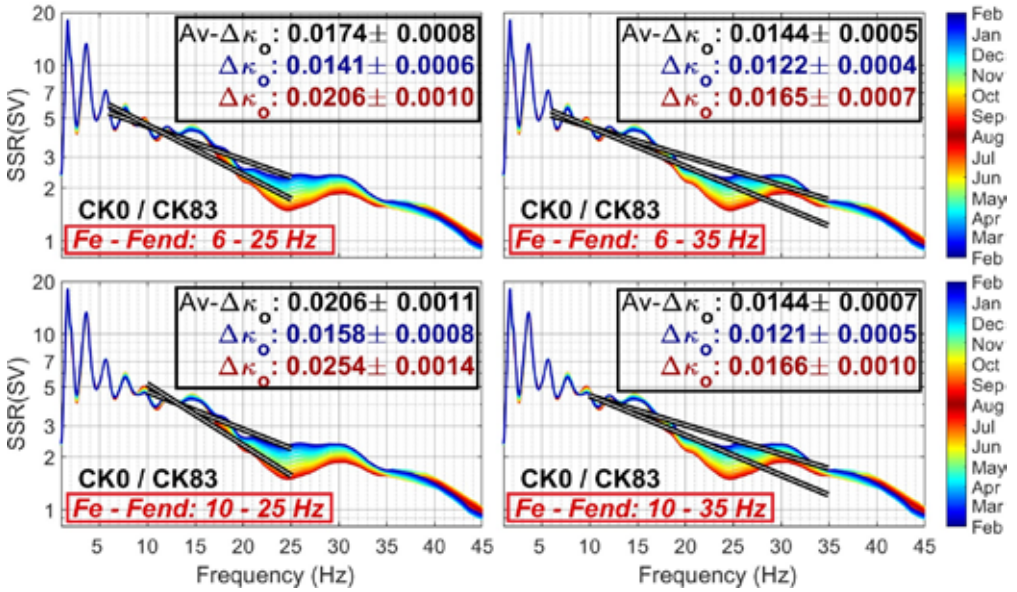

Figure 5. Mean Standard Spectral Ratios (SSRs) (for the 1st day of each month) between CK0 and CK83 stations colored according to the date of occurrence of. Subplots differentiate in the frequency range used for the linear regression. Double lines mark the regression results for the two extreme $\Delta\kappa_0$ cases (summer vs winter). On the top right of each subplot, the mean $\Delta\kappa_0$ and $\Delta\kappa_0$ values corresponding to the two extremes of the modelled seasonal variation are noted.

Conclusions/Discussion

Despite its limitations, kappa remains a valuable parameter for understanding high-frequency attenuation and

conducting site-specific hazard analyses. Its practical utility has made it a significant parameter of engineering seismology, but ongoing research aims to refine its estimation techniques and improve its integration into seismic hazard models. By addressing its limitations and standardizing methodologies, the role of kappa in seismic hazard analysis can be further enhanced.

In this work we addressed an additional process that may add to the lumped character of this single-number descriptor of high-frequency attenuation, i.e., the soil-atmosphere interaction. We specifically examined if the high-frequency part of the earthquake spectrum, i.e., the part commonly used for the computation of kappa, changes with a seasonal periodicity. To do so, we comparatively examined kappa values at one surface and one borehole, bedrock station.

Our results demonstrate that the difference in κ_0 values of the two examined stations exhibit considerable variability due to seasonal weather conditions, the frequency range used in the computation of the parameter, and potentially source processes. The pronounced seasonal variation observed at the surface soft soil site CK0 highlights the influence of rainfall-induced changes in ground humidity on near-surface attenuation. This finding challenges the common assumption of a static, site-specific κ_0 value and requests further research on the possible need to consider seasonal variability of high-frequency ground motion in seismic hazard assessments.

The frequency-dependent behavior of κ_0, evident in the variations observed across different tested frequency ranges, suggests that attenuation slopes might not be uniform across the entire high-frequency spectrum at a given site. This observation warrants further investigation to understand the underlying mechanisms driving these frequency-specific variations. It also adds to previous discussions in the published literature about the need to standardize the methods for computing kappa to be able to compare kappa values from different regions and studies and limit its broader applicability in seismic hazard models (e.g., Ktenidou et al., 2014).

This study also confirms the effectiveness of using SSR(f) for more robust κ_0 estimation, providing lower standard deviations compared to traditional methods based on individual kappa factor differences.

Overall, this research provides additional insights into the complex nature of κ_0 and its potential variability. Further research is needed to investigate seasonal variations of kappa at a statistically significant number of sites, quantify dependencies and develop improved predictive models that incorporate these sources of variability for enhanced accuracy and reliability.

EXTENDED ABSTRACT 106

Digital model of Hydrological components, Mean annual Temperature, Precipitation and Evapotranspiration in Macedonia, Greece

Grimpylakos, Georgios[1]
(1) Department of Geography, University of the Aegean, Mytilene, Greece

Introduction / Background

River hydrology and morphology provide a relationship between flowing water and the physical environment of rivers. The hydromorphological regime (C11) is one of the hydromorphological quality elements of the WFD and is defined by the water flow's characteristics regarding quantity and dynamics hence to each connection to ground waters (Rinaldi et al. 2013b, Belletti et al. 2015, and Kilinc & Kay 2018). In recent years, 2009-2025, the classification of a river's hydromorphology is directly correlated with the classification and characterization of a river's morphology and hydrology which are recognized as fundamental intergrading components for studying, analysing and understanding it's behavior in order to adapt and suggest appropriate river management applications (e.g., Sear et al. 1995, Gilvear 1999, Kondolf et al. 2003, Downs and Gregory 2004, Brierley and Fryirs 2005, Brierley and Fryirs 2008; Meitzen et al. 2013, Tadaki et al. 2014, Belletti et al. 2015). The increased concern of quality, regarding river water and its habitats, combined with their correlation with the river's degradation have become important elements of hydromorphological assessment (Kilinc & Kay 2018). Furthermore, floods are common in certain areas of the world, and there have been more than 400 major floods during 2000-2024 with more than 70 billion Euros (EM-DAT, 2024).

Objectives

This study aims to create digital maps of hydrological components, such as Mean Annual Temperature, Precipitation and Evapotranspiration, which are recognized as essential components for the study and modeling of hydrological cycle, river management and hydrological natural hazards and point out the need for high spatial resolution.

Study area

Macedonia is a district of North Greece as shown at Figure 1. Studying area is a polygon that includes all the watersheds of Macedonia's torrents and rivers, resulting in a polygon the boundaries of which differ from the boundaries of Macedonia's political district and define it as an area of North Greece. The boundaries of each watershed were determined by the Ministry of Rural Development and Food in collaboration with the Institute of Geology and Mineral Exploration and always according to the WFD guidelines for water bodies. The study area is 36.290 km^2, has a perimeter of 2.163 km and includes 77 different torrents in which main rivers are divided according to WFD, and their watersheds area is of 2,9-4.775 km^2.

Data and Methodology

To study the climatic parameters for a given area, a 30-year period with good spatial and temporal distribution is needed.

For our study area, 85 meteorological – climatological stations (mentioned as MCS) from the Ministry of Rural Development and Food (82) and Hellas Gold (3) provided data which correspond to different time periods during an eighty-year period (1930-2010) and include daily, monthly and annual measurements of precipitation, while 43 of them included also daily monthly and annual measurements of temperature. After sorting the data from all 85 MCS the best period corresponded to 1974-2004, as the number of stations with daily and continuous data was higher (Grimpylakos 2020).

Specifically, to estimate the mean annual precipitation, 163.254 measurements belonging respectively to 40 MCS were used (Figure 1,3) and a subset of 20 MCS (figure 2,4). The second map of Precipitation was created using a subset of 20 MCS which also had adequate Temperature data for the creation of the Temperature and Evaporation map.

To estimate the mean annual temperature, approximately 800.000 measurements of daily minimum and maximum temperature, obtained from 43 MCS, during 1930-2010 were examined. The same thirty-year period 1974-2004 with

consistent daily data of 255.326 measurements were used, belonging respectively to the same 20 stations of the second map of precipitation (Figure 2,4).
The average initial MCS spatial distribution was 1/38,7km^2. After sorting and evaluating data, the overall spatial distribution of MCS for the precipitation map at figure 3 is 1/82.25km^2 and for temperature (figure 5), precipitation (figure 4) and corresponding evapotranspiration map (figure 6) is 1/164.5km^2. However, there are areas with lower density of approximately 1/300km^2 for maps at figures 4,5,6 and of 1/180km^2 at figure 3.
A very basic problem in spatial analysis is interpolating a spatially continuous variable from point samples. There are many different spatial interpolation techniques. Some of the most used interpolation methods to model spatially distribution from point data are: Inverse Distance Weighting (IDW), spline and ordinary kriging. Overall, anomalies of local scale can be adjusted without affecting the values derived from interpolation at other points on the surface (Burrough and McDonnell 1998).
Inverse distance weighted (IDW) is a method of interpolation that estimates cell values by averaging the values of nearby measured data points. This technique weighs the points closer to the prediction location greater than those farther away, hence the name inverse distance weighted (Watson and Philip 1985). However, the main problem with this technique is that it assumes that maximum and minimum values are measured at the sampled points and all other points have values between those values.
Spline is an interpolation method in which cell values are estimated using a mathematical function that minimizes overall surface curvature, resulting in a smooth surface that passes exactly through the input points. It is a deterministic, locally stochastic interpolation technique, which represents two-dimensional curves on three-dimensional surfaces (Eckstein 1989; Hutchinson and Gessler 1994).
These methods are known as deterministic interpolation methods because they are directly based on the surrounding measured values and use specified mathematical formulas that determine the smoothness of the resulting surface. On the other hand, kriging uses statistical models that include autocorrelation among measured points, to predict the values at unknown points. The most applied form uses “semivariogram” among pairs of sampled points. The Kriging interpolation method was developed by Matheron (1970).
All data were divided into 2 groups. The first group was named “training” and content 90% of sample points while the second group was named “test” and content 10% of the sample points. Training group’s measurements were used for predicting the values of the examined variable at whole Macedonia by using the aforementioned interpolation methods. Test’s group was used to validate the results of each method as shown at table 1.
The correlation between elevation and mean annual temperature, precipitation and evapotranspiration was checked with SPSS program and the results are shown at table 2.

Table 1. Root mean square error of each applied technique was calculated and IDW shows significant higher accuracy.

Interpolation techniques	IDW	Kriging	Spline	Polynomial
Root Mean Square Error	0,091	0,133	0,159	0,134

Figure 1. Map projecting the spatial distribution of the 20 meteorological – climatological stations with continuous temperature data during period 1974-2004, at North Greece.

Results and Discussion

Mean monthly precipitation was estimated for each month at all 20 (that have also good spatial-temporal distribution of temperature data) and 40 (with no adequate distribution of temperature data) MCS and then the mean annual precipitation was calculated for all of them. The highest possible correlation between Precipitation and elevation was not significant R^2<0,29 (Table 2) and so an equation for the estimation of the mean annual precipitation for each cell of Macedonia could not be used. Four different interpolation techniques were examined, and the root mean square error was estimated for each technique (Table 1). The IDW method was found to be the most accurate one and two thematic maps were created showing the mean annual precipitation in Macedonia North Greece. The spatial distribution of the mean annual precipitation that derived from the 40 MCS during 1974-2004 is projected at Figure 3. The spatial distribution of the mean annual precipitation that derived from the data of 20 MCS, a subset of 40, during 1974-2004 is projected at Figure 4.

The thematic map that derived from the 20 stations at Figure 4 did not include 20 stations of Figure 3, so it was missing mean annual precipitation values between 417,0 – 417,3 and 853,8 – 999,8 as these data did not exist at the 20 stations. The data distribution of the 20 stations at West, Central and South Macedonia is very sparse, resulting in much less precipitation zones. The map of 40 stations has much better spatial distribution and is more accurate than that of 20 stations and is suggested for analysis purposes). Precipitation increases with elevation, but as there is lack of MCS at elevation above 1250m, there are also no values above 1000mm at the produced map for precipitation (figure 6), Koumaria has the highest mean annual precipitation of 1020,4mm at 700m elevation.

Figure 2. Map projecting the spatial distribution of the 40 meteorological – climatological stations with continuous precipitation data during period 1974-2004, at North Greece.

Figure 3. Thematic map projecting the spatial distribution of mean annual precipitation (mm) at Macedonia of North Greece. The data derived from 40 meteorological – climatological stations during period 1974-2004 and the cell size is 750m.

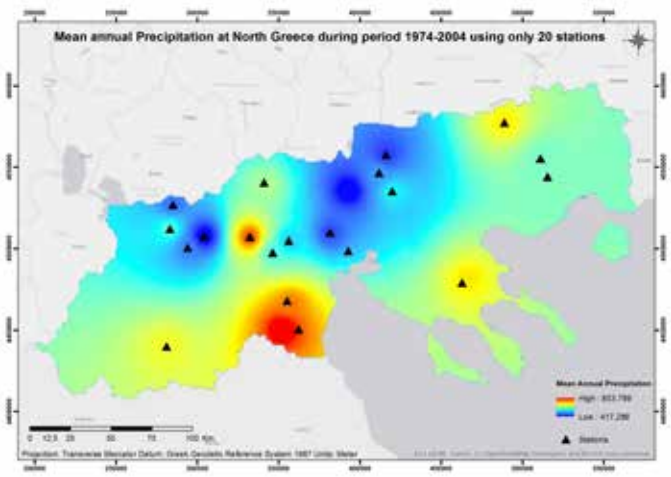

Figure 4. Spatial distribution of mean annual precipitation at Macedonia Greece derived from 20 meteorological stations during period 1974-2004

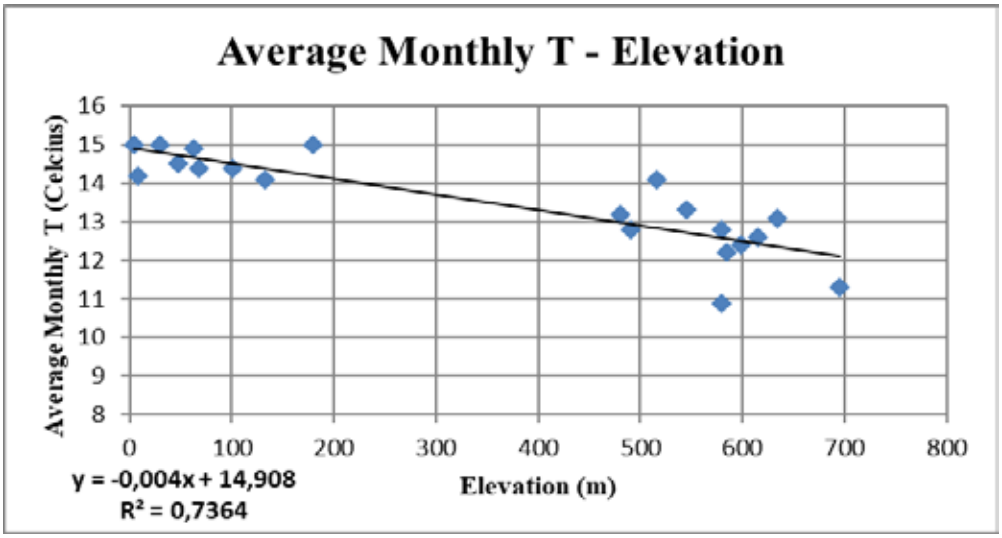

Chart 1. Correlation of mean annual temperature with elevation using linear equation.

The mean monthly temperature for each of the 20 MCS was calculated and then, the mean of these values gave the mean annual temperature for each station. There is a significant correlation between Mean annual Temperature and elevation as shown at (Chart 1), with $R^2 = 0,7364$, and the corresponding equation shows that the temperature declines as the elevation rises. This equation was applied using the raster calculator of ArcMap 10.3 and high-resolution Digital elevation model (DEM) with 28.3mx28.3m cell size, which was constructed from the Advanced Space borne Thermal Emission and Reflection Radiometer (ASTER) of NASA Terra satellite. The corresponding map was created (Figure 5).

Table 2. Correlation of Variables Temperature, Precipitation and evapotranspiration of each method of Thornthwaite, Turc and Coutagne with Elevation.

Elevation	Examined Variable				
	T (°C)	P(mm)	Thornthwaite	Turc	Coutagne
Pearson	-0,851	0,306	0,156	-0,072	0,108
R-square	0,723	0,094	0,024	0,005	0,012

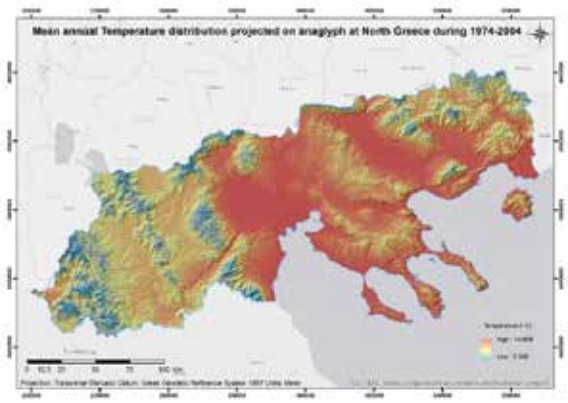

Figure 5. Mean annual temperature distribution at North Greece derived from 20 meteorological – climatological stations during period 1974-2004, projected on anaglyph.

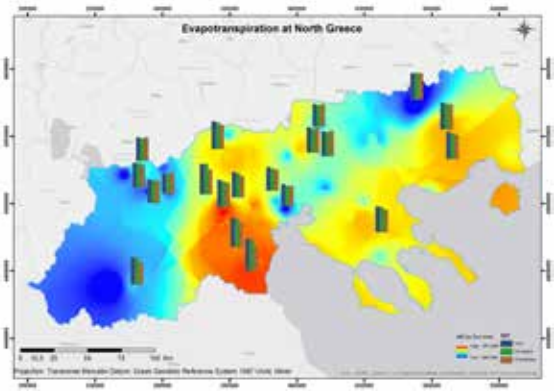

Figure 6. Thematic map of AET by all methods and with IDW by Turc nethod, cell size of 750m.

Actual evapotranspiration was calculated with Turc, Coutagne and Thornthwaite methods for each month at each one of the 20 MCS (Figure 2). AET by Turc method is higher than Thornthwaite method at all stations and in 19 of 20 stations it is higher than Coutagne method, while Coutagne is higher than Thornthwaite method at 15 of 20 stations. On the other hand, Turc method is the most easily applied method of all, as Coutagne method is not always applicable and Thornthwaite's method uses parameters that differ according to elevation and the spatial distribution of each examined place, which makes it very difficult to apply this method at all stations. No significant correlation between elevation and evapotranspiration was found (Table 2). Lastly, the Thornthwaite method is underestimating evapotranspiration in comparison with the other two methods. All AET are projected at each station, while Turc method with the highest AET is projected using IDW spatial interpolation (Figure 6). As Turc method is the easiest applied method, other researchers can use this method and compare their results with figure 6.

Conclusions

A significant correlation, with R^2 = 0,7364 (chart 1), between Mean annual Temperature and elevation was found and the corresponding equation is **T = - 0,004 * E + 14,908** (T is mean annual temperature and E is elevation). The thematic map projecting the distribution of Mean annual Temperature and the elevation is shown at Figure 5. However, there is a significant gap in the MCS regarding elevation 200-450 m, which was necessary for data consistency. The temperature values were estimated through extrapolation, therefore there is also a limitation for areas with elevation above 700m. A better elevation distribution in MCS is suggested for future work.

The mean annual precipitation at each MCS was estimated, but there was no significant correlation between elevation and Precipitation at Macedonia to create an equation. For future work, better elevation distribution of the MCS is suggested. For the creation of the Precipitation maps, 4 different spatial interpolation techniques were examined (Table 2) and IDW method was applied as it had the lowest Root Mean Square Error (Figures 3 and 4). Highest

spatial distribution of stations at figure 3, with 40 MCS, clearly shows the need of good spatial distribution of MCS, as figure 4 with 20 MCS misses values between 417,0 – 417,3 and 853,8 – 999,8.
The mean annual actual evapotranspiration at each one of the 20 MCS was estimated using Turc, Coutagne and Thornthwaite methods and their values are displayed at figure 6. The thematic map (Figure 6) projecting the evapotranspiration distribution by Turc method at Macedonia was created using the IDW spatial interpolation method. The AET used only the Precipitation at the same 20 stations that Temperature data were available and not from the 40 MCS where the precipitation has higher values 853,8 – 999,8. This means that AET at the rest area of the map could be underestimated.
Lastly the need for high spatial-temporal distribution of MCS is clearly shown, but also a good elevation distribution of MCS is also needed and suggested for better results in the future.

Acknowledgments

Special thanks to all geologists that worked during 2011-2012 at the Department of Geology and Hydrology of Ministry of Rural Development and Food and to Emeritus Professor Karakostas Theodoros for scientific advice in the field of methodological approach, selection and evaluation of data station and time series, the interpretation of data and the validation procedure.

The Pheneos palaeolake in N. Peloponnese, Greece

Groumpou M.[1], Koukouvelas I.[1], Nikolakopoulos K.[1], Sanjuan J.[2], Papadopoulou P.[1], Iliopoulos G.[1].

(1) Geology Department, Patras, Greece, mgroumpos@gmail.com

(2) Department of Earth and Ocean Dynamics, Barcelona, Spain

Introduction

Pheneos polje, located in northern Peloponnese (Greece) is strongly linked to the homonymous mythical lake. Throughout the past millennia, flooding events in the southern part of this polje have given rise to a lake. The myths associated with the lake revolve mostly around its drainage periods, with local populations suggesting that Hercules himself excavated openings to the ground with his bare hands to rescue the villagers from flooding (Jones, 1988). In reality, the water drains through sinkholes that are part of the region's karstic system (Tsoflias, 1973). In the southernmost part of the polje, distinct step-like scarps on the landscape serve as indicators of past lake levels (Figure 1). These scarps, representing notable geomorphological features, have been documented by Pausanias and other historical travelers (Groumpou, 2024). The primary objective of this study was to verify these features as relict shorelines of the ancient Pheneos lake.

Figure 1. Scarps on the landscape in the southern part of Pheneos polje indicating past lake levels.

Methods

Two distinct datasets, consisting of orthophoto maps and digital surface models (DSMs) were used to identify and map the step-like landforms across the landscape. The first dataset consists of a 50 cm spatial resolution orthophoto map and a 5 m pixel size DSM, whereas the second dataset consists of an orthophoto and a DSM of 4 cm spatial resolution. ArcMap 10.8 was used to display and analyze the two datasets. Subsequently, fieldwork was conducted to examine the characteristic features of the stepped landforms, and 35 surface sediment samples were collected from the different step-like scarps across the southern margins of the polje and processed for micropalaeontological analysis.

Results

The results reveal that the step-like scarps in the landscape consist of alternating coarse-grained gravel material and fine-grained material rich in gravel containing lacustrine taxa, which were deposited in a nearshore environment (Groumpou et al., 2023). A pattern of at least four such alternating sediment deposits has been mapped from the orthophoto maps, corresponding to distinct palaeoshorelines (Figure 2). These deposits contain a micropalaeontological assemblage comprising charophyte remains (gyrogonites and oospores), ostracods and gastropods. The most representative taxa of the identified micropalaeontological assemblage are *Nitellopsis obtusa* (Desvaux) Groves, 1919, *Sphaerochara prolifera* (Ziz. Ex. A. Braun) emend. Soulié-Märsche, 1989, *Chara vulgaris* Linnaeus, 1753, *Ilyocypris bradyi* Sars, 1890, *Ilyocypris inermis* Kaufmann, 1900, and *Candona neglecta* Sars, 1887 (Figure 3). Based on the ecological preferences of these taxa and their geographical distribution along the southern margins of the polje, three distinct lacustrine palaeoenvironments are identified: i) ephemeral lake (possibly annual) dominated by *S. prolifera* which is present up to an altitude of 710 m ii) cold and oligotrophic lake environment characterized by

the presence of *N. obtusa* and *I. inermis*, observed up to an altitude of 729 m and iii) warmer and mesotrophic lake, extending to altitudes of up to 744 m.

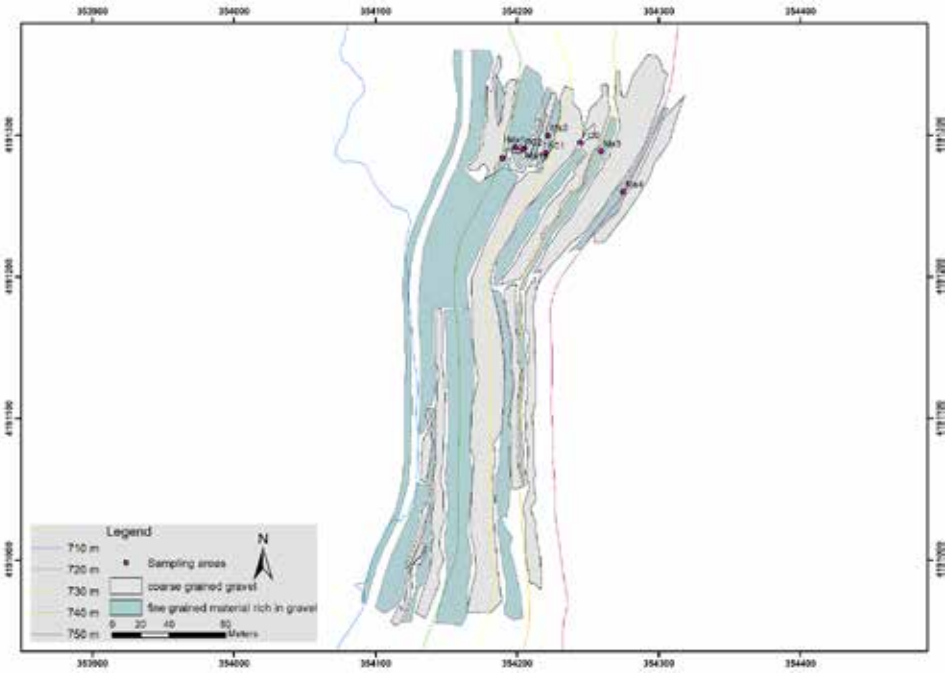

Figure 2. The mapped alternations of the studied sediment material, highlighting distinct palaeoshorelines on the southeastern part of Pheneos polje.

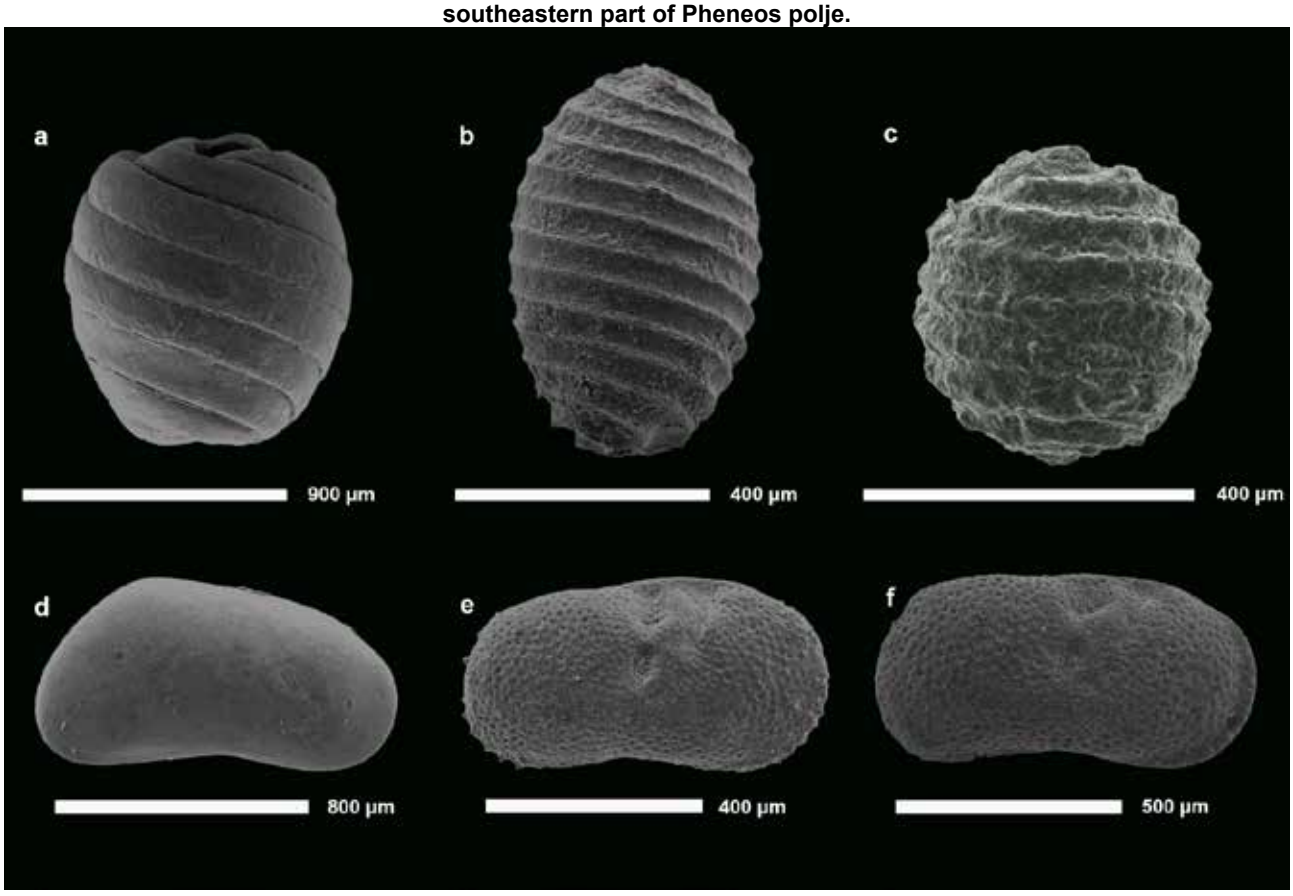

Figure 3. The most representative taxa of the identified micropalaeontological assemblage: a) *Nitellopsis obtusa*, b) *Chara vulgaris*, c) *Sphaerochara prolifera*, d) *Candona neglecta* e) *Ilyocypris bradyi* and f) *Ilyocypris inermis*.

Conclusions

The analysis of the stepped landscape in the southern margins of Pheneos polje revealed a sequence of at least four alternating sedimentary deposits, enriched with lacustrine taxa and which are indicative of near-shore depositional environments. The possible boundaries of Pheneos palaeolake are mapped and three distinct lacustrine palaeoenvironments were recognized based on the ecological preferences of the respective taxa (Groumpou et al., 2023). These findings provide insights into the Holocene dynamics and depositional history of the Pheneos polje.

Estimation of soil vulnerability index in the metropolitan area of Thessaloniki (Greece)

Grylionaki M.[1], Theodoulidis N.[2], Panou A.[1], Chatzidimitriou P.[1]

(1) Department of Geophysics, Department of Geology, Aristotle University Thessaloniki, Thessaloniki, Greece
mariagrilionaki@gmail.com

(2) Institute of Engineering Seismology and Earthquake Engineering (ITSAK), Thessaloniki, Greece

This paper presents an effort to assess the liquefaction potential across the Thessaloniki metropolitan area by calculating the Soil Vulnerability Index (SVI or Kg) for the surface geological formations and comparing the results with those of previous research. The SVI is associated with shear strain (γ) imposed on surface geological layers and has been effectively correlated with building damage and soil failures, such as liquefaction. To determine the dynamic properties of surface formations, including fundamental frequency (fo) and corresponding amplitude (Ao), the Horizontal-to-Vertical Spectral Ratio (HVSR) method of microtremor measurements was used. A total of 190 microtremor measurements were analyzed, revealing a good correlation between the SVI and liquefaction potential based on previous studies. High SVI values, indicative of increased liquefaction potential, are linked to low fundamental frequencies, high amplitudes, and are predominantly found in areas near the coast, where thick coastal soft deposits and riverbeds are prevalent. Additionally, strain (γ) values, which are related to SVI, were calculated for various peak ground acceleration scenarios and seismic basement velocities (Vb) specific to Thessaloniki. The results, represented in spatially interpolated maps generated via Geographic Information System (QGIS), align quite well with previous liquefaction potential studies conducted throughout the city using different estimation methods. This agreement encourages the use of microtremor measurements, directly linking them to liquefaction potential by employing the methodology utilized in the current study, in other regions as well.

EXTENDED ABSTRACT 109

Seismotectonics of the NE Aegean region: The Lesvos Island and the Gulf of Edremit

Levent Gülen
Sakarya University, Serdivan, Sakarya, Türkiye, lgulen@sakarya.edu.tr

Introduction:

Active tectonics of the Aegean is mainly influenced by the interactions of the North Anatolian Fault (NAF) branches, that extend into the Aegean Sea, the counter clockwise rotation and westward extrusion of the Anatolian block, the Hellenic Trench retreat, and the left-lateral strike-slip Pliny-Strabo Shear Zone (PSSZ), that extends towards the Isparta Angle (IA), (Dewey & Şengör, 1979; Taymaz et.al., 1991; Yılmaz & Gürer, 2013). The right-lateral strike-slip NAF gradually gains an additional normal component to the west of 31° E and its branches form the North Aegean Trough (NAT) and Skyros-Edremit Trough (SET) in the North Aegean Sea (Figure-1).

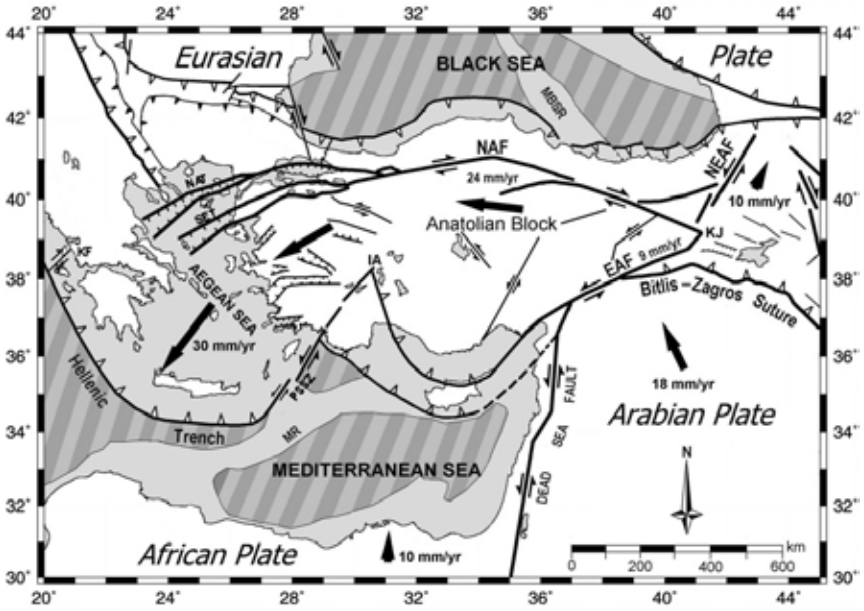

Figure 1. Simplified tectonic map of Turkey and surrounding regions (modified after Gülen et al, 2002).

The Aegean region is one of the rapidly deforming and seismically most active regions of the world as evidenced by historical and instrumental period earthquakes. More than 16 earthquakes with M > 6.5 have occurred since the mid-19th century in the North Aegean Region (Papadopoulos et al., 2002; Ganas et al., 2014). More than 32 major historical earthquakes have occurred just in the Lesvos Island and the Gulf of Edremit area and 22 of them occurred in 1800's (Ambraseys & Jackson, 2000; Ambraseys, 2002; Ambraseys, 2009). The historical earthquakes define an elongate zone extending in NW-SE direction that is parallel to the NE coastline of the Lesvos Island, which may indicate the presence of an unmapped major fault that is orthogonal to the Aghia Paraskevi Fault that traverses the island in NE-SW direction (Figures-2 & 3). The magnitudes of historical Lesvos earthquakes of 1739, 1809, and 1867 were determined as 6.8, 6.6, and 7.0, respectively (Karakaisis et al., 2010). The 1867 Lesvos earthquake was the most destructive among the historical earthquakes. The Oct. 26, 1889 earthquake was also a major earthquake that occurred in the western part of the Gulf of Edremit. This earthquake did not only totally ruin many towns in Lesvos, but also felt strongly as far as Çanakkale in the north and the Rhodes Island in the south (Ambraseys, 2009).
The instrumental period, 6 October, 1944 Gulf of Edremit Earthquake with M_w=6.7 occurred on the Edremit Fault Zone with a normal fault mechanism solution. This earthquake created a minor tsunami with a maximum inundation distance of 170 m. in the town of Ayvalık, on the Turkish coast (Altınok et al., 2012-a; Altınok et al., 2012-b; Sözbilir et al., 2016; Figure-2). Recently the 8 January, 2013 Lemnos Earthquake with M_w=5.7 (Kiratzi & Svigkas, 2013; Kürçer

et. al., 2013; Ganas et al., 2014); the 6 February-20 March, 2017 Gülpınar Earthquake Sequence (Gülen & Yalçın, 2017; Poyraz et al., 2017, Utkucu et al., 2017; Özden et al., 2017; Sözbilir et al., 2018; Ganas et al., 2018; Bekler et al., 2019; Koçyiğit & Gürboğa, 2021), and the 12 June, 2017 Lesvos - Karaburun Earthquake with M_w=6.3 (Kiratzi, 2018; Papadimitriou et al., 2018; Chousianitis & Konca, 2018; Utkucu et al., 2021) occurred in this region (Figure-3). The centroid moment tensor solutions indicate that 2017 Gülpınar, and 2017 Lesvos Earthquakes were caused by normal faulting, whereas the 2013 Lemnos Earthquake was caused by strike-slip faulting (Figure-3). More recently another earthquake sequence had started on 7 January, 2023 with an earthquake of M_w = 5.0 and continued with an earthquake of M_w=5 on 10 January, 2023, both located next to each other on the north coast of the Lesvos Island (Figures-3 and 6).

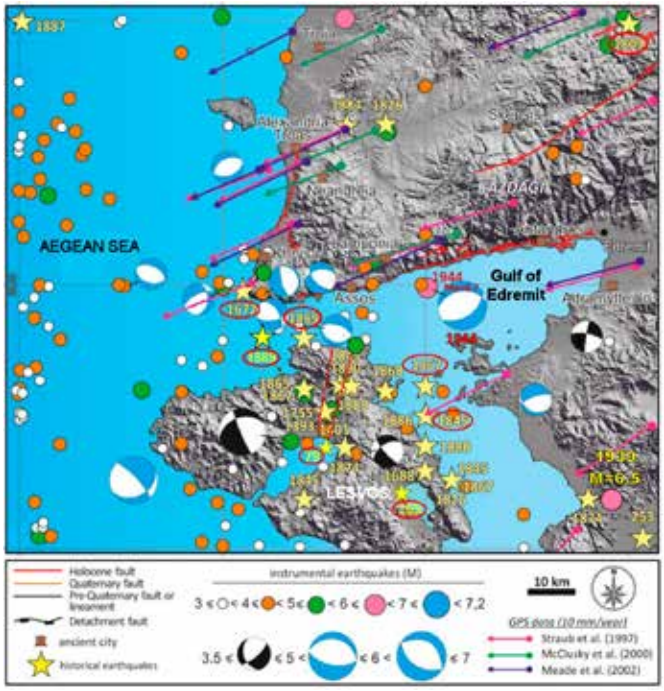

Figure 2. Seismicity map of the Lesvos Island and vicinity until 2017 (modified after Sözbilir et al., 2016).

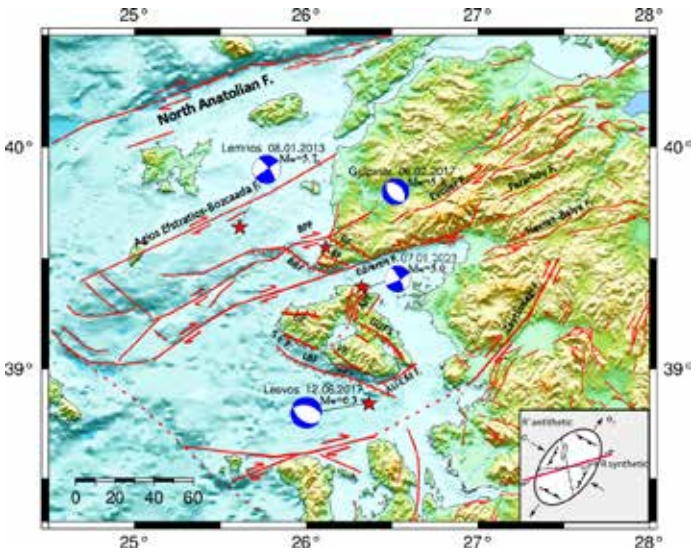

Figure-3. Map of recent earthquakes with $M_w \geq 5.0$ that occurred in the Lesvos Island and the Gulf of Edremit region.

The 6 February-24 March 2017 Gülpınar (Ayvacık, Çanakkale) Earthquake Sequence

An earthquake with moderate magnitude M_w=5.3 occurred on 6 Feb., 2017, at 03:51 (UTC) in the Gülpınar (Ayvacık, Çanakkale) region at a depth of 6 km (Poyraz et al., 2017). A second event with M_w=5.1 on the same day at 10:58; a third event with M_w=5.3 on 7 Feb., 2017, at 2:24; and a fourth event with Mw=5.2 on Feb., 12, 2017 at 13:48 were occurred. 26 aftershocks with M_w=4-5, and more than 2000 aftershocks with M≥2.0 occurred in this region between February 6 – March 24, 2017. These earthquakes occurred where there is a normal fault system (Gülpınar-Tuzla, Balabanlı, and Babakale Faults), which have been mapped by field studies (Yılmaz and Karacık, 2001; Sözbilir et al., 2018; Koçyiğit & Gürboğa, 2021). A panoramic photo taken looking in the NW direction shows the textbook example of stair steps like normal fault system in the Gülpınar-Tuzla area (Figure-4). Epicenters of these earthquakes plot in an elongate zone that strikes in the NW-SE direction (Figure-5). The moment tensor solutions of the main shock and a great majority of the aftershocks indicate normal faulting mechanism with NW-SE fault strike (Poyraz et al, 2017; Gülen & Yalçın, 2017; Bekler et al, 2019). The hypocenter depths of the aftershocks are in the range of 5-20 km and the distribution of aftershock hypocenters define normal faulting with a listric fault geometry that dips to SW (Figure-6).

Figure-4. A panoramic photo showing the normal faults in the Gülpınar-Tuzla area (looking towards the NW direction).

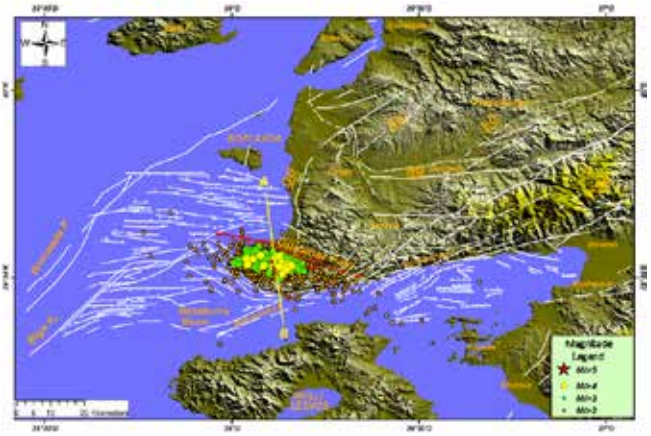

Figure-5.Seismic activity map of the the 6.02-24.3, 2017 Gülpınar Earthquake sequence (modified after Yaltırak et al., 2012).

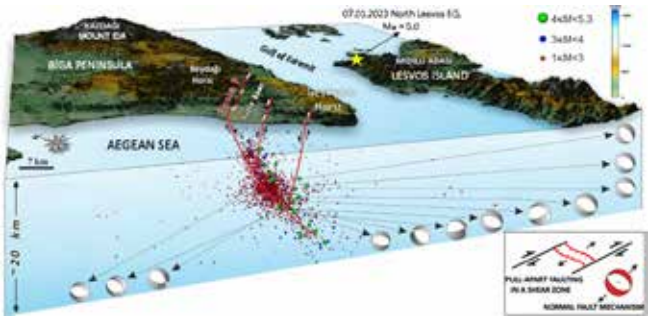

Figure-6. Block diagram of the 6 February- 2017 Gülpınar Earthquake sequence activity (modified after Sözbilir et al, 2018).

The January 7-10, 2023 North Lesvos Earthquake Sequence

An earthquake of moderate magnitude M_w=5.0 occurred on January 7, 2023, at 01:52:57 (GMT) at a depth of 6 km. along the northern coast of the Lesvos Island (Kartal and Kadirioğlu, 2023). The location of this earthquake is shown with a yellow star in Figure-6. On the same day an aftershock of M_w=4.7 occurred at 06:39:30. As of January 7, 2023, nearly one thousand earthquakes with magnitudes; varying between 0.8-5.0 have been recorded by the Disaster and Emergency Management Presidency of Türkiye. On January 10, 2023 another M_w=5 earthquake occurred in the same area. The aftershocks occurred at a depth range of 5-20 km with almost vertical geometry. The epicentral distribution of the aftershocks define an elongate zone extending in the NE-SW direction. Thus, centroid moment tensor solutions of 7 events with $M_w \geq 4.0$ indicate that these earthquakes were caused by a right-lateral strike-slip fault with an average strike of N60°E. The right-lateral strike-slip Aghia Paraskevi Fault is the most prominent tectonic feature on the Lesvos Island and it cuts the central part of the island coast to coast and it was the source fault of the historical 1867 destructive earthquake (Chatzipetros, et al., 2013).. The Aghia Paraskevi Fault has 5 fault segments and the southern 4 of these segments have NNE-SSW strikes (Chatzipetros, et al., 2013). Only the northernmost Sykamia segment has NE-SW strike and the January 7-10, 2023 earthquakes may be associated with the Sykamia segment of the Aghia Paraskevi Fault (Kartal and Kadirioğlu, 2023).

Conclusions

The active tectonics of the NE Aegean region can be explained by the mega-horse-tail geometry of the right-lateral strike-slip North Anatolian Fault's branches and other faults that extend with NE-SW strikes from the mainland Türkiye into the Aegean Sea. The historical and instrumental period seismicity, bathymetry, seismic reflection profiles, field studies, GPS measurements clearly corroborate this conclusion. The insets given in Figures 3 and 6 provide the simplest explanation for the active tectonics of the northern Aegean, which exhibits a NE-SW extensional tectonic regime. In the inset of Figure-3 the strain ellipsoid for a right-lateral strike-slip fault is shown with the positions of σ_1 and σ_3 principle stress axis', as well as the R and R' orientations. Similarly, the inset of Figure-5 also shows how extension takes place in a right-lateral strike-slip shear zone. The fault map given in Figure-5 shows the development of NW-SE trending normal faulting within a NE-SW trending right-lateral strike-slip shear zone that is perfectly consistent with the simple strain ellipsoid and pull-apart faulting explanations.

The fundamental cause of the overall Aegean extensional tectonic regime needs an explanation as well. The subduction transform edge propagator faults (STEP faults or simply tear faults) of the Kefalonia and the Pliny-Strabo Shear zones on both sides of the Hellenic Trench (Özbakır et al., 2023; 2020), as well as the North Anatolian Fault facilitates the Aegean continental lithosphere thrust over the subducting slab (remnant of the Neo-Tethys) causing trench retreat. The trench retreat and the associated mantle flow in that direction causes stretching of the ductile lower crust, which in turn creates an extensional tectonic regime in the brittle upper crust, thus thinning and expanding the surface area of the Aegean continental crust (Gülen, 1990). Supporting evidences for these conclusions were obtained by mantle seismic anisotrophy and seismic tomography studies recently (Jolivet, et al., 2009; Rappisi et al, 2024). In summary, the fundamental cause of the Aegean extension is the drag forces exerted by mantle flow to the Aegean continental lithosphere (Gülen, 1989; 1990).

EXTENDED ABSTRACT 110

The rocks connect us: Volcanic geoheritage of Lesvos Geopark (Greece) and Ida Madra Geopark (Türkiye)

Erdal Gumus[1], Nikolas Zouros[2]
(1) Balikesir University, Balikesir, Türkiye, erdalgumus08@gmail.com, (2) Aegean University, Mytilene, Greece

Introduction

Both Lesvos UNESCO Global Geopark, (Greece) and Ida Madra Geopark (Türkiye) include a variety of geological heritage sites of international significance and are characterized by rich geodiversity. The majority of the geological heritage sites present in the respective territories are related to volcanism, with the 72% of the geosites in Lesvos Geopark and 62% of the geosites in Ida Madra Geopark found on igneous rocks. Highlighting the shared and complementary geohistorical context of neighboring geoparks can enhance the interpretation, conservation, and promotion of geoheritage in a holistic manner and cooperation between territories.

The Aegean region is among the most tectonically active regions on Earth due to the subduction of the African plate beneath the Eurasian plate and the westward extension of the Anatolian microplate. Consequently, the region saw extensive extrusive and intrusive volcanism during the Miocene period (Bozkurt et al. 2005, Innocenti et al. 2009). The vigorous volcanic activity created complex volcanic formations. The geosites of Lesvos Geopark (Greece) and Ida Madra Geopark (Türkiye) are closely associated with Miocene volcanism and tectonics.

A Geopark might be likened to a chapter in a novel; it may be coherent independently but remains incomplete without the additional chapters that contribute to the overarching narrative. In this regard, the coinciding and complementary geosites of the Lesvos Geopark and Ida Madra Geopark may offer a more comprehensive perspective for both. Both Geoparks belong geologically to the Sakarya - Pelagonia massif (Figure 1).

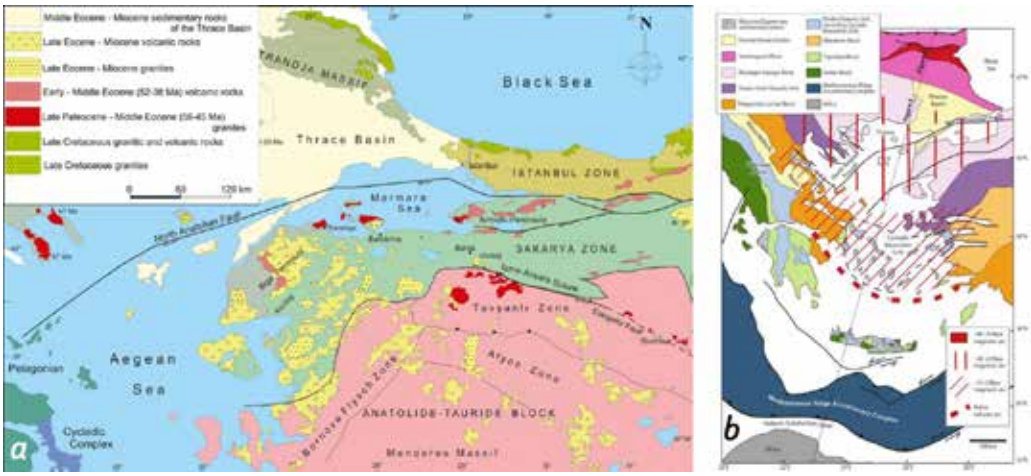

Figure 1. Simplified tectonic map of the North Aegean (a) (Okay et al., 2022) Aegean region (b), (Vouduris, 2018)

The Lesvos Geopark was founded in 2000 as one of the four primary partners of the European Geoparks Network. It is founding member of the Global Geoparks Network since 2004 and recognized as a UNESCO Global Geoparks in 2015. The Lesvos Geopark is distinguished by its exceptional abundance of fossilized trees and volcanic terrains. (Zouros *et al*., 2003, 2004, 2009, 2010)

The Ida Madra Geopark was established in 2019 and designated as a UNESCO candidate in 2022 (Gumus et al., 2021). The Ida Madra Geopark features the prominent Mt. Ida, composed of metamorphic rocks, alongside Mt. Madra, recognized for its Kozak granitoid (Gumus, 2022).

The two nearby geoparks are close enough to share a common geotectonic setting (Figure 2).

Figure 2. Location map of the Lesvos Geopark (Greece and the Ida Madra Geopark (Türkiye)

Objectives

This study intends to demonstrate how rocks and their geohistorical background can play an important role in bringing together neighboring and geologically interconnected territories. Their geological background can be the basis for the development of common research, educational and geo-touristic activities and provide a stable bridge for collaboration, common activities and cultural exchange.

This study is based on the classification, comparison, and interpretation of the volcanic geosites of the neighboring Lesvos Geopark and Ida Madra Geopark in a comprehensive manner.

Findings

Both Lesvos and the Ida Madra Geopark are significantly influenced by volcanism and associated landscapes, with 72% of geosites in Lesvos Geopark and 62% in Ida Madra Geopark located on igneous lithology (Figure 3).

The geosites of volcanic origin exhibit unique features, including diverse volcanic landscapes, intrusions, domes, columnar lava formations, lava flows, pyroclastics, hot springs, waterfalls, fossils, caves, and canyons.

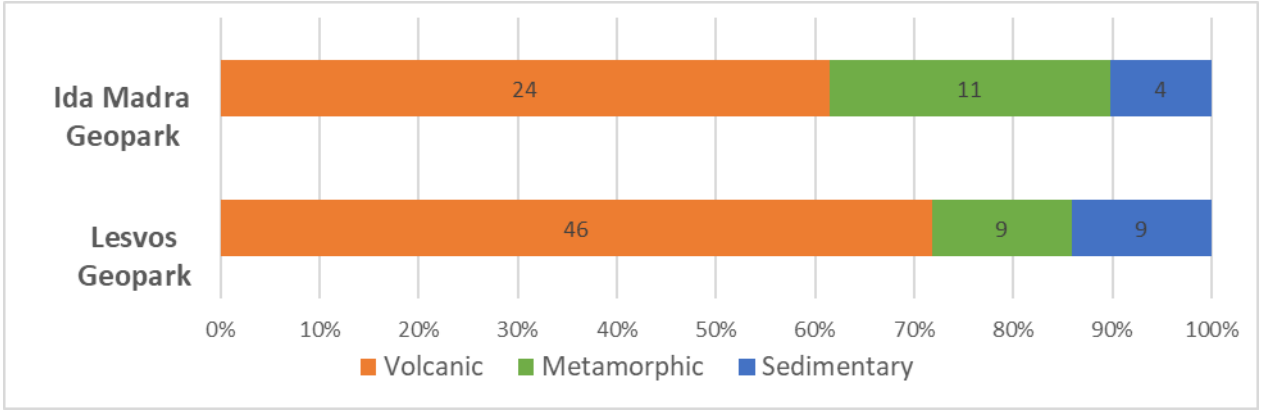

Figure 3. Geosite lithology comparison of Lesvos Geopark and Ida Madra Geopark

The variety of volcanic geosites of both Geopark facilitate a more thorough spatiotemporal interpretation of volcanism in the region. In certain instances, analogous geological processes resulted in comparable

formations, whereas in other cases, they produced distinctly unique appearances. For instance, both geoparks feature characteristic spheroidal exfoliation forms that are nearly identical in size and shape (Figure 4).

Figure 4. Spheroidal exfoliation geosites: Tatlısu geosite /Ida Madra Geopark (a), Vatousa geosite /Lesvos Geopark (b)

The westward extension of the Anatolian microplate dominates the active tectonics that governs both Geoparks. As a result, Miocene volcanics have been affected by major active faults creating impressive fault scarps during Quaternary (Figure 5).
Furthermore, the scientific importance of these geosites is highlighted by their extensive use in geo-education and in enhancing public awareness regarding natural disasters.

Figure 5. Aghia Paraskevi fault scarp geosite/ Lesvos Geopark (a), Pelitköy fault scarp geosite, / Ida Madra Geopark (b)

Conversely, analogous lithologies give rise to entirely distinct geosites and landscapes. For example, the differential weathering of thick ignimbrite deposits along vertical fractures resulted in finger-like columns in Lesvos Geopark, whereas the same lithology, when subjected to a spheroidal fracture pattern, revealed a turtle back-like landscape in Ida Madra Geopark (Figure 6).

Figure 6. Aslanalan geosite/Ida Madra Geopark (a), Candles geosite/Lesvos Geopark (b)

Intrusive volcanics significantly contribute to the geological features of both geoparks. The western section of the Lesvos Geopark features prominent volcanic formations, including the Ipsilou dome, Eressos dome, Mesotopos dome, and Mythimna dome. In contrast, the Ida Madra Geopark is distinguished by its granitic intrusions, exemplified by Mt. Çataldağ and Mt. Madra (Figure 7).

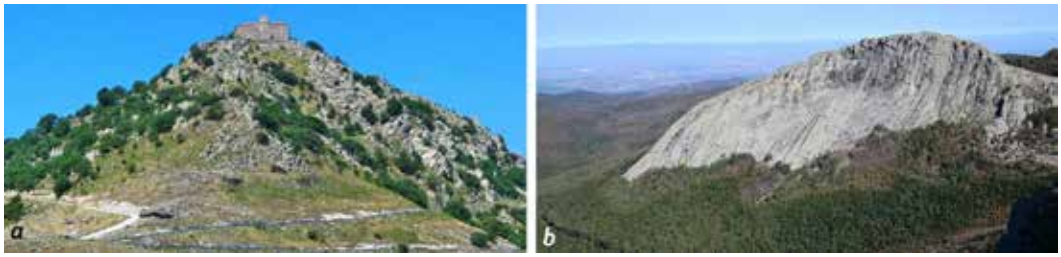

Figure 7. Ipsilou volcanic dome geosite/ Lesvos Geopark (a), Çataldağ granite slab geosite /Ida Madra Geopark (b)

Results and Conclusion

The Miocene volcanism which has significantly shaped both Lesvos Island and the Ida Madra Geopark area, may serve as a geological reference framework frame for cooperation in conservation, education, and research.

This geological continuum hosts inherently related yet fully distinct geosites within both Geoparks. Tracking the geological links between Lesvos Island and Ida Madra Geopark could help to provide a more thorough understanding and interpretation of the region's and Earth's overall geological evolution.

In the last decade, there has been a growing trend in reciprocal visits between Lesvos Island and Balikesir Metropolitan Area, evidenced by the traditional connections between Mytilene and Ayvalik as well as the establishment of new ferry routes and destinations connecting the two territories.

This fact presents significant potential for development of collaborative educational initiatives, including field excursions and Erasmus Exchange programs, as well as geotourism activities like offering inter-geopark tour packages.

Abstract

The Troodos Mountain region, including the Troodos UNESCO Global Geopark, is increasingly vulnerable to the impacts of climate change, facing both environmental degradation and socio-political challenges. Within the ClimEmpower project, we apply an integrated methodological framework combining climate modeling, geospatial analysis, and community engagement to assess these effects. Climate projections are based on downscaled outputs from the EURO-CORDEX initiative (RCMs under RCP4.5 and RCP8.5 scenarios), while trends in temperature and precipitation are quantified using 25 years of daily data from local meteorological stations. Geospatial analysis utilizes shapefiles of the study area and climate-related indicators to produce climate risk maps. These maps integrate environmental datasets with socio-economic vulnerability information gathered through Community of Practice (CoP) meetings. The CoP sessions also offer critical insights into local experiences, resource management challenges, and governance gaps faced by residents. Preliminary results indicate rising temperatures and declining precipitation patterns, correlating with increased drought stress, wildfire risks, and biodiversity shifts within the region. This participatory, data-driven approach underscores the need for adaptive and inclusive governance strategies tailored to the specific vulnerabilities of mountain communities. Our findings contribute to evidence-based policymaking aimed at enhancing regional resilience to climate change.

EXTENDED ABSTRACT 112

Geoconservation in Portugal: an overview

Henriques M.H.[1], Custódio S.[1], Carvalho I.S.[1,2]

(1) Geosciences Centre, Department of Earth Sciences, Faculty of Sciences and Technology, University of Coimbra (Polo II), Rua Sílvio Lima 3030-790, Coimbra, Portugal, hhenriq@dct.uc.pt (2) Department of Geology, Federal University of Rio de Janeiro, Cidade Universitária - Ilha do Fundão, CCMN/IGEO 21.949-900, Rio de Janeiro, Brazil

Introduction

Geoheritage and geotourism help to promote inclusive and sustainable economic growth, full and productive employment and decent work for all, in line with the Sustainable Development Goals of the 2030 Agenda (Gill, 2017). This is a particularly important issue for peri-Mediterranean countries, whose economy is heavily dependent on tourism, mostly seasonal and concentrated on beaches. Tourism in Portugal reached historic highs last year and contributed to around half of the real growth in Gross Domestic Product (GDP), generating a direct and indirect contribution of 33.8 billion euros to GDP in 2023, which corresponds to 12.7% (INE, 2023). Diversifying the tourism offer and creating products in low-density territories represents a challenge for consolidating the country's tourism industry and making it compatible with sustainable development goals.

Protecting and valuing the geological heritage of Portugal is an important asset in promoting sustainable, non-seasonal tourism which is reflected in the well-being of the residents. It is up to the political authorities to implement public policies that guarantee the effective geoconservation of these territories, and for other sectors of society to become more involved in safeguarding their geoheritage.

There is no specific legislation on geoconservation in Portugal. The national law to protect natural areas (Decree-Law nº19/93 of 23rd July) defines several different categories created mainly for biological purposes with only one category remaining to include sites of geological interest that deserve to have their physical integrity safeguarded (Henriques, 2004). As so, the geological heritage of Portugal is protected at national level through Natural Monuments, which are part of the National Network of Protected Areas (Table 1). These are defined as natural occurrences containing one or more aspects which, due to their uniqueness, rarity or representativeness in ecological, aesthetic, scientific and cultural terms, require their conservation and the maintenance of their integrity (ICNF, 2025).

Table 1. Natural Monuments of Portugal that are part of the National Network of Protected Areas.

Name	Characterization	Classification date	Level
Pegadas de Dinossáurios de Ourém/Torres Novas	The largest Middle Jurassic (Bajocian-Bathonian) sauropod trackside (147 meters long) known in the world.	1996	National
Carenque	One of the largest and earliest (Lower Cretaceous) known continuous dinosaur tracks (127 meters long) produced by two herbivorous quadrupeds and possibly bipedal carnivores.	1997	National
Lagosteiros	High quality Upper Jurassic dinosaur tracks.	1997	National
Pedra da Mua	Trails of Tithonian age that record the first evidence of gregarious behavior among sauropods recognized in Europe.	1997	National
Pedreira do Avelino	The prints of the smallest sauropod known in Europe of Kimmeridgian age.	1997	National
Cabo Mondego	Jurassic record including the Bajocian GSSP and the Bathonian ASSP.	2007	National
Portas do Ródão	An imposing gorge carved out by the River Tagus in the quartzite ridges of the Perdigão mountain range, with a 45 meters wide bottleneck.	2009	National
Canhão Cársico de Ota	One of the most interesting "canyon" valleys in the Portuguese karst regions, with almost vertical escarpments carved into the Upper Jurassic limestones.	2019	Local
Livraria do Mondego	Sequence of subverticalized Armorican quartzites, in thick layers with well-defined stratification surfaces, which resemble the arrangement of a set of books on a shelf, and which refers to the name given to the site.	2024	Local

The first classified geological sites in Portugal date back to 1996 and 1997 and refer exclusively to dinosaur tracks, which reflects how dinosaurs captivate humans and are a charismatic component of our contemporary human existence (Yates and Peacock, 2023). The following decade saw the classification of the last two national Natural Monuments, which no longer refer to geological heritage of the paleontological type like the previous ones but can be included in the stratigraphic type (Habibi *et al*., 2018). Among them is the Cabo Mondego Natural Monument, located on the west coast of the country, with a particularly significant record of the Middle and Upper Jurassic (Fig. 1), and which is part of the territory related to the ongoing "Atlantic Geopark Project", aimed at a future application to the Global Geoparks Network (Custódio et al., 2024, 2025 this volume).

Figure 1. The extraordinary Middle Jurassic stratigraphic record of Cabo Mondego Natural Monument, where the Bajocian GSSP (A and B) and the Bathonian ASSP (C) were defined. The Upper Jurassic record includes dinosaur footprints on the surface bedding plane (D and E), as well as convoluting bedding and soft sediment injection structures (E) interpreted as dinoturbation structures (Carvalho *et al*., 2022).

Natural Monuments of national rank are managed by a national, centralized entity, the Institute for Nature Conservation and Forests (ICNF), which belongs to the Ministry of Environment and Energy. The same Ministry runs a database of geological sites located in national territory intended for scientific, technical, and educational purposes, to support nature conservation and land use policies, with free access and constant updates with the collaboration of the geological community (Fig. 2). It includes nearly four hundred geological sites distributed by 26 thematic categories following a methodology adapted to national-level inventories originally defined by ProGEO (the European Association for the Conservation of Geological Heritage) and IUGS (the International Union of Geological Sciences) (Brilha et al., 2005; LNEG, 2025). But the first national inventory of geological heritage, which brings together the main sites in Portugal where elements of geodiversity (minerals, fossils, rocks, geoforms) with high scientific value occur, was the result of a research project that took place between 2007 and 2010 at University of Minho and is available through the ICNF website (Fig. 3; Geossítios, 2025). The two inventories are currently being merged in a strategy to promote geoconservation in Portugal more effectively (Aires et al., 2023).

Despite being classified and formally protected, the Natural Monuments of national rank have not been the subject of valuation and monitoring interventions, procedures that are required in effective geoconservation practices (Henriques *et al.*, 2011). The classification of a natural monument aims to protect natural values, namely notable

occurrences of geological heritage, in the integrity of their characteristics and in the immediate surrounding areas, and the adoption of measures compatible with the objectives of their classification (ICNF, 2025), i.e., the promotion of scientific research, geoeducation and geotourism. The current conditions of the Portuguese Natural Monuments of national rank are a long way from such goals and the communities that occupy the territories are completely oblivious to the geological heritage that surrounds them.

Figure 2. The official website of the National Inventory of Geological Heritage at the Laboratório Nacional de Energia e Geologia (LNEG, 2025).

Figure 3. The official website of the National Inventory of Geological Heritage at the Instituto da Conservação da Natureza e das Florestas (Geossítios, 2025).

This top-down nature conservation strategy has proved to be totally inappropriate and has not contributed to harmonious integration between communities and nature. In parallel with the Portuguese state's disinvestment in the conservation of the country's geodiversity, a number of local initiatives have sprung up for this purpose. Among them are projects aimed at integrating territories into the UNESCO World Geoparks Network.

The bottom-up approach

The first Portuguese Geopark to join the UNESCO World Geoparks Network was Naturtejo in 2006, followed by Arouca, the Azores, Terras de Cavaleiros, Estrela and Oeste (CNU, 2025; Fig. 4; Table 2). Rather than emerging from

a nationwide political decision, UNESCO Global Geoparks (UGGp) are established through a bottom-up process involving all relevant local and regional stakeholders and authorities in the area, deeply committed to the exploration, development and celebration of the links between the geological heritage and all other aspects of the area's natural, cultural and intangible heritage (UNESCO, 2025).

Figure 4. UNESCO Global and Aspiring Geoparks in Portugal (modified after AG, 2025).

UGGp proved to be a sustainable strategy for protecting the geological heritage of Portugal. This may have inspired the Portuguese political authorities to change the legislation on the protection of geological heritage, allowing the creation of Local Natural Monuments. Proposals for their creation come from the local authority, as well as their management, once the classification has been approved by the national authority. The last two Natural Monuments to be classified by the Portuguese State have this status (Table 1).

Table 2. UNESCO Global Geoparks in Portugal.

The relevance of community involvement in geoconservation

Nature conservation in Portugal was initially governed by top-down approaches, based on centralized classification initiatives that resulted in difficulties in the management of protected areas. The geological heritage classified as Natural Monuments covers around 1500 ha, of which around 1000 ha correspond to the Portas do Ródão Natural

Monument (ICNF, 2025), a territory included in the Naturtejo Geopark and therefore subject to the geoconservation requirements of UNESCO's Global Geoparks Network (GGN, 2025). But the rest of the area, although classified, has not been valued and, in some cases, is at risk of destruction due to lack of monitoring. The potential for using these sites of recognized scientific and educational interest is practically nil, since they lack the infrastructure to support visitors and the information to understand how the site record contributes to understanding the history of the Earth. The Natural Monuments are briefly described on the official ICNF website, which is the only information available to anyone wishing to visit them.

The creation of geoparks, which emerge from local initiatives, with extensive community involvement in all stages of geoconservation, has proved to be the most effective way of guaranteeing the integrity of geological objects with heritage value, as well as their enjoyment by society. They demonstrated to be a viable approach to the development of areas with remarkable geological heritage which can be adapted to various social and economic contexts as well as cultural ones (Henriques and Brilha, 2017).

Portuguese authorities recognized the relevance of community involvement, and the last two Natural Monuments to be classified in Portugal are already local in scope, and their geoconservation is expected to be more effective. Moreover, the organization of nature protection at state level was altered to integrate the National Network of Protected Areas (a government initiative and responsibility) with classified areas with alternative management systems like those integrated into the Natura 2000 Network and other areas classified under international commitments assumed by the Portuguese State, such as RAMSAR Sites, Geoparks and Biosphere Reserves (SNAC, 2025). However, the maintenance of national natural monuments without improvements that allow them to be used for educational and/or geotourism purposes is a waste of an economic, social and environmental asset.

Conclusions

With regard to geoconservation in Portugal, there is a state entity that aggregates information on the inventory of the country's geological heritage, in close collaboration with the academic community – the Laboratório Nacional de Energia e Geologia, which is a state laboratory of the Ministry of the Environment and Energy (LNEG, 2025). Within the same Ministry, the ICNF oversees the National Network of Protected Areas, which aims to ensure the protection of the geological heritage and the integrity of its characteristics, in the territorial context in which they are located (ICNF, 2025). In this sense, it is possible to say that the country's geological heritage is reasonably well known and inventoried. But geoconservation refers to more than the inventory of a territory's geological heritage. In Portugal, all the other steps that make it possible to guarantee the physical integrity of geological sites (classification, monitoring), as well as their enjoyment for educational and geotourism purposes (valuation) has been assumed fundamentally by local and/or private initiative. It is essential to provide the ICNF with the necessary means to ensure the monitoring and valuation of the protected areas for which it is responsible, i.e., the National Natural Monuments.

Introduction

The processes that govern the formation and evolution of beach zones include marine and terrestrial processes; the former, in the case of an essentially tideless environment, refer to the incoming waves, their transformation and breaking conditions that induce nearshore currents and sediment transport, while the latter to the delivery of terrestrial sediment (i.e. cliff erosion, river inputs). These processes acting in different times (from seconds to decades) and spatial (for a few meters to km) scales, are subjected also to the various human (direct or indirect) interventions. Such an indirect anthropogenic intervention is climate change which among other impacts causes the rise of sea level; the latter has a significant impact on beach zone evolution with undesirable consequences to coastal ecosystem services with coastal tourism being among them.

The purpose of the present study is to provide an estimate of shoreline retreat associated with the sea level rise (SLR) for the year 2100, according to the latest IPCC 2021 report (Masson-Delmotte et al., 2021), in the case of three beaches in Evia facing the Aegean Sea (Figure 1). The three beaches are (from north to south) Korasida, Heromylos and Limnionas, selected based on their size in both width and length, together with their direct exposure to incoming waves from the NE, E and SE directions (open Aegean Sea), making them highly relevant for assessing the impact of sea-level rise on coastal retreat. The first two beaches have been formed in front of schist formations while the third one in front of marbles, with both formations belonging to the Styra Nappe of the Cycladic Blueschist Unit (Xypolias et al., 2003).

Figure 1. The location of the beaches under investigation.

Methods

Shore-normal profiles were measured with the use of a Leica Distance Meter (subaerial part) and a Portable Handy Depth Sounder Hondex PS-7 (subaqueous part). For the geographical position of profile, a Topcon GPS was used. Reanalysis of hourly wave data, regarding the neighbouring area of Kimi (shown in Figure 1), were obtained from the Copernicus platform, covering a period of 20 years (1/1/2002 - 31/12/2021).

For the purpose of the present study the highest (1%) of the wave characteristics (height (H) and period (T)) have been identified for each of the three predominant directions. For the estimation of shoreline retreat the most common method, the Bruun's rule (Bruun, 1962), has been used (Figure 2), which is based on the change of the beach's morphometric characteristics due to the rise of the sea level, assuming a shoreline retreat retaining unchanged beach profile, with the eroded sediment deposited on the shoreface, retaining depth unchanged. Therefore, the calculated estimates could be considered as indicative.

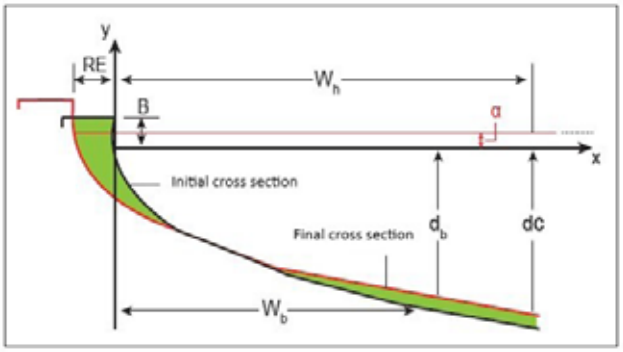

Figure 2: Illustration of Bruun's rule (from Poulos and Karditsa, 2020).

The retreat (RE: retreat) of the beach boundary is given by Brunn's (1962) relationship (equation 1):

$$wE = \frac{W_C \ a}{d_c + B} \qquad (1)$$

Where, (α): the sea level rise; (dc): the maximum depth of bottom sediment mobilization given by Hallermeier (1981) (equation 2); (W_C): the horizontal distance of dc from the shoreline; and (B): is the berm height.

$$dc = 2.28\ H_e - 68.5\ (H_e^2 / gT_e^2) \qquad (2)$$

where, (e: extreme) values (with a yearly exceedance of 0.137%) of wave height (H) and Period (T) and (g) earth's gravity.

The retreat of all beaches was calculated for the various Shared Socio-economic Pathways (SSP) scenarios provided by IPCC (Masson-Delmotte et al., 2021), which are: SLR = 0.28 m (SSP1a-1); SLR = 0.60 m (SSP2-4.5); SLR = 1.01 m (SSP4-8.5).

Results

The basic morphometric and wave characteristics of the three beaches are presented in Table 1. The wave characteristics refer to the wave height (H_e), period (T_e) , direction, closure depth (d_c) and its distance from the shore (W_c) for the extreme values of H and T. Limnionas beach is the widest beach (39 m), followed by Heromylos (28 m) and Korasida (22 m). All three locations have similar beach heights (< 3 m), while Korasida has the steepest subaerial slope. Heromylos and Korasida have higher significant wave heights compared to Limnionas. Finally, Heromylos has the greatest depth of closure, followed by Korasida and Limnionas.

Table 1. The basic morphometric and hydrodynamic characteristics of the 3 beaches.

	Morphometric characteristics			Hydrodynamic characteristics				
	Beach Width (W) (m)	Beach Height (B) (m)	Shoreface slope (β_f)	Wave Direction	H_e (m)	T_e (s)	d_c (m)	W_c (m)
Heromylos	28	2.8	0.045	NE	5.1	8.3	11.3	250.5
Korasida	22	2.6	0.090	SE	5.2	8.9	11.7	129.7
Limnionas	39	2.7	0.060	E	3.7	8.9	7.6	128.2

The estimated retreat for the three SSP sea level rise scenarios is shown in Table 2. For all sites, both the absolute retreat (Re in meters) and the retreat relative to the beach width (Re in %) increase significantly with increasing expected sea level rise (0.28 m from SSP1 to 1.01 m SSP4).

Heromylos is the most vulnerable of the three sites, even under moderate sea level rise (SSP2-4.5), and shows the highest retreat values (Re=18.8 m (67.1%) under the worse scenario SSP4-8.5. Korasida shows moderate retreat values, while under the SSP4-8.5 scenario Re is 9.6 m (43.5%). Limnionas is the least affected but still shows significant impacts. For example, under SSP4-8.5 the overtopping reaches 12.2 m (31.3%), which is the lowest of the three sites.

Table 2. The estimated retreat (RE) for the three beaches with respect to the sea level rise ("α" in equation 1) related to the weak (SSP1a), moderate (SSP2-4.5) and worse (SSP4-8.5) case scenarios due to climate change.

Sea Level Rise Scenarios		**Heromylos**	**Korasida**	**Limnionas**
SSP1a–1: 0.28 m	Re (m)	5.2	2.7	3.4
	Re (%)	18.6	12.1	8.7
SSP2-4.5: 0.60 m	Re (m)	11.2	5.7	7.2
	Re (%)	39.8	25.9	18.6
SSP4-8.5: 1.01 m	Re (m)	18.8	9.6	12.2
	Re (%)	67.1	43.5	31.3

Discussion and Conclusions

The three beaches exposed to the open Aegean Sea are expected to retreat by 2.7-5.2 m for the SSP1a-1 scenario, by 5.7-11.2 m for the moderate SSP2-4.5 scenario and by 9.6-18.8 m for the worse SSP4-8.5 scenario by 2100. The differences between the retreat values are due to their different morphodynamic and hydrodynamic characteristics, as shown in Table 1. Heromylos experiences the highest retreat under all scenarios, reaching 18.8 m (67.1%) under SSP5-8.5. Korasida and Limnionas show lower but still significant retreat values, with Korasida reaching 9.6 m (43.5%) and Limnionas 12.2 m (31.3%). The vulnerability of Heromylos and Korasida beaches is also related to the fact that they are exposed to the highest wave heights (5.1-5.2 m). On the other hand, they show the most dramatic retreat. Limnionas beach is exposed to the lowest wave heights (3.7 m). The relatively lower retreat values under all climate scenarios may also be related to the higher beach elevation or better natural resilience to sea level rise.

Given the economic, ecological, and social importance of these beaches, proactive measures need to be considered to mitigate the effects of rising sea levels and associated coastal hazards. Implementing a combination of continuous monitoring to predict beach response and adaptive strategies (eg. nature based solutions and interventions) will support preserving the value and function of these coastal areas in the face of climate change.

BULLETIN OF THE GEOLOGICAL SOCIETY OF GREECE, SP. PUBL.

EXTENDED ABSTRACT 114

Contribution to the stratigraphic study of the pyroclastic Formations of the Lesvos Petrified Forest, Lesvos Island, Greece.

Iliopoulos, G.[1], Papadopoulou P.[1], Valiakos, I.,[2], Zouros, N.[2,3]

(1) Department of Geology, University of Patras, Patras, Greece, iliopoulosg@upatras.gr (2) Natural History Museum of the Lesvos Petrified Forest, Sigri, Greece (3) Department of Geography, University of the Aegean, Mytilene, Greece

Introduction / Background

Lesvos Petrified Forest represents one of the most important monuments for the geological heritage of Greece. It is located on the western peninsula of Lesvos Island and has been recognized as a Natural Monument since 1985, covering an area of 15.000 hectares. Silicified tree trunks, both lying and in upright position, as well as fossil leaves of lower Miocene age are found enclosed in pyroclastic and volcaniclastic material deriving from a nearby stratovolcano chain (Zouros et al., 2015). The protected area of the Lesvos Petrified Forest became one of the 4 first European Geoparks in 2000 and global geopark in 2004. In 2015 Lesvos Island became a UNESCO Global Geopark with the petrified forest as the main geological heritage area of international significance. Recognized as one of the first 100 IUGS geological heritage sites, the Petrified Forest is a locus for research, education, and sustainable tourism.

Recently, the construction of the new Kalloni-Sigri road brought to light new fossiliferous localities (Zouros at al., 2015, 2022). Construction works with extensive new roadcuts, exposed several artificial sections along the road, which on the one hand brought to light numerous fossilized trees and leaves, and on the other hand enabled the stratigraphic research of the volcanoclastic rocks at Akroheiras Hill (within the protected area of the Lesvos petrified forest) which contain them (Fig. 1A), and allowed the detailed stratigraphic analysis of the Sigri Pyroclastic Formation (Pe-Piper et al. 2019b).

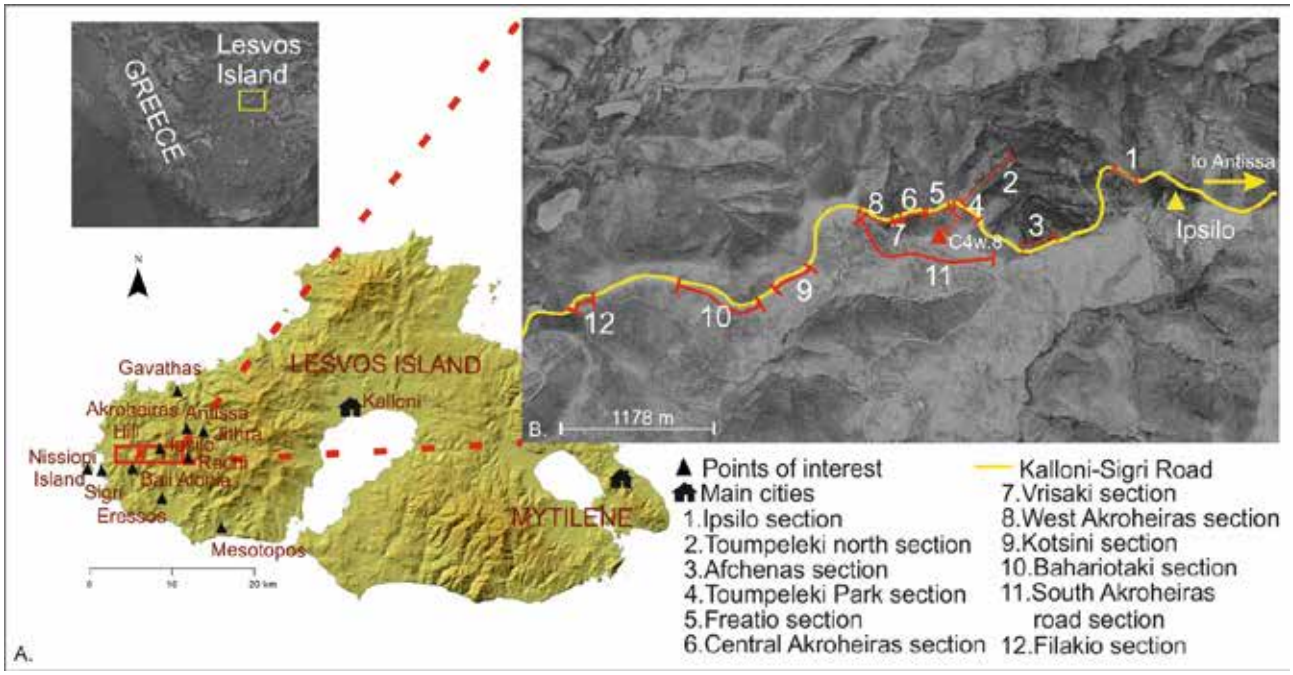

Fig. 1: A. DEM image of Lesvos Island. Main cities, villages and main points of interest are noted. The study area is noted with the red rectangle. B. Satellite image of the study area, where the 12 studied sections (red lines) are highlighted.

Twelve different sections located along the new road that cuts across Akroheiras Hill (Fig. 1B), were stratigraphically recorded and are presented herein, while a new stratigraphic scheme for the pyroclastic deposits of Lesvos is proposed.

Geological setting

During the last fifty years the volcanic rocks of Lesvos have been extensively studied and mapped (Hecht, 1974a, b, c; Pe-Piper, 1978; 1980; Pe-Piper et al., 2019b), and the overall stratigraphic structure of the volcanic formations of the Island has been provided (Pe-Piper & Piper, 1993; Pe-Piper et al., 2019a, b). Pyroclastic and volcaniclastic rocks of several

hundred meters extend at the western part of the Island and are known until now as the Sigri Pyroclastic Formation (Pe-Piper 1980; Pe-Piper et al., 2019b), lying above Permian schists and marbles (Katsikatsos et al., 1982). Sigri pyroclastics are mostly tuffs containing exceptionally preserved silicified trunks and fossilized leaves (Velitzelos & Zouros, 1997; Zouros et al., 2007; Zouros, 2021; Liapi et al., 2022; Tsitsou et al., 2022; Liapi et al., 2024). The age of Sigri pyroclastics has been estimated between 21.5 and 18.0 Ma (Pe-Piper et al., 2019b). The stratovolcano chain follows the dominating NNE-SSW dextral strike-slip tectonic regime of the Aegean-Anatolian microplate (Yilmaz et al., 2000). In Lesvos Island three successive neotectonic stages have been reported since the Miocene: a) the earliest one is of Upper Miocene age, based on its relation to synchronous volcanism and associated rocks, and formed strike–slip faults of E–W to ENE–WSW strike b) the second one took place in the Pliocene and formed normal faults of NW–SE strike, as well as strike–slip faults of NNE–SSW strike c) finally, the active stage since the Pleistocene forms E–W trending normal faults (Chatzipetros et al., 2013)

Material and Methods

Detailed stratigraphic logging was conducted in twelve sections along the new road cuttings from Moni Ipsilou Hill to Fylakio (Fig. 1A). Stratigraphic logging was performed in many places of each site as the lateral continuity of the layers was interrupted by faults, and lateral changes of the pyroclastic material occurred. The lithological characterisation of the pyroclastic rocks follows Fisher & Schmincke (1984) and Francis & Oppenheimer (2003). The presence of the most prominent fallen or standing tree trunks was noted, as well as the respective fossil leaf horizons. Basic sedimentary structures were also recorded. Rough stratigraphic cross sections containing the most important features of each section (characteristic horizons, major faults etc) were recorded and photos of each section were taken. Identification of the stratigraphic discontinuities took place (particularly erosional unconformities which mostly correspond to palaeosoil horizons). These discontinuities as well as some fine tuff layers, which present obvious and recordable lateral continuity, were used for the correlation of the different stratigraphic columns in each section, and subsequently for the correlation of the different sections.

The different formations were distinguished using criteria of the International Commission on Stratigraphy (Murphy and Salvador, 1999), as well as using physical characteristics of the rocks. Subdivision of formations in members took place when possible, taking into account erosional unconformities or/and palaeosoil development. In addition, palaeosoil horizons were also used to distinguish the different eruption phases.

Results

The prevailing lithology of pyroclastic rocks from the study area are tuff layers (fine to lapilli tuffs), with thicknesses ranging from a few millimeters to several meters characterized by sharp contacts. Grading is common (normal, reverse or normal to reverse), and pumice and lithic lapilli are often present. Pyroclastic rocks are often intercalated with volcaniclastic layers namely channeled or layered tuffaceous conglomerates and sandstones. The recorded palaeosoil horizons present thicknesses from a few millimeters to around ten centimeters or more and are easily traced by their black, green or/and red color. Neither their color nor their thickness appears stable laterally. They often evolve to thin horizons of fine tuff or even they disappear leaving only a discontinuity, many times difficult to observe. Their coloring is attributed to alteration due to the circulation of hydrothermal fluids (Pe-Piper et al., 2019a). The layers are dipping with a general NE-SW orientation and low angles (3-16˚). Some differentiations were noticed as NE-SW (sections 4, 12) and NW-SE (sections 10, 12) orientations also occur, which are attributed to the described above tectonic regime.

Several high angled (60-90˚) faults, deforming the studied sections have been observed. Most of them are sinistral strike slip faults with NE-SW or NNE-SSW directions (sections 1, 3, 4, 5, 7, 8, 9, 10, 11, 12). N-S directed faults were also noticed (sections 1, 4, 5, 10, 11). Additionally, E-W or WSW-ENE directed sinistral strike slip faults (sections 3, 6, 7, 10, 11) and a few NW-SE normal faults (sections 1, 10) were also recorded. The lateral continuity of the sections is interrupted by Quaternary channels. Their position is controlled by faults as it has been also implied for the older channels (Lamera et al., 2004), which are uplifting the western blocks.

Twelve sections were lithostratigraphically recorded in detail namely Ipsilo section, Toumpeleki north section, Afchenas section, Toumpeleki section (east and west part), Freatio section, Central Akrocheiras section, Vrisaki section, West Akrocheiras section, Kotsini/Bachariotaki sections, South Akroheiras road cut section and Filakio section (Fig.1B).

Ipsilo section stretches for 250 m at the foot of Ipsilo Hill (Fig.1B, Section 1) and has a recorded thickness ranging between 4 and 20m. It presents pyroclastic tuffs with high pumice content at its base, while at higher levels locally developed palaeosoil horizons were recorded. The stratigraphy of **Toumpeleki north section** was recorded along a narrow natural section across a stream valley north of the road (Fig.1B, Section 2). A total of 65 m of pyroclastic material was recorded. Brown volcanic material was recorded at the base of this section. Upwards the sequence is composed of both coarse and lapilli tuffs with a characteristically high percentage of pumice at the lower part. Further upwards lapilli tuff layers exist for at least 55 m. **Afchenas section (**Fig.1B, Section 3) consists of thick (around 60m) reddish chaotic (poorly sorted) polymictic,

mostly clast supported volcaniclastic deposits with substandard stratification and angular clasts. Wedged laterally secondary fine grained layers with high pumice content can be seen. **Toumpeleki Park section (east part)** (Fig.1B, section 4, Fig. 2) consists mostly of coarse and lapilli tuffs and some volcaniclastic layers, often containing transported trunks and branches (with thickness 16m). Seven palaeosoil horizons were recorded from bottom to top. Standing fossil trunks implying the presence of a respective forest were recorded on six of the palaeosoil horizons. Fossil leaves were recorded on at least three stratigraphic horizons. **Toumpeleki Park section (west part)** presents 90m of pyroclastic rocks. The lower 37 m consist mostly of both coarse and lapilli tuffs with intercalations of palaeosoil horizons and volcaniclastic layers, often containing transported trunks and branches. In total, eight palaeosoil horizons and two disconformities were recorded from bottom to top. Standing fossil trunks were recorded in four palaeosoil horizons and fossil leaves were recorded just in one case. At the upper stratigraphic levels (from 37 to 90 m column height) of this section a concise stratigraphic recording was conducted (due to vegetation cover) revealing a more coarse grained stratigraphic sequence. **Freatio section** (Fig.1B, Section 5) is a very unique and important site because of the exceptionally high number of transported fossilized trunks that have been excavated and are preserved on site. The section has a length of more than 100m and is delimited in both sides and on top of the west end by Quaternary channels. It consists mostly of fine and coarse tuff layers and volcaniclastic sediments with a total thickness of around 14m. Four palaeosoil horizons were recorded. Standing trunks were recorded on three horizons. At its lower part a thick (4.60 m) lahar which turns into a mud flow deposit at the top exists. A large number of transported trunks were excavated lying in different orientations. This accumulation is interpreted as a log jam. **Central Akroheiras section** (Fig. 1B, Section 6) is lying west from Freatio section. It stretches for more than 290m and the thickness of the pyroclastic sequence is more than 40m. It consists mostly of coarse and lapilli tuffs and some very characteristic volcaniclastic sediments that have been deposited in small rivers. The upper stratigraphic levels present an overall more coarse-grained lithology and thicker layers. Nine palaeosoil horizons and a disconformity were recorded. Standing fossil trunks were recorded on three palaeosoil horizons. Fossil leaves were recorded at several stratigraphic levels. **Vrisaki section** (Fig. 1B, section 7) is a small section consisting mostly of tuffs (coarse /lapilli tuffs and tuff breccia) and volcaniclastic sediments with a total thickness of 20m. Seven paleosoil horizons were recorded between the volcaniclastic layers. This section presents lateral continuity with **West Akroheiras section** which lies immediately westwards. It consists of coarse tuffs, lapilli tuffs and less of tuff breccia layers. Volcaniclastic layers also exist. The total thickness of the pyroclastic layers of this section is 22m. Seven palaeosoil horizons were recorded in this section. Standing fossil trunks were recorded in three palaosoil horizons. Fossil leaves were recorded in great numbers in many locations throughout this section. The upper stratigraphic levels show an overall different lithology. Most of the layers are thick and coarse grained and bear a lighter color. **Kotsini-Bachariotaki sections** (Fig. 1B, sections 9 & 10 respectively), stretch for more than 870 m along the road. The total thickness of the pyroclastic layers that were recorded is 21m. A characteristic palaeosoil horizon with multiple standing trunks can be noticed in both sections. Fossilized leaf litter was noticed in the lower part. Its upper part appears thicker and coarser grained with transported volcanic bombs. **South Akroheiras road section** (Fig.1B, section 11) stretches for 1424 m along the road that leads to Bali Alonia Petrified Forest Park. A variety of layers from volcaniclastic layers to tuff breccia with varying thicknesses (from 2 cm to approx. 30 m) were recorded. Palaeosoil horizons, fossil trunks and fossil leaves were also recorded in some places. The stratigraphic sequence is disrupted by faults and thus the correlation with the other sections was difficult. However, the existence of common very thick (1-30m) tuff breccia layers and the decreased frequency of palaeosoil horizons must be noted.

Fig. 2: Panoramic view of east Toubeleki park section (section 4). Toubeleki park section (east) consists a characteristic section where seven palaeosoil horizons (PS4e.1-7) can be seen (red lines). The red arrows indicate the position of standing fossil trunks.

Filakio section (Fig.1B, section 12) stretches for 140 m along the new Kalloni-Sigri road towards Sigri. It is the western of the studied sections, but it is one of the most important since a large number of both standing and fallen trunks were excavated. It is composed of relatively thick lapilli tuffs, tuff breccia, discontinuous thin palaeosoil horizons and conglomerate lenses at its lower part (road level) and thinner tuffs and volcaniclastic layers with intercalations of palaeosoil horizons upwards (Filakio Park level). The total thickness of this sequence is 12.5 m. Five palaeosoil horizons were recorded and standing fossil trunks were recorded in three of them. The lower part of the section shows volcaniclastic characteristics with thin intermittent palaeosoil horizons.

Discussion

The studied sections provide a detailed stratigraphic record of the broader Akroheiras Hill pyroclastics. The lateral continuity of the layers is often interrupted by post deposition Quaternary erosional surfaces, the road construction works and the severe faulting. The recorded faults have vertical displacements from a few centimeters up to 10m (i.e. Freatio section). Thus, the different characteristic horizons (palaeosoils and disconformities) from each section were correlated. The correlation of the different sections revealed that many palaeosoil horizons bear trunks in upright position recorded in at least one of the studied sections (Fig.3).

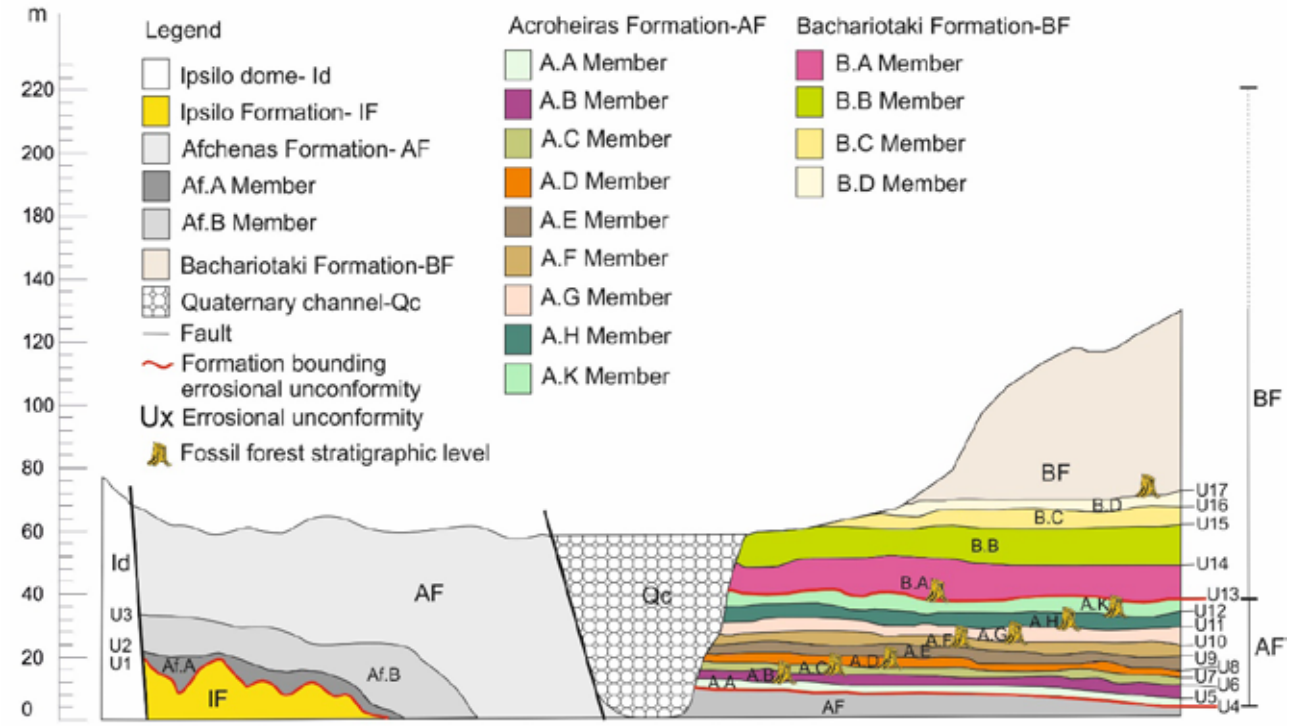

Fig. 3: Simplified synthetic section of Akroheiras Hill presenting the relative position of the described in the text Formations, Members and disconformities/palaeosoils (Us).

Moreover, four new Formations have been established namely Ipsilo Fm, Afchenas Fm, Akroheiras Fm, and Bachariotaki Fm (Fig. 3), replacing Sigri Pyroclastics Fm, which from now on will be considered as the Sigri Pyroclastics Group.

Ipsilo Formation: The pyroclastic rocks of this formation consist coarse and lapilli tuffs with characteristically high percentage of pumice (vitric tuffs) (up to around 50%). Secondary channels also exist. Fossilized wood is scarce in this formation and no trunks in upright position exist. Its lower limit was detected in Toumpeleki North section, where it comes in contact with brown ignimbrite (0-3m). The nature of their contact could not be evaluated due to limited exposure. Its upper limit is a distinct disconformity which can be seen in several sites along the road (U1). In places a weak palaeosoil horizon can be noticed. The total visible thickness of Ipsilo Formation pyroclastic rocks is five m but increases eastwards and may reach up to 20m.

Afchenas Formation: Thick (around 60m) reddish chaotic (poorly sorted) polymictic, mostly clast supported volcaniclastic material with substandard stratification and angular clasts can be seen along the road. Secondary channels can also be noticed. Its upper stratigraphic levels can be seen in the lower part of Freatio section and the lower part of Filakio section. In this part thin intermittent palaeosoil horizons and conglomerate lenses are detected. No or limited fossilized wood can be found in this

formation except its upper limit, where also trunks in upright position were noticed. The material is probably of fluvial origin and may represent hyperconcentrated or gravelly debris flows (Pe-Piper et al., 2019b) carrying mostly andesitic blocks and has been deposited close to the source. This formation outcrops also at Rachi area as mentioned in Pe-Piper et al. (2019b). The total thickness of this Formation is at least 58m. The lower part of this Formation can be divided in two Members, Af.A and Af.B.

Akroheiras Formation: the pyroclastic rocks of this formation are made of relatively thin (0.5 cm to 7m) fine grained secondary pyroclastic layers (predominantly lithic, fine or/and coarse tuffs and minor lapilli tuffs) intercalated by repeated palaeosoil horizons. Standing and fallen fossilized trunks as well as fossilized leaves are found in great numbers in this formation. The different layers are the result of pyroclastic avalanches (lahars, debris and mud flows) as well as river flows with limited lateral continuity. This formation comes in contact with the underlying Afchenas Formation through the disconformity/palaeosoil horizon U5 (Fig.3), while its upper limit is set to the disconformity signified by palaeosoil horizon U14 (Fig.3). Its total thickness is approximately 30m. Parts of the pyroclastics of this formation are exposed in several of the studied sections (Toumpeleki east, Toumpeleki west, Freatio, Central Akroheiras, Vrisaki, West Akroheiras and Filakio). Nine members are distinguished (Members A.A-A.K) separated by 9 palaeosoil horizons respectively (palaeosoils U6-U14, Fig. 3).

Bachariotaki Formation: The pyroclastic layers of this formation appear thicker (up to 30 m in Bali Alonia Section) and overall, more coarse grained than the other formations. They consist mostly of lapilli tuffs and tuff breccia with transported blocks and volcanic bombs. Volcaniclastic layers are also present. The stratigraphy of this part of the sequence appears complicated due to the multiple thick lobes that can be noticed and intense tectonism. Moreover, there are no adequate sections to record the stratigraphy in detail due to the high vegetation cover of the Akroheiras Hill slopes. Based on the total thickness of the recorded layers in the upper part of Akroheiras Fm and in South Akroheiras road section, the total thickness of this formation is estimated as 200m up to the hilltop of Akroheiras Hill. Both transported and standing trunks exist in this formation too although their frequency is reduced. Its upper limit is unknown due to erosion and vegetation cover (on top of Akroheiras Hill). In the lower Bachariotaki Fm, which is exposed in Toumpeleki Park west, Central Akroheiras, Vrisaki and West Akroheiras, four Members have been established (Members B.A, B.B, B.C, BD) bounded by the relative erosional unconformities/palaeosoils (U15-U19). Pyroclastic layers of this formation are also exposed in Kotsini/Bachariotaki sections as also in South Akroheiras road sections, but the existence of multiple faults does not allow the correlation of these layers and thus no other members are established for this formation for the time being.

The high pumice content of Ipsilo Formation may imply pyroclastic deposits deriving from ignimbrite or deposited during the same ignimbrite-forming eruption (Fisher and Heiken, 1982). As implied by Piper et al. (2019b) the location of the main source of Sigri pyroclastics was most likely in the wider Mesotopos area. It is possible that Ipsilo Formation was coeval with an ignimbrite forming eruption happening in Mesotopos prior to Eressos dome intrusion/extrusion as this could account for the high percentage of pumice and the low lithic content of this formation. The presence of the ignimbrite in Toumpeleki north section may contribute to this. On the contrary, due to the high lithic content of Afchenas Formation it may have derived from an Eressos Fm dome that had already been extruded during the formation of this sequence. In both formations a low time gap between the volcanic phases is implied by the reduced number of palaeosoil horizons that were formed or/and preserved. Ipsilo and Afchenas Formations bear little or no fossilized wood, nevertheless, they serve as the base of the fossiliferous Sigri pyroclastics.

Akroheiras Fm shows a high number of palaeosoil horizons and units. Each unit was formed when pyroclastic material deriving from neighboring volcanoes lying eastwards (Kouli and Seymour, 2006) was remobilized, enriched with water and flowed down the pre-existing alluvial system. These secondary pyroclastic flows reached the plain area lying further to the west carrying also fallen trunks and leaves. Each palaeosoil horizon is marking the cessation of the volcanic activity for a certain period of time. Therefore, the recorded palaeosoil horizons can serve as markers for distinguishing between different eruptions as has also been mentioned by Piper et al., (2019b) for the recorded palaeosoil horizons of Central Akroheiras area. At least 9 eruptive phases are evidenced in this part of the sequence corresponding to the establishment of the respective members.

When there was enough time between the previous and the next eruption, forests were developing on the formed soils. Thus, in Akroheiras Fm, nine (9) successive forest forming periods were recorded. The forests were buried later on under water saturated with cold pyroclastic material. Because the flows were not hot enough to burn the trees and because there was water in them the tree trunks and the leaves that were buried under anoxic conditions (otherwise the wood would have been decomposed) were preserved and then had the opportunity to get fossilised.

Within the lower part of Bachariotaki Fm at least four more eruptive phases are assured with one more forest developing period. In total, in Akroheiras and the lower part of Bachariotaki Fms 13 eruptive phases which correspond to the 13 defined members of the formations are mentioned herein. Moreover, at least 10 successive forest forming periods are witnessed by the different stratigraphic levels of the standing trunks.

Conclusions

- A new stratigraphic model is hereby proposed based on the lithology of the layers and the major stratigraphic hiatuses for the previously called Sigri Pyroclastic Formation (Pe-Piper, 1980; Pe-Piper & Piper, 1993; Pe-Piper et al., 2019b), and

which herein is revised as the Sigri Pyroclastic Group.

- Four pyroclastic formations are introduced for the Sigri pyroclastic rocks, Ipsilo Fm, Afchenas Fm, Akroheiras Fm and Bachariotaki Fm, bounded by erosional unconformities.
- Akroheiras Fm is further divided in Members A.A to A.K., as is also the case for the lower part of Afchenas Fm (Members Af.A and Af.B) and the lower part of Bachariotaki Fm (Members B.A to BD). The different Members are also bounded by palaeosoils and respective disconformities that correspond to different volcanic eruptions.
- Thus, at least 13 eruptive phases are identified. The cessation of each eruption was followed by the formation of a palaeosoil and the subsequent development of a forest on it.
- At least 10 successive forest developing periods have been recorded until now in the Akroheiras Hill pyroclastic sequences. It is certain that more forest forming events are hidden below the dense vegetation in the wider area of the Sigri pyroclastics.

EXTENDED ABSTRACT 115

Geological study of the basement structure in the wider area of Filiro (Circum-Rhodope Belt, Central Macedonia, Greece)

D. Ioannidis, E. Katrivanos, A. Chatzipetros

School of Geology, Department of Structural, Historical and Applied Geology, Aristotle University of Thessaloniki, Greece, dioannif@geo.auth.gr

Abstract

The western border of the Serbo-Macedonian massif with Circum-Rhodope belt has been a subject of discussion in the past. Several questions have been raised about the geological structure of the study area (NE part of Thessaloniki, Pefka, Filiro, Asvestochori), based on variations in structural and lithological characteristics. Field – structural and lithological data were initially collected and then the geological structure and the tectonostratigraphy of the study area were visualised. In the area of interest there are characteristic rocks of both continental and oceanic crust in contact, as a result of past tectonic events (D1-D6 deformation events). Older tectonic events of compressive ductile stress regime (D1-D2) are correlated with the tectonic emplacement of ophiolites and the general terrane accretion, whine newer ones of brittle stress regime (D4-D5) are related with the thrusting and the creation of tectonic slices, as well as the inversion of the whole series. The lithological units of the area have been inverted by these tectonic events (D4-D5). As a result, the older rocks are placed tectonically on top of the younger ones. Compression forces have created a fold-and-thrust belt with a sense of movement to-the-SW. A lithological unit belonging to the Serbo-Macedonian massif is tectonically intercalated between the lithological units of Circum-Rhodope belt. The pre-alpine basement in the study area is of Serbo-Macedonian origin and the tectonic movement of the tectonic slices was accomplished on this basement.

Geological setting

The study area is geologically located mainly within the Circum-Rhodope Belt, which is part of the Internal Hellenides. The Circum-Rhodope Belt is traditionally divided into three units (from north-east to south-west):Deve Coran - Dubya, Melissochori - Cholomontas, Aspri Vrisi - Chortiati (Mountrakis 2010).

The Circum-Rhodope Belt was characterised palaeogeographically as the continental slope of the Greek hinterland during Jurassic. The presence of the oceanic crust of the Axios Zone at its eastern boundary, the turbiditic character of its rocks and the origin of its sediments from the Serbo-Macedonian Massif as described in Meinhold and Kostopoulos (2013) are indications consistent with this model. Structural and lithological features of Circum-Rhodope Belt show many variations. Thus, several questions have been raised about the geological structure of the study area.

The Serbo-Macedonian Massif starts from the Greek-Bulgarian border and extends in a northwest-southeast direction to the coast of Sithonia and Mount Athos peninsulas. Its western boundary is the contact with the Circum-Rhodope Belt , while its eastern boundary is in the basin of the Strimonas river, where it meets the Rhodope Massif. The similarities that appear in the rocks of the Serbo-Macedonian are many, however the massif has been divided into two units, namely Kerdyllia and Vertiskos.

Palaeogeographically, the Serbo-Macedonian Massif, together with the Rhodope Massif, expresses the Greek hinterland. Its rocks represent a continental crust with evidence of orogenies older than the Alpine (Papanikolaou 2015). There are views that consider the Serbo-Macedonian Massif to be part of the Eurasian plate and views that place it within the Cimmerian blocks that were attached to Eurasia. What is important, however, is that the Serbo-Macedonian Massif was not part of Gondwana at the start of the Alpine cycle, but was already in Eurasia undergoing the effects of the Ercynian orogeny (Papanikolaou 2015).

In this paper we present new field and structural data from the study area to investigate the shallow structural configuration and the geological structure of the basement, as well as the deformation phases and geotectonic evolution in general.

Methodology

The identification and differentiation of the cartographic units was the first step in a traditional field-work way (Figure 1). Then, based on field-structural data we decipher the deformation events (Table 1) that affected the units and we construct the tectonostratigraphic column (Figure 2). The final stage is to produce the geological cross-sections (Figure 3). All the field structural data were measured and verified using a geological compass. The points chosen for measurement were the contacts between two cartographic units, the foliation of the rocks, the folds (limbs and b-axis) and the mirror surfaces of the faults. Many structural features (foliation, lineation, folds, faults, kinematic markers, slip lines) were identified, measured and helped to distinguish the tectonic events (Table1), providing information on the stress field of the epoch in which they acted and on the kinematics of deformation. The analysis of the tectonic structures (folds, faults, tectonic contacts and lineation) was carried out in order to distinguish the tectonic events find the temporal succession of the deformation events with the final result being the understanding of the geological history of the area. The tectonic structures studied belong to the macroscopic scale.

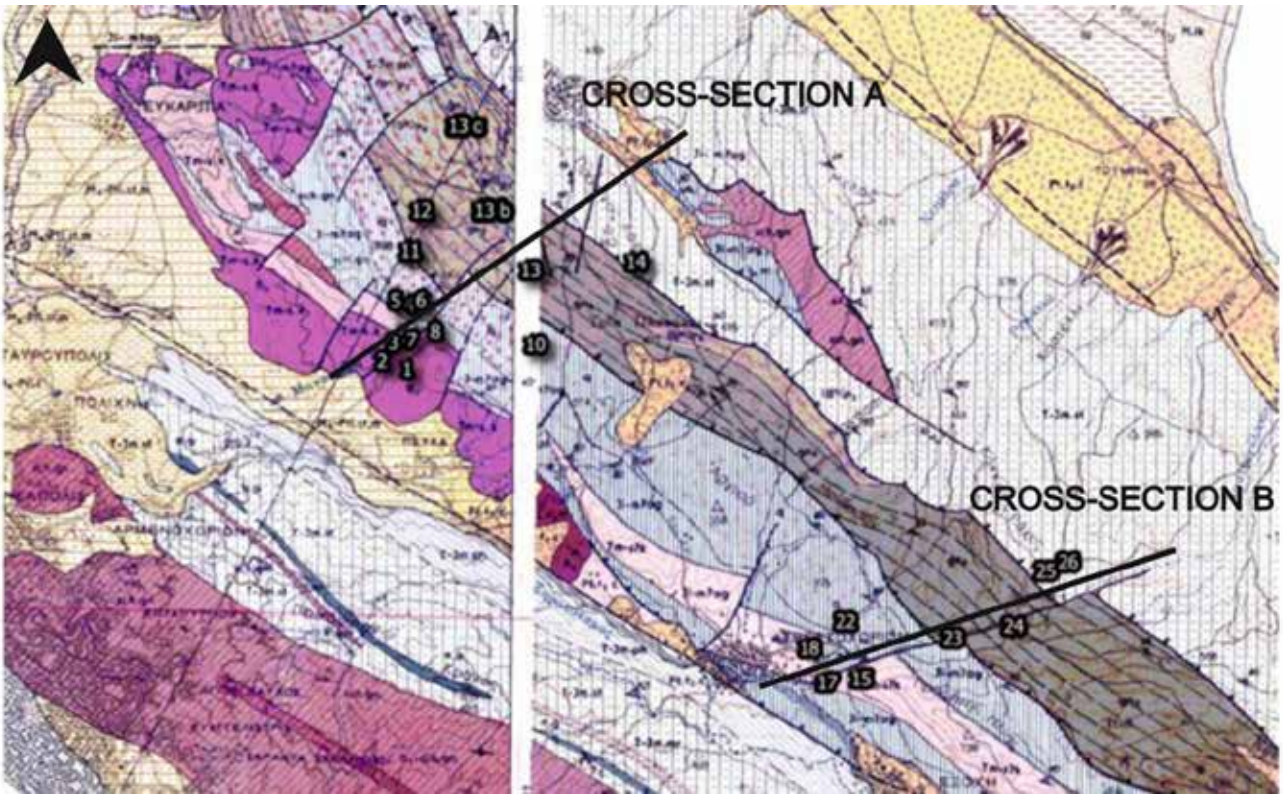

Figure 1.Geological map of the study area with field measurement points and location of geological sections. According to the geological mapping (Kockel et al.1970a Thermi sheet, Kockel et al.1970b Thessaloniki sheet).

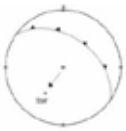

Results

The data analysed showed that the geological structure that exists today was not created by a single tectonic episode, but is the result of a series of deformation events. The newer events overprinted the older ones, making it more difficult to identify them. The distinction macroof the deformation events was based on the geometric characteristics of the tectonic structures (orientation, position, shape) and their kinematic analysis. The tectonic structures formed by compressive forces are due to the convergence of the African plate with Eurasia, the destruction of the Tethys Ocean and the increase in the thickness of the continental crust. Extensional structures followed the compressive ones, first with the collapse of the compressive structure and later with back arc extension.

We distinguished six main deformation events (D1-D6) in the study area (Table 1) which is coherent to similar studies in the broader area (Kilias et al. 2010, Katrivanos et al. 2013, 2016, Kilias 2024), revealing that the Internal Hellenides underwent complex deformation and metamorphism during the Alpine orogeny. The rocks appear to be inverted, with the older rocks tectonically superimposed on the newer ones. The degree of metamorphism increases to the northeast, i.e. towards the upper tectonostratigraphic horizons. The tectonic contacts between the formations are due to the action of reverse faults. Parts of the Serbo-Macedonian Massif were trapped between the units of the Circum-Rhodope Belt (Aspris Vrysi - Chortiati, Melissochori - Cholomonta). In this way, continental crustal rocks came into contact with rocks characteristic of the oceanic crust and deep-sea sediments. The sense of movement was from north-east to south-west. The geological structure of the tectonostratigraphic column (Figure 2) and of the two geological sections(Figure 3) prove that they belong to the same geotectonic zone (Circum-Rhodope Belt), have been affected by common deformation events and consist of the same formations.

However, there are some differences between the two areas: In the Asvestochori area, no occurrences of microgneiss and augen gneiss have been found. Thus, the Serbo-Macedonian Massif in the area consists only of greenschist. The degree of metamorphism of the greenschist is obviously greater than that of the surrounding rocks, but it does not reach the degree of metamorphism of the gneiss rocks of the Pefka-Filiro area. In the area of Asvestochori, the formation of clay shales contains interbeds of graphitic shales. In the Pefka area, graphitic shales are absent or could not be found. Finally, the orientation of the formations in the two areas shows a slight deviation from NW-SE in the Pefka-Filiro area to WNW-ESE in the Asvestochori area.

Table 1. Deformation events based on our field- structural observations and on other similar studies (Kilias et al. 1999,2010,Tranos et al. 1999, Katrivanos et al. 2013,2016, Kilias 2024)

DEFORMATION EVENTS (D)	AGE	STRESS REGIME & DEFORMATION CONDITIONS	STRUCTURES	KINEMATICS	GEODYNAMIC RESULTS
D1	MID-LATE JURASSIC	COMPRESSION DUCTILE	NOT FOUND		Ophiolite obduction and thrusting
D2	LATE JURASSIC-EARLY CRETACEOUS	COMPRESSION DUCTILE	CLOSED FOLDS & SCHISTOSITY CREATION		Thrusting and terrain accretion (photo 1,2)
D3	LATE CRETACEOUS	EXTENSION	NOT FOUND		Basin formation

Photo 5: D4 event ,open fold with a direction to WSW (Svoula flysch)
Photo 6: D6b event, normal fault

Conclusions

- The whole area was affected by a polyphase deformation (D1-D6 events), that started in ductile conditions (D1-D3) and continued with brittle conditions (D4-D6).
- Older tectonic events of compressive ductile stress regime (D1-D2) are associated with the tectonic emplacement of ophiolites and the general terrane accretion, whine newer ones of brittle stress regime (D4-D5) are related to the thrusting and the creation of tectonic slices, as well as the inversion of the whole series.
- During the D4 deformation event, parts of the Serbo-Macedonian Massif were tectonically intercalated within the Circum-Rhodope Belt formations.
- In Oligocene – Miocene, the localized conditions of the stress regime fall into the category of transpression, while in the same age ductile extension prevails to the east (Pangaion unit) and brittle extension prevails to the west (Paiko unit).
- We consider that the pre-alpine basement in the study area is of Serbo-Macedonian origin and the tectonic movement of tectonic slices was accomplished on this basement.

EXTENDED ABSTRACT 116

Integrating Geotechnical Data and Site Response Analyses in the Municipality of Chalandri, Athens, Greece

Ioannidou Despoina *Civil Engineer T.E. MSc, d.ioannidou12@gmail.com, CLPW, Athens, Greece & University of the Aegean, Greece*
Ktenidou Olga – Joan *Civil Engineer, PhD, Researcher National Observatory of Athens, Greece*

ABSTRACT: I
n this work, the properties and the dynamic response of the soil formations in the area of Chalandri are investigated. Its main points are the collection and synthesis of all available data from 92 sampling boreholes, the estimation of shear velocity (Vs) through empirical correlations, the 1-D dynamic analysis of soil profiles modelled from 42 borehole locations, the zonation of the area according to site response and the production of maps showing the spatial distribution of the main characteristics of ground motions (fundamental period and amplification factor). Finally, these results were correlated with the building damage caused by the 1981 earthquake in Alkyonides.

INTRODUCTION

Local soil conditions are one of the most important factors determining the strong ground motion and consequently the seismic hazard at a specific location. Site effects have been known to modify the duration, amplitude and frequency content of ground shaking. The most commonly considered case is that of increased amplitude at specific frequencies related to the material properties (e.g. shear-wave velocity) and geometry (e.g. layer thickness), which is referred to as site amplification. Simpler cases refer to simple soil layers over bedrock while more complex ones include basin edges, topographic features, and other cases of lateral discontinuities (Bard, 1999, (Kausel & Roesset, 1984), (Pitilakis et al, 1999a) (Chavez-Garcia et al, 2000), (Raptakis et al, 2005).
The present work, which is the result of postgraduate work within the framework of the inter-institutional postgraduate program "Natural Hazards and Disaster Management" (co-organized by the University of the Aegean, the Aristotle University of Thessaloniki and the National Observatory of Athens), aims to utilize as much as possible the available information for an initial assessment of the seismic response at a large number of points in the Municipality of Chalandri, taking into account the influence of local soil conditions and their change within the area. The Municipality of Chalandri was chosen as a study area due to its size and population, but also due to the availability of a large number of data that remained unexploited for decades.

COLLECTION AND PROCESSING OF GEOTECHNICAL AND GEOPHYSICAL DATA

An extensive effort to collect data and technical information from boreholes and geotechnical surveys carried out in past decades for the Municipality of Chalandri in the Prefecture of Attica. This search, resulted in the discovery of 10 geotechnical surveys consisting of 92 sampling boreholes, which occupy most of the Municipality (as it was defined in earlier days, before its extension north), and one cross-hole test site (figure 1).
All boreholes and geotechnical surveys were drawn from the project archive of the "Geotechnical Engineering and Geology" department of the Central Laboratory of Public Works (TGMT/KEDE/YPOME).
The geological background of the Municipality of Chalandri is structured by alpine formations ('Allochthonous Unit of Attica" which includes the 'Athenian Schists" and the 'Upper Cretaceous Limestones") which are covered by significantly thick Post-alpine formations, (Lekkas et al., 1999). The Post-alpine formations are represented by Neogene and Quaternary sediments. The Neogene sediments found in Chalandri are continental formations of Upper Miocene age. (Mariolakos & Fountoulis, 2002). The Quaternary deposits that overlie all of the previous formations are loose deposits from river alluvium, of mixed phase.
From the processing and evaluation of the data from the boreholes, it became possible to distinguish the soils into three soil units I, II, III. These units represent the geological formations of the subsoil of Chalandri and are categorized into geotechnical units Ia, Ib, Ic for the Quaternary deposits and IIa, IIb for the Neogene sediments (Upper Tertiary deposits). This distinction was the result of the evaluation of the physical and geotechnical properties of the soil materials, with the aim of grouping them into specific units, characterized by a certain framework of homogeneity in terms of their mechanical behavior. The geotechnical units (Ia, Ib, Ic) consist of alternations of sandy clay with clayey silty sand and gravels of clayey composition. Unit IIb consists of lean and fat clay and unit IIa consists of marls which overlie unit IIb. Finally, unit III represents the rocky bedrock of the municipality, which consists mainly of clayey shale and cohesive shale (Table 1).
After the thorough recording and detailed statistical processing of 793 samples and 2734 tests, which included data from tests of physical properties (grain size distribution analysis, Atteberg limits, etc.), mechanical properties (unconfined compressive strength, etc.), the SPT standard penetration test, the Chalandri area is characterized by a general geotechnical section, which

consists of recent deposits (manmade fill, sandy clays, sandy silts, sandy gravels), of Upper Tertiary deposits consisting mostly of reddish-brown sandy clay and interspersed in places with layers of clayey marl and loose conglomerates and bedrock, which consists of Athenian Schist, limestone and cohesive conglomerates.

The difference seen in the processing of geological and geotechnical data is the progressive increase in the thickness of the Upper Tertiary deposits and correspondingly the increase in the depth of the rocky bedrock (Figure 2).

Therefore, according to this important detail, the area was divided, depending on the depth of the rocky bedrock, into six (6) zones, which are: Zone A: 0 – 5m., Zone B: 5 – 10m., Zone C: 10 – 20m., Zone D: 20 – 30m., Zone E: 30 – 40m. and Zone ST: >40m. (Figure 3). There is a clear NNW-SSE trending boundary in the zonation map which represents the Chalandri fault (Christoulas, et al 1983), and marks an abrupt change in sediment thickness either side.

It is worth noting that no rocky bedrock was found in zone ST, although the deepest drillings exceeded the drilling depth of 70m. Also, zone ST was deemed appropriate to be divided into two subzones (subzone ST and ST_1), which present a differentiation in terms of stratigraphy. Specifically, subzone ST_1 consists of layers of conglomerates and marls before the reddish-brown sandy clay which is the main material of the Upper Tertiary deposits.

STUDY OF SEISMIC RESPONSE OF SOIL FORMATIONS

The shear wave propagation velocity Vs, in soil formations, due to the lack of a sufficient number of geophysical tests, was estimated approximately through the very extensive data of the standard penetration test Nspt (621 tests). After reviewing the literature and comparing a large number of relationships, the following empirical relationships were selected, from studies in Greek soils.

(Raptakis, et al 1994)

$Vs\ (m/sec) = 99.95\ (N_{60})^{0.237}$ (Medium – Dense sands, Nspt>10) (1)

$Vs\ (m/sec) = 192.41\ (N_{60})^{0.131}$ (Gravel soils) (2)

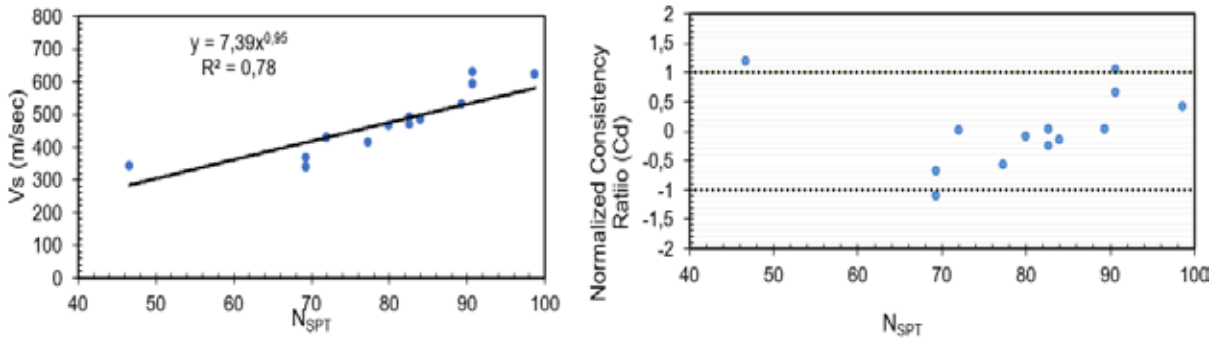
$Vs\ (m/sec) = 10.78\ (N_{60})$-299.3 (Marls) (3)

(Athanasopoulos, 1995)

$Vs\ (m/sec) = 85.3\ (Nspt)^{0.42}$ (Gravel soils) (4)

(Tsiabaos & Sabatakakis, 2011)

$Vs\ (m/sec) = 112.2\ (N_{60})^{0.324}$ (Clay soils and marls) (5)



$Vs\ (m/sec) = 79.7\ (N_{60})^{0.365}$ (Sandy soils) (6)

For soils consisting of clays, Vs was estimated approximately by the empirical correlation of the results of the single cross-hole test with the average of the Nspt blows for the corresponding depths of the cross-hole test values, of all the projects under study through the following relationship:

$Vs\ (m/sec) = 7.39\ (Nspt)^{0.95}$ (7)

The data and the trend line for relationship (7) are shown in figure 4.

Figure 4: Correlation between Nspt and Vs values for clays (Nspt>8) (left) and normalized consistency ratio $C_{(d)}$ (right).

The normalized coherence ratio C(d) is given by equation 8:

$C(d) = (Vsm - Vsc) / Nspt$ (8)

where Vsm are the measured values from the cross-hole test, Vsc are the calculated values from equation (7), and Nspt are the uncorrected values of the SPT blows. Figure 4 (right) shows the comparison between the Vsm and Vsc values. The C(d) values appear close to 0, which means that the proposed equation performs well in predicting Vsc (Table 2).

The Vs adopted for the bedrock of Chalandri is 1600 m/sec for the clayey shale of Athens (Koukis & Sabatakakis, 2000). For the seismic bedrock of zones ST and ST_1 the shear velocities adopted are 750 m/sec and 850 m/sec respectively, values representative of very hard soils and sandy clays (Chen & Ong, 2012), (Jia, 2018).
In every location of the soil profiles analyzed, the average mass density of the rocky bedrock was assumed to be equal

Table 2: Average SPT blow counts and shear wave velocities Vs for the geotechnical units of the Municipality of Chalandri

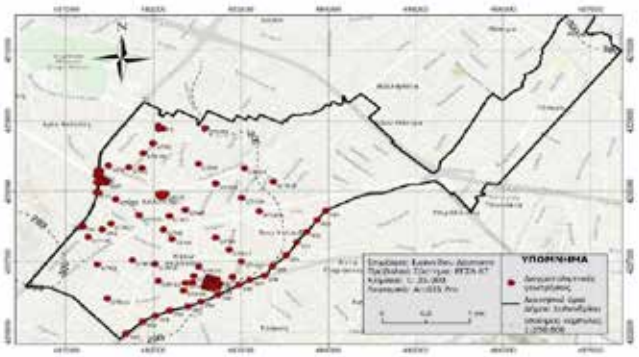
*Because geotechnical units A and Ia have similar geotechnical properties and the average velocities Vs estimated are practically the same, for reasons of simplification of the seismic analysis, the two units were merged.

to 23 kN/m3 (Koukis & Sabatakakis, 2000) while the seismic bedrock (zone ST and ST_1) was assumed to be 22 kN/m^3 since no harder formation has been found in this zone and the average density value for the Upper Tertiary deposits was calculated to be 22 kN/m^3. The hysteretic damping ratio was assumed to be equal to 2% for the rocky-seismic bedrock and 3% for the soil layers overlying the bedrock.
The seismic excitation used for the analysis of the seismic ground response is the Athens earthquake of September 7, 1999, with a magnitude of Mw 5.9. The accelerogram chosen as the input motion was recorded at the DMK station (EKEFE Demokritos) of the National Earthquake Research Center in the area of Agia Paraskevi (NOA, 1975) and had an epicentral distance from the rupture of 25 km (esm-db.eu, Luzi et al., 2020) (figure 5). This station was chosen because it is the only one in the vicinity that lies on rock conditions. Figure 6 shows the acceleration time series at DMK station, as well as the acceleration response spectrum in the 3 components of the recording.
After merging similar soil profiles, 42 soil profiles were solved in the Chalandri area using 1D equivalent linear analysis method with the DEEPSOIL software (Hashash et al., 2020). According to this method, for any seismic excitation, the differential equations are solved using Fourier analysis in the frequency domain. Using this model and the corresponding geotechnical and dynamic properties and layer thicknesses for each zone, the corresponding transfer functions were calculated for each soil profile (Figure 7, where the groups of transfer functions for zones A, C, ST and the corresponding response spectra for damping ratio of ξ=5%, i.e. for a reinforced concrete structure, are shown).

Figure 5: Location of the DMK accelerometer (red cicle)



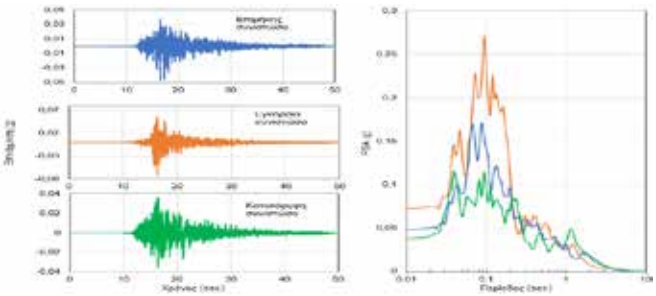


Figure 6: Acceleration time series and response spectra at DMK station

Figures 8 and 9 show the spatial distribution of the fundamental period T0 and the amplification factor in this period A0. Among the calculated values, the other values were estimated using the spatial interpolation method “Krigging”. The maps, in addition to the spatial distribution of the above parameters, also show the locations of the buildings that suffered significant damage from the 1981 Alkyonides earthquake (Christoulas et al., 1983). Also shown are the EC8 soil categories for each soil profile as calculated from the relation for shallow seismic profiles (>30m):

Log Vs 30 = (a + b) log (Vs (d)) (Boore, 2004) (9)

where Vs (d), the average velocity value for a soil profile depth of less than 30 m, a and b, coefficients for each 1m. from 10m. to 29m.

Figure 7: Transfer functions (left) and response spectra (right) computed from the 1D analyses at each borehole location within each zone (zones A,C,ST)

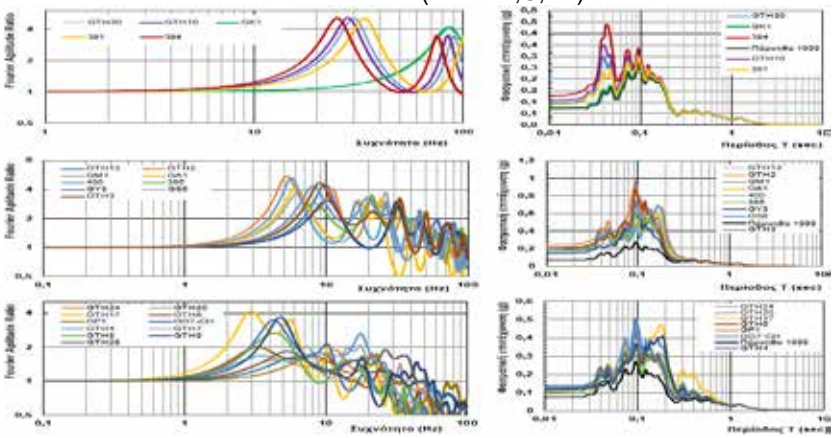

Figure 8: Spatial distribution map of fundamental period T0

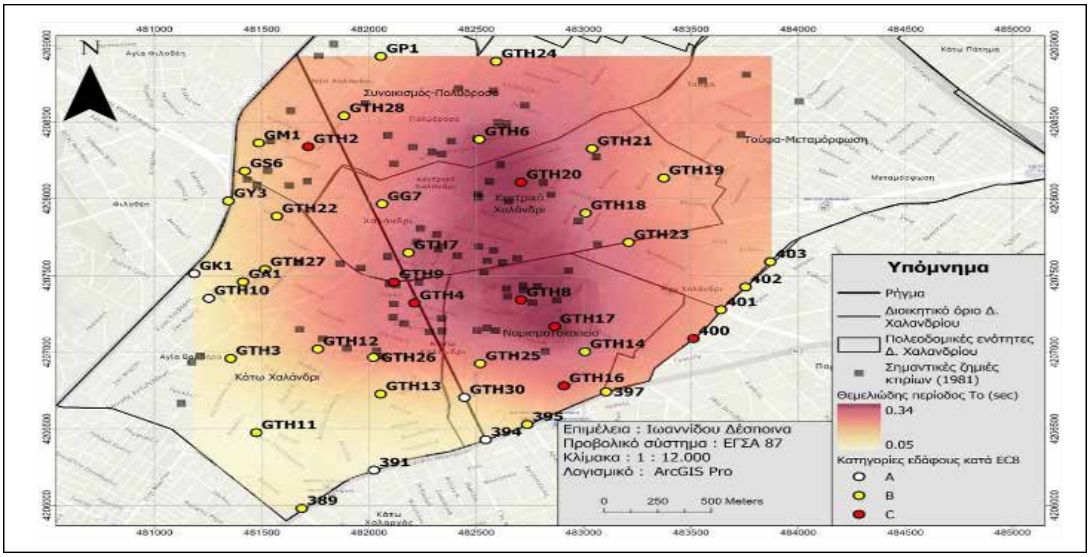

Figure 9: Spatial distribution map of amplification factor A0

Studying the maps of figures 8 and 9, and comparing the most significant building damages caused by the Alkyonides earthquake in 1981, most of the damages are observed in the northeastern and eastern part of Chalandri and mainly in central Chalandri, where the thickness of the soil deposits exceeds 20m. (zones D, E, ST), giving periods from 0.15 to 0.34 sec, values that affect single-storey to four-storey buildings. In the SW part of Chalandri, the damages appear at soil deposit depths of up to 10m. and are clearly less than in the previous case.

Evaluating all the above results and observations and according to the spatial distribution maps that were constructed, we reach the following conclusions:

• In the area of eastern Chalandri (central Chalandri, Synoikismos – Polydroso) the deepest soil deposits prevail without the rocky subsoil being known, resulting in the longest fundamental periods found of the order of 0.12sec – 0.34sec. These conclusions are restricted by the lack of basement rock in the boreholes in zone ST.

• In the area of the Nomismatokopeio, in addition to the deep deposits that prevail, the soils are looser (small number of Nspt blows, category C according to EC8), resulting in large amplification factor of the order of 4 due to the stronger impedance with the considered subsoil.
• Finally, in Kato Chalandri it seems that two areas with different depths of soil deposits prevail. To the west and around the administrative boundaries of the Municipality, shallow soil deposits prevail with cohesive soils with fundamental period of the order of 0.06sec, while further east, the deposits become deeper with looser soils giving amplification factor of the order of 4 and fundamental period of the order of 0.20sec. This is probably why the damage in the Kato Chalandri area is concentrated in its eastern part.

In this study, despite the large amount of geotechnical data collected and analyzed, unfortunately it was not possible to find geophysical data, with the exception of a cross-hole test. Thus, the estimation of Vs was based on empirical formulas in correlation with the Nspt blows and the results of a single cross-hole test. This lack of data constitutes one of the main limitations of the present study, combined with the fact that the depth of most boreholes does not reach 30 meters and often does not reach the bedrock (this latter limitation leads to the lack of content of the seismic analyses at shorter periods that would be associated with the deeper soil layers). On the other hand, the relatively small difference between the Vs of the soil layers leads to relatively low levels of amplification, which for higher impedance values would potentially lead to higher ground motion around the resonance frequencies. In the future, and towards a more theoretical investigation of uncertainties, a new analysis could be carried out including variations in the Vs values, following statistical processing and randomization of the profiles. Furthermore, given that maximum ground accelerations greater than 0.20 g were estimated at the surface of some soil profiles, it would be advisable to carry out a non-linear analysis of the soil formations. This could lead (due to the reduction of the stiffness and the velocity Vs in the shallower layers) to somewhat lower amplifications and natural frequencies.

Seismic vulnerability of cultural heritage. The case of the archaeological museum of Rhodes: building performance, safety of the public and exhibits

Irakleidis A.-K.[1] Ktenidou O.-J.[2]

(1) Civil Engineer, graduate of the Inter-Institutional Master Course «Natural Hazards and Disaster Mitigation»

(2) Senior Researcher at National Observatory of Athens, Greece

Introduction / Background

Natural disasters and especially earthquakes in seismically active areas such as Greece, constitute the most significant risk that threatens tangible cultural heritage: buildings and other structures (bridges, aqueducts, etc.), archaeological and historical sites but also artifacts of everyday life, funerary objects, works of art, etc. that are kept in warehouses or exhibited in museums.

The vulnerability of buildings belonging to cultural heritage is high: constructed of load-bearing masonry – a brittle material – they do not possess the structural characteristics that allow them to absorb the energy released by an earthquake, without being subject to damage and ultimately collapse. Respectively, objects placed on pedestals, shelves, in display cases or suspended from ceilings and walls, etc., under a strong earthquake run a high risk of suffering damage that is often irreversible, even when the museums themselves remain intact.

In recent major earthquakes in Greece, as well as in other seismically active countries, monuments and museum exhbits were the ones that were most affected.

The aim of this paper is to demonstrate the relationship between the requirement for the protection of human life, while simultaneously protecting the monumental values carried by buildings and objects that belong to cultural heritage.

A case study of a building located in an area with a rich seismic history was examined, for which it was possible to collect data in order to highlight the objectives of the work. The Archaeological Museum of Rhodes was chosen, that is a building built from the island's Hospitaller Knights of St. John (1310-1522) as their New Hospital. The building was completed in 1489 and is located within the Medieval City of Rhodes, an area where data on the dynamic behavior of its soil formations is available from previous studies, while the bibliography is rich in data for the structural types and the mechanical properties of the materials of the buildings of this World Heritage Site.

The seismic vulnerability of the building was studied with modern computational methods, following the provisions of the Code for interventions in buildings made of load-bearing masonry (KADET), while the stability of exhibits on pedestals was calculated with procedures proposed in the American regulation FEMA P-58 and other sources. The results of the preliminary analyzes are interesting. On the one hand, as expected, the iconic medieval building turns out to fall short of modern requirements for the seismic vulnerability of museum buildings. On the other hand, museum exhibits that are placed on the museum floors with conventional support methods (usually on pedestals that are not anchored to the floor) prove to be particularly vulnerable to earthquakes – indeed considerably smaller than those expected to cause damage to the building itself. The above results are consistent with what has been observed in recent and past earthquakes. For this reason, extensive research on this field is undergoing internationally in order to mitigate seismic risk for monuments and museum exhibits.

Seismic vulnerability of the archaeological museum of Rhodes

From an architectural point of view, the building under study is a Gothic building with Renaissance elements. In plan, it covers an area of approximately 3600 m^2 with a maximum dimension in the N-S direction of 65 m and in the E-W direction of 60 m. It has two floors and its main morphological characteristic is the large atrium in the center that covers an area of approximately 500 m^2, which is surrounded by the rooms. The first floor is dominated by the large "patients' hall", an elongated hall on the facade of the building (eastern side) measuring 54.0 m x 14.0 m, with a central arcade consisting of 7 intermediate octagonal columns. The height of the large hall is greater than the rest of the floor by approximately 3.0 m and dominates the facade of the building.

The buildings' load bearing walls are made of three-leaf masonries. The main building material is the local yellowish sandstone, which is the material of all the buildings of the medieval city and its fortresses. The mechanical characteristics of the walls were assumed to be the same as those used in a recent research work for the nearby Arsenal de Milly (Cattari et al, 2015). The ground floor ceiling is made of masonry vaults, while the first floor is covered with reinforced concrete slabs that are the result of the most recent large scale intervention on the building, dated back in the 1920's when Rhodes came under the Italian colonial rule.

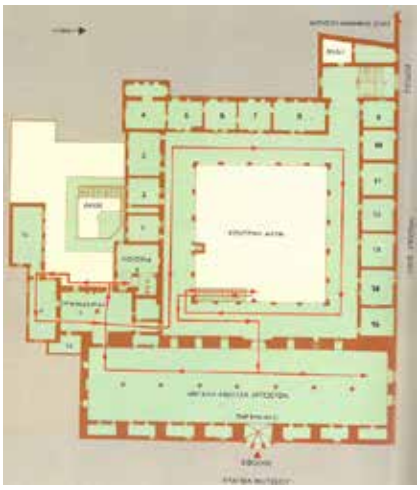

Figure 1: Plan of the 1st floor of the museum (source: I. Kollias, 1991, The Knights of Rhodes)

The underground conditions of the Medieval City of Rhodes were studied in the past by the Aristotle Polytechnic School (1997) and results for the dynamic response at the ground surface were taken into account in the analyses. In the next figure the division of the medieval city of Rhodes in distinct zones is presented.

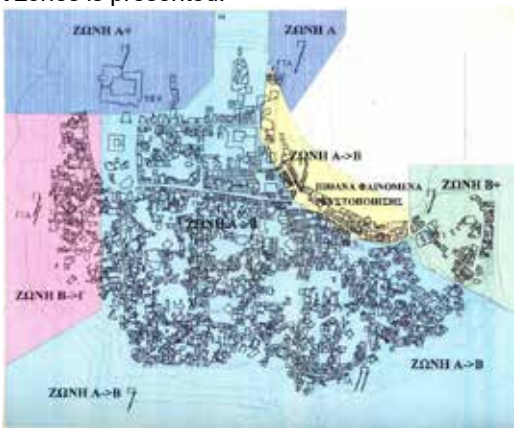

Figure 2: Division of the Medieval City into distinct zones according to their seismic response

The building was simulated with the equivalent frame model method, using the specialized commercial software package 3MURI. This method reduces the plane walls into three types of elements: piers (vertical elements), lintels (horizontal elements) and rigid nodes.

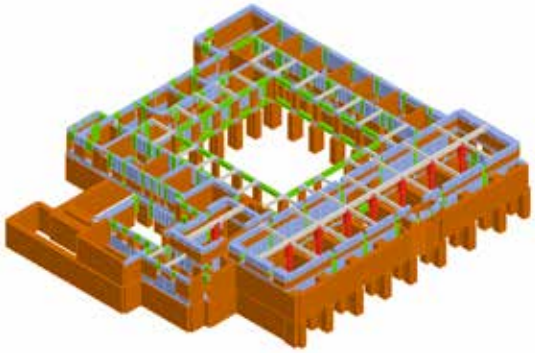

Figure 3: Three-dimensional model of equivalent frames (3MURI software)

Two types of analysis were performed on the geometric model of the building:
a) Modal analysis, which determines the vibration modes of the building and their degree of participation in the overall response of the structure, and

b) equivalent static nonlinear analysis (pushover).
The modal analysis of the model provides all possible eigenmodes of the building's oscillation and contributes to a better understanding of its dynamic behavior in the frequency domain.
From the analysis performed, it was found that the significant eigenmodes that oscillate at least 75% of the seismic mass of the building per direction are more than one and they are ranging between 0,13s and 0,23s – it is a very stiff building indeed. This fact is not surprising. Despite the existence of rigid concrete slabs on the roof of the first floor, diaphragmatic behavior is not ensured. The slabs lack of continuity over the entire surface of the building's floor plan, as they are interrupted by the large atrium in the center the different level of the building's two largest rooms at the first floor.
On the other hand, the pushover analysis helps to identify the weaknesses of the structural system and assess its seismic adequacy for a selected performance level and level of the seismic hazard. A variety of performance levels may be introduced and checked depending on the significance and the level of exposure of the examined building. In the case study, these levels were determined by the current Greek regulation (KADET) for museum buildings, which are significantly higher than those for typical residential buildings.
Despite certain limitations of the application of pushover method to this building, it provides some useful insight to its response. The building shows significant damage for most of the examined scenarios at its upper floor, while the ground floor remains intact. This means that if a desired level of safety, as determined by the current seismic regulations should be reached, measures to strengthen the building's upper floor should be studied and implemented.

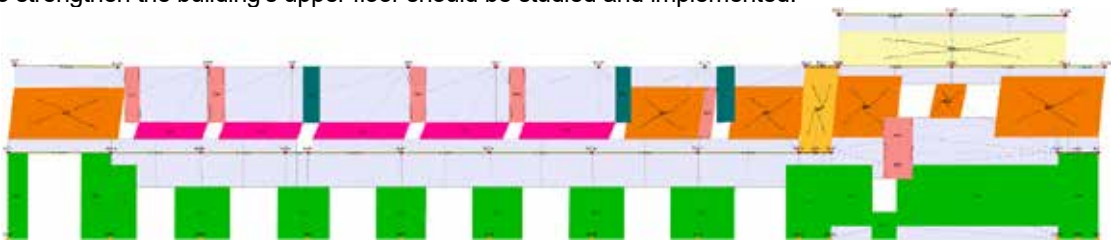

Figure 4: Illustration of the plane model of a characteristic wall of the building at the last step of the pushover analysis (3MURI software). With different colors are shown the different modes and levels of failure of the elements.

Seismic vulnerability of museum artifacts

The stability of museum artifacts depends on many factors, such as the characteristics of the incoming earthquake, the response at each point of the building, the location, the materials involved and the method of support of the exhibits etc. In the present study, a simplified method of analysis of the stability of museum exhibits that are mounted on pedestals that rest freely on the museum floor was used. The procedure is provided in the American code FEMA P-58 and its application field includes the seismic stability of building equipment items, such as libraries, devices freely placed on the floor, etc.
In the method, two limit states are examined: the limit state against overturning and the limit state against sliding, whichever appears first. Its philosophy is based on the assumption that objects are allowed to slide or rock, up to a maximum limit, which is determined by a median maximum floor velocity. This limit is determined in such a way that if the object slides, the distance traveled does not endanger its integrity due to a fall or collision, while if the object rocks, it does not risk overturning after a few rocking cycles. In the present work, although median maximum floor velocity is calculated, a more conservative approach is adopted due to the great importance of the exhibits: it is the onset of rocking or sliding which signals failure. And as the sliding coefficient is a more controllable parameter, the critical acceleration $S_{a0}S_{a0}$ for the onset of rocking was considered as a criterion of failure.

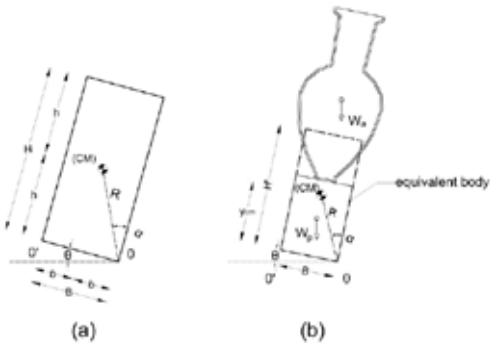

Figure 5: Geometric definitions of the method by Spyrakos et al (2017)

Using the formulas of the aforementioned method, the stability of a large number of objects from the museum's sculpture exhibition was examined, taking into account in a simplified manner their actual geometric characteristics. From the calculations performed, it was found that failure of exhibits is expected even for small earthquakes. The percentage of failure is increased when artifacts are exhibited on a higher floor, where seismic acceleration is amplified compared to the ground acceleration.

It is indicated that for an earthquake for which the museum building should not develop damage (performance level A2 according to the Greek intervention code), at least 7% of the exhibits are expected to begin to rock. This percentage is increasing significantly if these exhibits are placed on a floor.

It is concluded that even if the results of the simplified calculations presented in this chapter are conservative and based on assumptions that have large margins of error, they confirm what is already known from recent international and local experience: museum artifacts are not earthquake-proof and the main risk they run does not come so much from the failure of the building as from the loss of their stability due to strong ground motion.

From this point of view, such simple calculation methods are extremely useful for quickly assessing the risk of overturning or sliding of exhibits, but they certainly do not replace more detailed and accurate methodologies which, however, require reliable data in order to be useful and practically usable.

Discussion

Seismic safety of museums and artifacts is a subject of great scientific and technological interest, on which research is being developed internationally. The building under study, the archaeological museum of Rhodes has a monumental character and at the same time it hosts an important archaeological exhibition. Thus, both the integrity of the building and the safety of the exhibits are of great importance.

The methodology used and analyses performed under the present work meet certain limitations and further work is needed. More specifically, regarding the study of the building, a more detailed knowledge of its structural system and the materials it consists of is required. More sophisticated analyses would give a better insight to its seismic response at every location, which would be particularly useful for a reliable analysis of the seismic performance of the building and for the stability analysis of the exhibits as well. Furthermore, more complex models for the calculation of the rocking characteristics of artifacts, based on detailed geometric mapping would provide a better understanding of their safety margins under earthquake loading and in the selection and development of new appropriate methods of supporting and displaying museum artifacts.

Acknowledgements

Among the people who helped in one way or another in the preparation of this work, we feel the need to acknowledge the contribution of Dr. Dimitrios Vamvatsikos, associate professor at NTUA, whose initial ideas and directions formed the basis for the present work.

EXTENDED ABSTRACT 118

Rock slope stability analysis on the road axis of Kleisoura – Kastoria, Greece

Irakliotis A. W.[1] Papathanassiou G.[1]
(1) School of Geology, Aristotle University of Thessaloniki, Greece, airak@geo.auth.gr

Background

Transport corridors, like other infrastructure such as fuel lines, telecommunication, water, sewage and energy corridors, are highly vulnerable to landslide phenomena. Landslides pose a threat to both infrastructure and human lives, with their impacts ranging from minor disruptions to economic catastrophes (Crozier et al., 2005). A variety of transport infrastructure projects require the excavation of rock cuts. The design process of rock cuts is usually concerned with details of the structural geology, meaning the orientation and characteristics of the discontinuities. In cases where the rock strength is much higher than the stresses in the rock, where there is little concern of fracturing, the design of slopes is primarily concerned with the stability of rock blocks formed by the discontinuities (Wyllie et al., 2017). The process of studying the discontinuities that characterize a certain rock mass should always involve a field investigation where geotechnical data is collected. This typically involves the collection of the discontinuities' orientation measurements using a geological compass, their characteristics, such as spacing, length and roughness, using a line measure and a profilometer, the compressive strength of their surfaces using a Schmidt hammer and more. In recent years remote sensing technologies such as the use of Terrestrial Laser Scanners or Airborne Laser Scanners have been extensively used to help assess hazards in rock slopes, particularly in regard to the mapping of discontinuities. A similar approach can be achieved using an Unmanned Aerial Vehicle (UAV) combined with the application of the photogrammetry method (Papathanassiou, 2022). Useful data, such as discontinuity orientation and certain characteristics, can then be extracted and used in rock slope stability analysis, in combination with the field obtained data.

Objectives

The present study focuses on the stability analysis of a rock slope along the Kleisoura – Kastoria road axis. One of its objectives is to highlight the usage of modern remote sensing techniques, particularly the use of Unmanned Aerial Vehicles, in the mapping of rock slopes and the evaluation of their stability. For the purposes of stability analysis both traditional and modern data collection methods have been utilized. The main objective is the assessment of the rock mass behavior, in order to predict future failures and suggest remedial measures to protect the infrastructure.

Methods

The methodology applied in this study can be divided into three parts.
The first part consists of the site reconnaissance where all available data concerning the study area was collected. This includes geographical, geological and hydrogeological data, as well as information concerning the tectonics and seismicity of the study area.
The second part includes the engineering geological field survey, where all necessary measurements, such as discontinuity orientations and characteristics, Schmidt hammer measurements, photographs and samples were collected. This phase also included the acquisition of all the necessary photographs for the creation of a 3D point cloud, using the methodology of UAV-based photogrammetry, described by Vasuki et al. (2014).
The third part of this study involves processing data acquired through field investigation and the analysis of the 3D point cloud. This includes generating stereographic plots to display discontinuity orientations and conducting relevant kinematic analyses. Noise removal from the 3D point cloud was performed to exclude elements not representing the anisotropic rock mass, such as vegetation, fallen rock blocks, and highly weathered material. The edited point cloud was then used for semi-automatic extraction of the main discontinuity set orientations using the open-source Discontinuity Set Extractor (DSE) software (Riquelme et al., 2014). Discontinuity spacing was then calculated through both manual analysis and automatic methods using DSE as a complementary approach (Riquelme et al., 2015). The volume of formed rock blocks was determined using two approaches: analyzing failed rock blocks present in the point cloud and applying Palmstrom's formula (Palmstrom, 2005) in combination with the previously quantified discontinuity spacings. Finally, areas of the slope most prone to rockfalls were identified, and rockfall trajectory simulations were performed. Based on these results, remedial measures were proposed and quantified for the studied slope.

Results

The studied slope consists of crystalline rock, specifically gneiss, belonging to the bedrock of the Pelagonic geotectonic

zone. It is characterized by three main discontinuity sets, while a fourth set is only observed locally. The rock exhibits varying degrees of weathering; in some areas, it is slightly weathered, while in others it is completely weathered, with some areas locally forming residual soil. The discontinuities vary in roughness, with JRC values ranging between 7 and 12. Clay infill material was observed in some of the discontinuities, and dripping water was also locally present. The minimum representative friction angle used in the kinematic analyses was calculated to be 43°. According to the kinematic analyses, the most common type of potential failure identified was wedge failure, followed by a small number of flexural toppling and planar failures. The blocks formed in the rock mass are characterized as small to medium in volume. The suggested remedial measure to protect the slope from potential rockfalls is the installation of a draped mesh, as there is insufficient space to construct a ditch capable of catching rockfalls on its own.

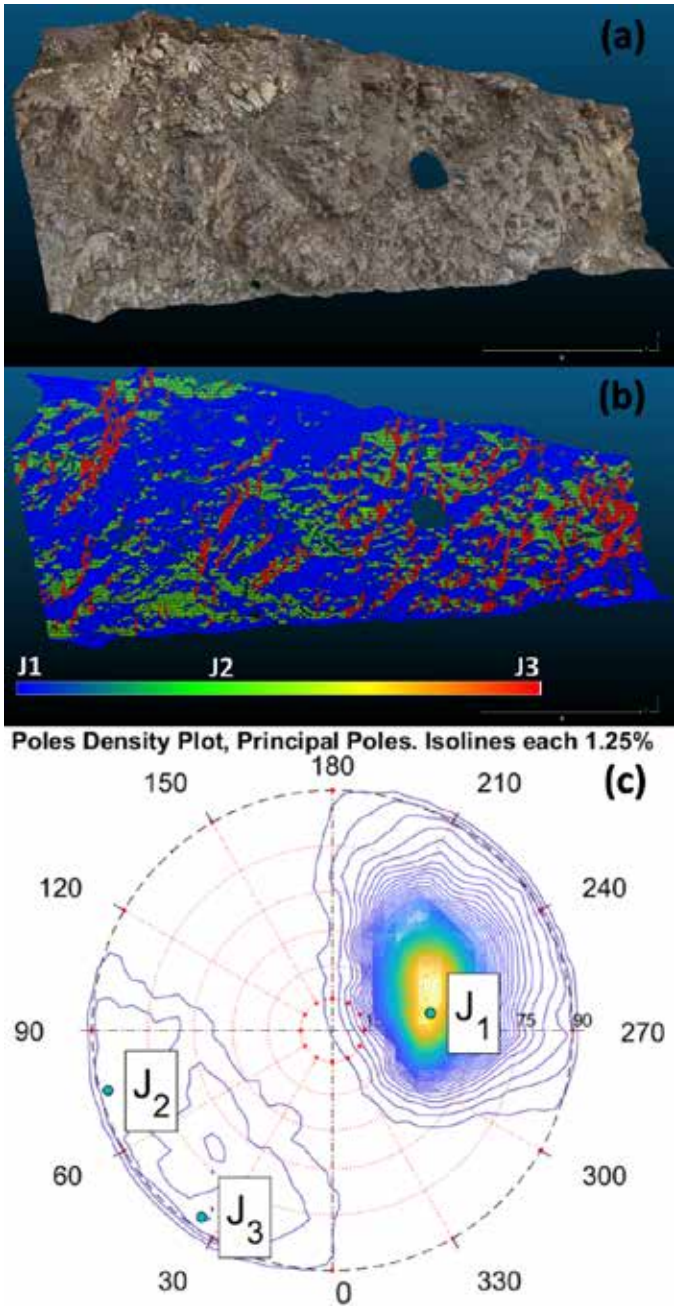

Figure 1. (a) Isometric front view of part of the slope, (b) the visual interpretation of the three main discontinuity sets extracted from the DSE analysis on the 3D point cloud and (c) the stereographic projection of the DSE derived discontinuity sets from the same part of the slope.

Acknowledgements
Part of the transportation costs to the study area were covered by the Research Committee of Aristotle University of Thessaloniki, as part of the corresponding author's master's thesis. Part of the analyses were performed using software provided by RocScience Inc. (Toronto, ON, Canada) under an academic license granted by the Department of Geology, Aristotle University of Thessaloniki.

Relict Taxa and Refugial Dynamics in the Corinth Gulf: Insights from the Pollen Record

Kafetzidou A.[1], Fatourou E.[1], Panagiotopoulos K.[2], Marret F.[3], Koukousioura O.[4,5] and Kouli K.[1]
(1) University of Athens, Greece, akafetzidou@geol.uoa.gr (2) Forschungszentrum Jülich, Germany (3) University of Liverpool, UK (4) University of Cologne, Germany (5) Aristotle University of Thessaloniki, Greece

Introduction / Background

Long pollen sequences covering the Quaternary period have enabled us to gain insight into the long-term variability and migration of the vegetation in the Mediterranean Basin in relation to climatic cycles (e.g., Magri *et al.,* 2017). Climatic fluctuations and ecological competition led to the gradual disappearance of several tree taxa, including Taxodioideae, Sequoioideae, *Sciadopitys, Tsuga, Castanea, Engelhardia*, and *Diospyros* (Suc *et al.,* 1995; Svenning, 2003; Farjon, 2005; Bertini, 2010; Popescu *et al.*, 2010). Deteriorated climatic conditions during glacial intervals forced the most demanding taxa into refugial areas, such as the Pindus Mountain Range, or southern regions of Italy and Greece (Suc et *al.,* 1995; Svenning, 2003; Bertini, 2010; Popescu *et al.*, 2010). Existing high-resolution pollen records from the southern Balkan show that the amplitude and timing of millennial-scale oscillations in temperate tree abundances depend on the latitude and altitude of the study area as well as its proximity to temperate tree refugia. Long pollen records located in mid-altitudes (between 400 and 850 m above sea level) across the Pindus Mountain Range, such as the Ioannina, Prespa and Ohrid Lakes sites suggest the survival of temperate tree populations during successive glacial-interglacial cycles (Tzedakis *et al.,* 2002, 2004; Panagiotopoulos *et al.,* 2014; Sadori *et al.,* 2016). Opposingly, in the Tenaghi Philippon pollen record from the north-eastern Greece, temperate trees often disappear and only occur during interglacial intervals. The vegetation at Tenaghi Philippon seems to have reacted in a more sensitive way to the climatic cycles, possibly due to the reduction in temperature and moisture (e.g., Tzedakis *et al*., 2006; Pross *et al.,* 2015; Koutsodendris *et al.,* 2023). The Quaternary climate-driven shifts significantly affected ecosystems, particularly at mid-latitudes (Lisiecki and Raymo, 2005; Joannin *et al.,* 2011). In Mediterranean Europe, the shift from the 41,000-year to the 100,000-year climatic oscillations resulted in an increase of in aridity, further impoverishing vegetation communities due to long-term cooling trends (Joannin *et al.,* 2011). This resulted in the gradual extinction of several tree taxa such as *Cedrus, Carya, Pterocarya, Juglans*, and *Zelkova* (Suc *et al.,* 1995; Svenning, 2003; Bertini, 2010). However, the sporadic and scattered nature of records only provides a partial chronostratigraphical overview of their distributions and extinctions, necessitating macroregional-scale adaptations. Despite the existence of some long continuous pollen records from the Balkan Peninsula, most of them are either far from tree refugial areas (e.g. the Tenaghi Philippon record that includes the MPT) or do not include the MPT interval (e.g., Ioannina, Prespa and Kopais). The evolution of north-south and west-east environmental gradients over long time scales, notably the sustained west-east precipitation gradient, has profoundly shaped the plant ecosystems in the southern Balkan Peninsula. This is evidenced by the contrasting vegetational responses observed between Tenaghi Philippon (e.g., Tzedakis *et al.,* 2006; Koutsodendris *et al.,* 2023) in the east and other western Balkan sites such as Lake Ohrid (Sadori et al., 2016; Donders *et al.,* 2021), Ioannina (e.g., Tzedakis *et al.,* 2002, 2003, 2004) and Prespa (Panagiotopoulos *et al.,* 2013, 2014). These findings highlight the need for further analysis of long-term pollen archives from the Balkan Peninsula to better understand the evolution of regional flora and the timing of relict species extinctions in the eastern Mediterranean.

The Gulf of Corinth pollen record provides significant insights into the persistence of relict taxa such as *Liquidambar*, *Carya*, *Pterocarya*, and *Cedrus* throughout the Pleistocene. These taxa, key components of temperate and riparian forests, persisted through multiple glacial-interglacial cycles, indicating the Gulf of Corinth region as a refugium in southeastern Europe. The region's unique climatic, topographic, and hydrological conditions enabled the survival of these taxa despite broader climatic fluctuations. *Liquidambar* displayed remarkable resilience, with a near-continuous presence from MIS 8 (300 ka) to ~13 ka BP, thriving during glacial phases in humid conditions. *Carya* persisted from MIS 24 (~923 ka) to MIS 8, with low percentages correlating with localized humid microclimates influenced by marine humidity. *Pterocarya* was present from MIS 13 (~500 ka) to MIS 3 (~36 ka), reaching higher abundances during glacial periods, indicating stable hydrological conditions in wet environments such as floodplains. Similarly, *Cedrus*, which gradually disappeared from the central and northern Balkans by the end of the Pleistocene, remained present in Gulf of Corinth sediments, suggesting local persistence rather than long-distance transport. These findings underscore the Gulf of Corinth's biogeographical significance as a biodiversity hotspot, providing exceptional conditions that allowed the persistence of relict taxa during the glacial maxima and interglacial periods of Quaternary.

The study highlights the region's role as a corridor for species persistence and migration in the Mediterranean. Understanding the resilience of these taxa offers valuable insights into reconstructing past vegetation dynamics, identifying refugia, and

predicting ecosystem responses to future climate change. The preservation and further study of this paleoenvironmental archive are important for advancing our knowledge of plant resilience, refugial dynamics, and climatic stability in the Mediterranean region.

Rare Insights in the Oligocene flora of Thrace (Greece): Preliminary results from the Rhodopi Petrified Forest

Kafetzidou A.[1], Koukousioura O.[2], Zotiadis V.[3], Kouli K.[1]

(1) National and Kapodistrian University of Athens, akafetzidou@geol.uoa.gr (2) Aristotle University of Thessaloniki, Greece (3) Edafomichaniki S.A., Athens, Greece

New fossil discoveries in the area of Thrace offer remarkable insights into the Oligocene vegetation and paleoenvironmental conditions of southeastern Europe. The plant fossil sites, representing some of the oldest Petrified Forests in Greece, preserve a diverse assemblage of both permineralized wood remains as well as leaf imprints of angiosperm trees. The fossil-bearing deposits comprise of successive pyroclastic series mainly consisting of tuffs intercalated with layers of sandstones, clays and marls. The pyroclastic sequence is linked to the volcanic activity in the Rhodope region during the Late Eocene to Oligocene (Georgiev and Marchev, 2005; Voudouris *et al.*, 2007).

Numerous permineralized well preserved wood specimens were identified, exhibiting the dominance of Fagaceae, mainly *Quercoxylon* sp., and the presence of thermophilic Lauraceae. The occurrence of several leaf litter horizons is recorded within the marl layers of the sequence. Among leaf imprints, the key taxa identified include Fagaceae (*Eotrigonobalanus* sp., *Quercus* spp.), *Myrica* spp., *Ziziphus* sp., *Laurophyllum* spp, *Dicotylophyllum* sp. and representatives of the Leguminosae (Figure 1).

Figure 1. a, b) Logging of the petrified trunks; c) branched petrified trunk; d) leaf imprints (scale: 10 cm).

Our findings show great similarities to those from the neighboring Bulgarian fossiliferous sites, as well as the petrified forest of Evros (Iamandei *et al.,* 2014, 2016, 2024; Velitzelos *et al.*, 2014; Velitzelos *et al.*, 1999, 2002). In the Bulgarian sites, petrified trunks within tuffs had provided a radiometric age ($^{40}Ar/^{39}Ar$) of approximately 31 million years (e.g., Iamandei *et al.*, 2014, 2016), confirming the Early Oligocene age of the fossils (Georgiev and Marchev,

2005). The volcanic activity, attributed to centers in Kotyli and Kalotycho (Caracciolo *et al.*, 2011), played a key role in the rapid burial and exceptional preservation of plant material. The studied fossil-bearing area in combination with the petrified forest of Evros (Velitzelos *et al.,* 2014; Velitzelos *et al.,* 1999, 2002) represent some of the oldest occurrences of paleovegetation in Greece.

EXTENDED ABSTRACT 121

Mapping the Geological Landscape of NW Bay of Navarino Through Time

Kaimakami M.[1]

(1) University of Peloponnese, Kalamata, Greece, mariakaim04@gmail.com

Abstract

This study explores the geological landscape of the northwest bay of Navarino and its influence on human settlement patterns. Using field surveys, GIS mapping, and optical microscopy, the research identifies key geological formations and their relationship with archaeological remains. The findings suggest that elevated limestone areas, such as the hills of Prophitis Ilias and Koukouras, were preferred for habitation, while fewer artifacts were found in the surrounding lagoon and cultivated areas. The study highlights the need for further research to confirm these observations and deepen our understanding of the region's historical development.

Introduction

The northwest bay of Navarino, located between modern Pylos and Romanos, is a significant cultural and environmental area, forming part of the Natura 2000 network. This study focuses on the region's geological and archaeological features, including the Gialova lagoon, Voidokoilia beach, Coryphasium peninsula, and surrounding hills and fields. Major archaeological discoveries include the Mycenaean tholos tomb of Thrasymedes, the Frankish Palaiokastro, and Nestor's Cave with Neolithic occupation traces. Since 2021, the Pylos Geoarchaeological Program (GEAPP) has been conducting research to investigate the area's natural and cultural environment. This study aims to analyze the geological landscape in relation to archaeological findings.

Geomorphology

The study area is part of the Gavrovo-Tripoli geotectonic zone, characterized by carbonate sedimentation from the Upper Triassic to the Upper Eocene. The western region, particularly the Coryphasium peninsula and nearby hills, consists mainly of Paleocene to Eocene limestone, while the Gialova lagoon lies on Holocene alluvial and fluvial deposits. Coastal sand dunes of Holocene-age, reaching up to 10 meters in height, dominate the shoreline. Tectonic movements and erosional processes have shaped the area, with evidence of past marine submersion and gradual land emergence over the past 9,000 years.

Historical Background

The Bay of Navarino has a long history of human presence, with research beginning with the University of Minnesota Messenia Expedition (UMME, 1953-1975) and continuing with the Pylos Regional Archaeological Project (PRAP, 1991-1999). Evidence of habitation dates back to the Paleolithic period, including tools and settlement in Nestor's Cave. During the Bronze Age, important settlements and burial monuments, such as the tholos tomb of Thrasymedes, indicate significant activity. In the Classical period, the region witnessed military conflicts, including the Battle of Sphacteria (425 BC). During the Roman and Byzantine eras, it remained an important center, while in the Frankish and Ottoman periods, fortifications were strengthened. The Battle of Navarino (1827) marked a turning point in Greece's independence.

Methodology

A field survey was conducted to record geological and archaeological features. Samples were collected for analysis using optical microscopy, and the data was digitized in ArcGIS 10.4.1. The mapping process included thematic layers for geological formations and archaeological discoveries. The coordinate system used was the Greek Grid Reference System (EGSA '87), and aerial photographs from 1945 were incorporated to enhance accuracy.

Key Sites of Geological and Archaeological Interest

- Voidokoilia Beach: Known for its circular shape, the beach comprises limestone, travertine, and dunes. Archaeological findings include ceramics and limestone walls, suggesting a Mycenaean harbor.
- Gialova Lagoon: A vital wetland with Holocene alluvial deposits with rich biodiversity. Drainage works in the 1960s uncovered a Classical and Roman cemetery.
- Divari Beach &Coryphasium Peninsula: The beach consists of alluvium and dunes, while the limestone-rich peninsula hosts ceramics, bones, and architectural remains.
- Prophitis Ilias Hill: Features prehistoric cemetery remains, limestone blocks with pillar holes, and ceramic depos-

its.

- Koukouras Hill: A primarily limestone hill with architectural structures and large limestone blocks indicating past settlements.
- Almyrolakka, Agios Nikolaos, and Kolopanas Beaches: Characterized by sandstone and brecciated limestone, with prehistoric ceramics and wall remnants.
- Agricultural Fields: Consisting of fertile alluvial soils, these areas exhibit limited archaeological finds due to extensive plowing.
-

Mapping and Rock Identification

The study area consists mainly of limestone, sandstone, breccia and flint. The Coryphasium Peninsula, as well as the hills of Prophitis Ilias and Koukouras, are primarily composed of limestone, while sandstones andfossilized aeolian sand appear on beaches such as Almyrolakka, Agios Nikolaos, and Kolopanas. Breccia was identified on the Coryphasium Peninsula, and flint was also present in various locations. A field survey was conducted to collect rock samples, some of which were analyzed using an optical microscope for better identification. The geological mapping revealed a more diverse rock distribution than previously indicated, enhancing our understanding of the region's geological composition.

Archaeological Findings and Settlement Patterns

Archaeological findings in the study area are mainly concentrated on the Coryphasium Peninsula and the hills of Prophitis Ilias and Koukouras, where limestone dominates. Few remains were found around the Gialova Lagoon, likely due to agricultural activities that have disturbed the soil over time. The region has been continuously inhabited since prehistoric times, with settlements, tombs, and artifacts indicating human presence. Changes in vegetation and land use over millennia have influenced the preservation and visibility of archaeological sites. Drainage works in the 20th century also exposed significant findings, highlighting the need for further research to understand human activity in relation to the landscape.

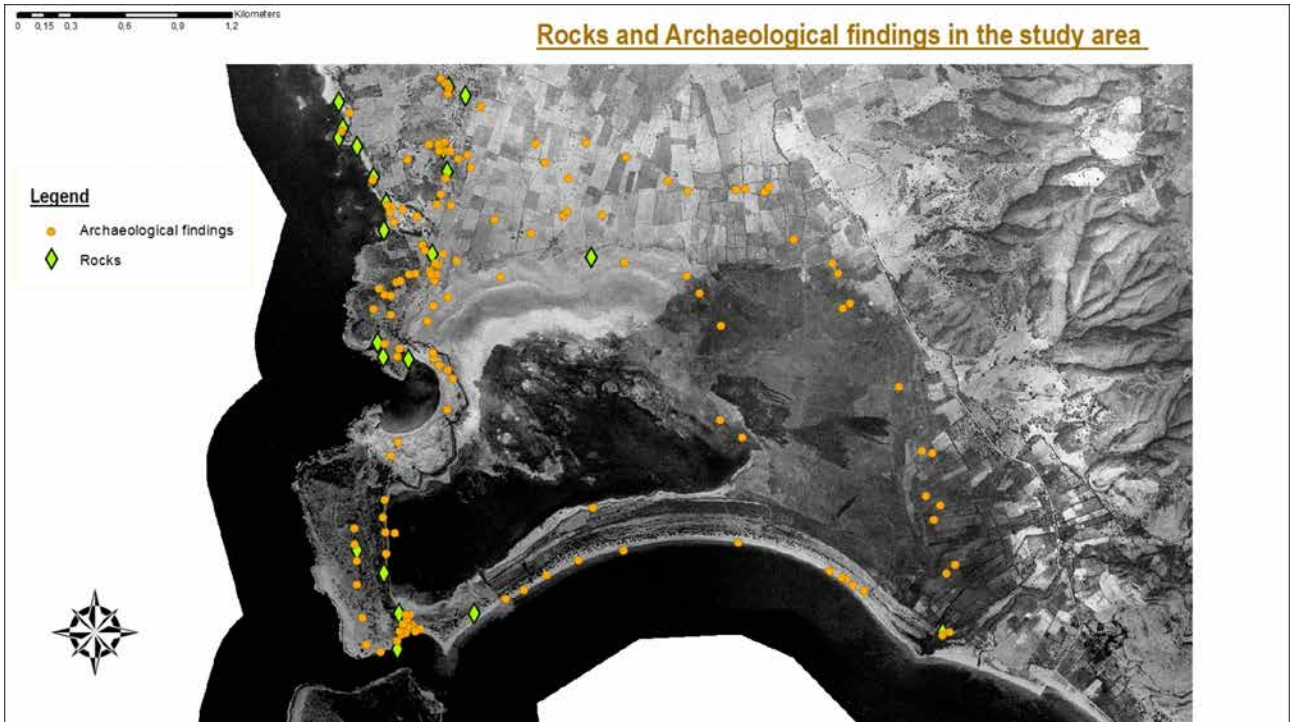

Figure 1. The map of the rocks and the archaeological findings in the study area © Maria Kaimakami.

Discussion

Most archaeological remains are located in elevated limestone areas, suggesting that strategic positioning and material availability influenced settlement choices. The scarcity of finds in the lagoon and cultivated areas may result from erosion, land disturbance, and accessibility issues. Geological mapping identified a wider variety

of rock formations than previously recorded, indicating the need for further research. A deeper understanding of archaeological distribution requires investigating environmental, geological, and socio-political factors that shaped human habitation in the area over time.

Conclusions

This research provides an initial understanding of the interaction between geology and human settlement in the northwest bay of Navarino. The concentration of archaeological remains in elevated limestone areas supports the hypothesis that geology influenced habitation choices. However, further research is needed to confirm these patterns, particularly in areas affected by erosion and modern land use. Increased survey efforts are essential to preserve and document archaeological evidence before it is lost. Understanding the geological factors that influenced human settlement in this region can contribute to broader studies of environmental and cultural history in coastal Mediterranean landscapes.

Acknowledgements

Rel thank Dr. G. Malaperdas, Environmentalist Cartographer – Land Surveyor – GIS & R.S. Analyst – Geoinformatics and Earth Studies, for his invaluable assistance with GIS mapping. I also thank E. Zymi, Associate Professor of Classical Archaeology at the Department of History, Archaeology and Cultural Resources Management at the University of Peloponnese, for her invaluable support with the archaeological part of my research and Dr. K. Theodorakopoulou, specializing in geoarchaeology and the use of archaeometric techniques, for her crucial help with the geological part. The first to assist me, N. Zacharias, Professor of Archaeometry, Environmental and Cultural Technology, sadly passed away before the completion of my research.He will be remembered as a distinguished scientist and professor. I am honored to conduct and present this research, as he greatly supported me throughout this endeavor.

EXTENDED ABSTRACT 122

The influence of DSMs spatial resolution on rockfall simulation.

Kakavas M.[1], Kyriou A.[1], Nikolakopoulos K.[1], Koukouvelas I. [1]

(1) University of Patras, Department of Geology, Patra, Greece, kakava.maria@upatras.gr

Abstract

Rockfalls are dynamic geological events characterized by the sudden detachment and descent of rock fragments from steep slopes. These events vary greatly in scale, velocity, and trajectory, influenced by factors such as slope geology, topography, and environmental conditions. This study examines rockfall hazards in Platiana, Greece, using simulation tools— RocFall 4.0, QProto, and HY-STONE. By applying Digital Surface Models (DSMs) with spatial resolutions ranging from centimeters to meters, the study demonstrates that higher-resolution DSMs more accurately simulate rockfall trajectories, velocities, and energy distributions. Coarse-resolution DSMs, however, tend to overestimate rockfall runout and simplify topography. The findings highlight the importance of selecting high-resolution DSMs for reliable hazard assessments.

Introduction

Rockfalls are natural phenomena where rock fragments abruptly detach and freefall from steep slopes, posing significant natural hazards in mountainous and hilly areas (Dorren, 2003; Wu et al., 2025). These phenomena exhibit considerable scale variability, velocity, and trajectory, influenced by factors such as the slope's geological composition, topography, and other environmental conditions (Hungr et al., 1999; Guzzetti et al., 2002; Borella et al., 2019). The unpredictable nature of rockfalls makes their risk assessment and mitigation a challenging task, especially in regions with steep and unstable terrains (Fell et al., 2008). To predict and manage rockfall hazards effectively, researchers employ advanced modelling techniques that integrate terrain analysis and remote sensing data, helping to estimate potential impact zones and identify areas at risk of rockfall events (Jaboyedoff et al., 2005). Digital Elevation Models (DEMs) are essential tools in rockfall hazard assessment, as they provide topographical data critical for simulating rockfall behaviour. DEMs allow the extraction of slope parameters that influence rockfall dynamics, including slope angle, roughness, and vegetation cover. The resolution of these models plays a pivotal role in the accuracy of rockfall simulations. Lower-resolution DEMs tend to oversimplify the terrain's features, leading to inaccurate predictions of rockfall trajectories and energy distribution (Keijsers et al., 2011). Alternatively, higher-resolution DEMs capture fine terrain details, improving the precision of simulations and offering more reliable hazard assessments (Pradhan et al., 2017; Kakavas et al., 2021; Kakavas et al., 2024). Consequently, rockfall simulation software incorporates DEMs of varying spatial resolutions to meet different analytical needs with finer-resolution models, typically producing more detailed and accurate results (Acosta et al., 2002; Baillifard et al., 2003; Kakavas et al., 2023). The scope of this study is to examine the influence of DEM resolution on rockfall simulations in Platiana, Greece, via RocFall 4.0, QProto, and HY-STONE software. The aim is to highlight the importance of DEM resolution in improving hazard predictions.

Study Area

Platiana is a village located in the Ilia prefecture of Peloponnese, Greece (Figure 1). The surrounding area is primarily composed of Upper Cretaceous limestones, as indicated by the engineering geological map of Greece, and is part of the Pindos geotectonic unit according to the Hellenic Survey of Geology & Mineral Exploration (HSGME) (Figure 2). This region is a segment of the broader Pindos Unit that has been thrust westward. Near the settlement, there are significant outcrops of limestone with varying thicknesses from thin to medium layers. According to Vagenas (2020), these limestone layers are locally intercalated with chert layers. Platiana experienced the devastating wildfires of 2007 and has been declared reforesting land over the past years. Following the natural reforestation, the vegetation levels have been fully recovered. However, from 2008 to 2018, the mountain slopes adjacent to Platiana were completely barren (Figure 1). Similar to other cases, the lack of vegetation exposed the slopes to corrosion factors that compromised their structural integrity and triggered the release of internal stresses. As a result, rocks of various sizes became detached from the main rock body and sliding, toppling or falling and proceeding downslope. Notably, on December 4, 2018, after heavy rainfall, a massive boulder approximately 10m³ in volume slid down the slope. Fortunately, it came to a stop in a churchyard, causing no casualties. During its down-ward course, the boulder penetrated two gabion retaining wall that served to protect the Platiana village (Figure 1). It is important to mention that, the rockfall simulations using pre-2018 DEMs (ALOS AW3D30, ASTER GDEM, SRTM30, SRTM90, and TanDEM_X), which capture the barren mountain slopes, demonstrated higher kinetic velocities, whereas those based on post-2018 DSMs (UAV, Greek Cadastral, and Ministry of Agriculture), reflecting restored vegetation, yielded lower kinetic energies.

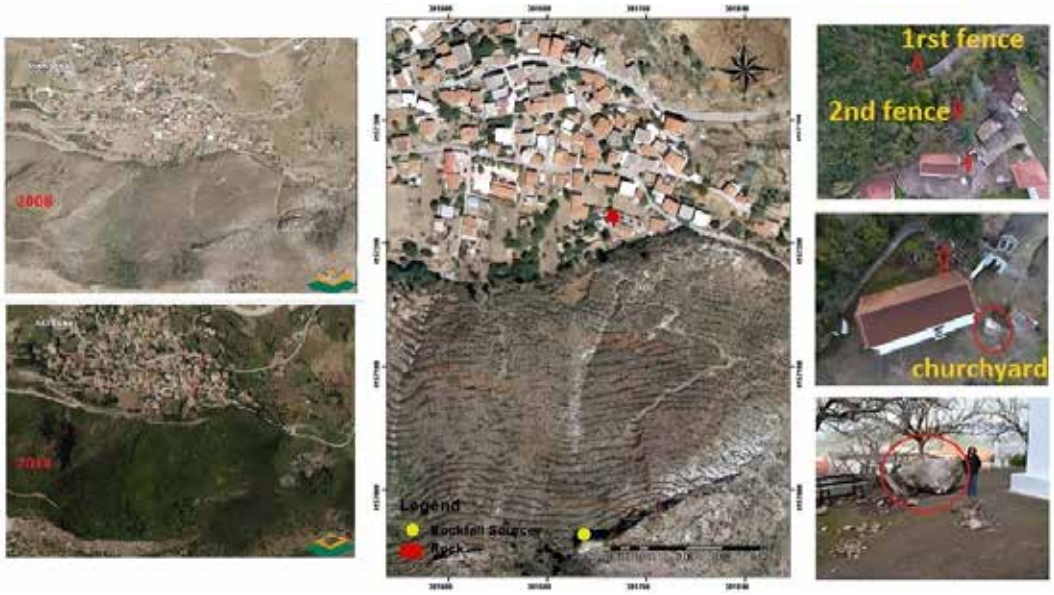

Figure 1. The images on the left (from Greek Cadastral, 2008) and below (2018) illustrate the natural reforestation of the slope adjacent to the Platiana village. The central map indicates both the rockfall source (yellow circle) and the boulder's final point (red circle). On the right, photographs show the aftermath of the rockfall event, including fence damage and the boulder in the churchyard.

Processing Tools

For this study, three rockfall simulation software were used. The first is RocFall 4.0 from Rocscience, which is a two-dimensional rockfall modeling tool for steep slopes. The detection of rockfall susceptibility is achieved through a lumped mass statistical analysis. This software comprises the collision theory and Newton's laws of motion, so as to simulate the path of the rolling rock mass/boulder (Rocscience, 2002). RocFall software calculates four parameters for the entire slope, including the final position of the rock, bounce height and velocity, as well as energies. The second software is QProto, which is an open-source geographic software and consists a plugin in the QGIS environment

(Castelli et al., 2021). GRASS GIS 7 is the base of this plugin as it optimizes for performance and large geospatial data analysis by offering powerful raster, vector, and geospatial processing engines in a single integrated software suite. It comes with a temporal framework for advanced time series processing and a Python API for rapid geospatial programming (Toma et al., 2021). The third software is HY-STONE which is a software developed for 3D numerical modeling of rockfall processes, including the simulation of the motion of non-interacting blocks, utilizing a high-resolution 3D description of slope geometry for accurate multiscale stochastic modeling (Crosta et al., 2004; Frattini et al., 2008; Agliardi et al., 2009). It is capable of modeling free fall, impact, and rolling of blocks, with energy loss simulations at impacts or by rolling based on a hybrid (cinematic and dynamic) approach.

Rockfall Simulation

For examining Platiana's rockfall phenomenon, slope profiles were selected and extracted from eight different resolution DSMs (Figure 3), aiming at simulations via RocFall, Qproto and HY-STONE software: one 5 cm spatial resolution DSM created by UAV data, one 5 m DSM from the Greek Cadastral, one 20 m DSM from the Ministry of Agriculture, three 30 m resolution DEMs (ALOS AW3D30 DEM, ASTER GDEM and SRTM30 DEM) and two 90 m cell size DEMs (SRTM90 DEM and TanDEM_X). The two barriers, drystone fences, were taken into account in software settings, as well as geological and material characteristics of the slope profiles. In situ surveys and literature data were accomplished (Figure 1) (Depountis et al., 2010; Sabatakakis et al., 2015; Vagenas, 2020).

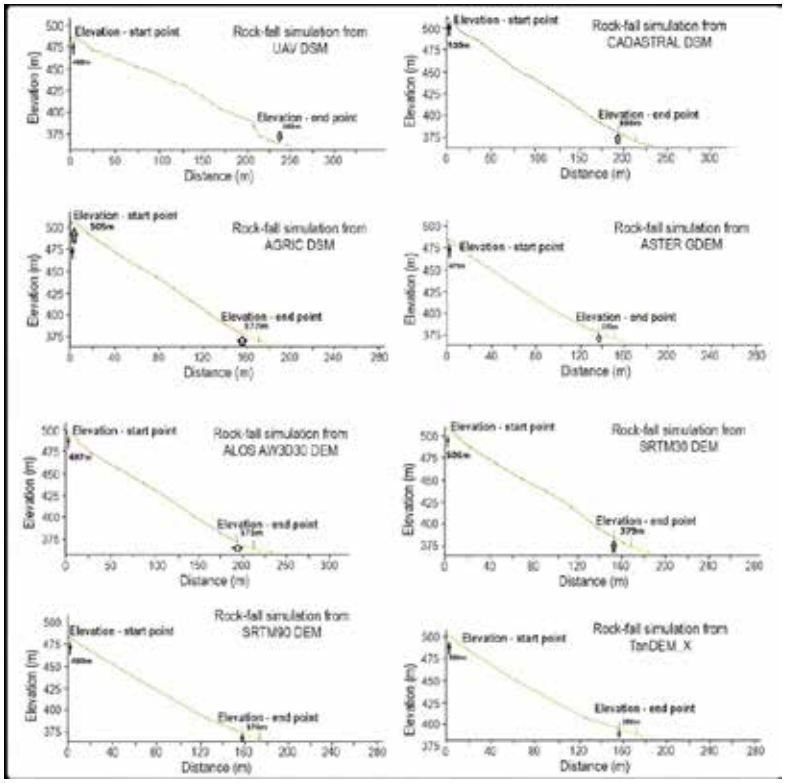

Figure 3. Two-dimensional rockfall simulations via RocFall software for the 2nd slope profile.

According to the figures above, only the UAV DSM created a detailed slope profile, with steep slopes and smooth areas. The other DSMs tended to flatten the topography. The rock in the UAV DSM slope profile jumped the first barrier/fence and broke the second barrier/fence. This result, in comparison with the field observations, is reliable, as the rock stopped a few meters before the end of the slope, in the churchyard (Figure 1). In the DSM from the Greek Cadastral, DSM from the Ministry of Agriculture, ALOS AW3D30 DEM, ASTER GDEM, SRTM30 DEM, SRTM90 DEM and TanDEM_X slope profiles, the rock rolled and stopped in the first barrier/fence. This is in contrast to the real trajectory. Therefore, only the UAV DSM simulated a trajectory close to the real.
