Highlights

Coupled to magmatic degassing of metal (loid)- and volatile-rich fluids, boiling, and fluid-seawater mixing mechanisms are responsible for Sb hyper-enrichment in the Kolumbo SMS mineralization. Our results raise the possibility of (sub) seafloor Sb-rich mineralization at Kolumbo and other submarine volcanoes along the 500 km of the Hellenic Volcanic Arc.

Introduction / Background

Antimony (Sb) is a metalloid of Critical Raw Materials (CRMs) that are both of great economic importance for the EU and of high supply risk (European Commission, 2023). Therefore, its sustainable supply greatly depends on understanding the Sb-ore precipitation mechanisms, especially stibnite (Sb_2S_3), the worldwide major source of Sb. A target setting to secure sustainable access to CRMs, including Sb and related metal(loid)s (Au, Ag, Ga, Ge, Te), is sea-floor massive sulfide (SMS) deposits worldwide. Recent advances in understanding Sb solubility and transportation in hydrothermal ore-fluids on land, showed mainly aqueous species of thioantimonite ($H_2Sb_2S_4$) and hydroxothioantimonite [$Sb_2S_2(OH)_2$], while vein-type stibnite precipitation was controlled by: boiling-related solubility reduction of $H_2Sb_2S_4$, and subsequent cooling-induced solubility decrease of $Sb_2S_2(OH)_2$ (Yu *et al*., 2023). Recently, Kodera *et al.* (2024), and Kaufmann *et al.* (2024), have suggested that hydrothermal fluid temperature decrease has been the main mechanism for stibnite precipitation in vein-type epithermal deposits on land (Slovakia). However, whether these phenomena can cause Sb mineralization (i.e., stibnite and Sb-bearing sulfosalts) in submarine hydrothermal systems, remains incompletely known. To our knowledge only Dekov *et al*. (2022) have dealt with the physicochemical conditions of stibnite precipitation at the Daiyon-Yonaguni Knoll (Okinawa Trough) hydrothermal barite deposits, and suggested that precipitation at ~80◦C, low $\log_{10}a$ of $Sb_2S_4^{2-}$ and Eh<0), from sub-seafloor phase separated fluids. Driven by the scarce knowledge on Sb enrichment (i.e., stibnite, Sb-sulfosalts) processes at seafloor hydrothermal conditions, we investigated the Sb-rich, polymetallic, SMS mineralization of modern CO_2-degassing, SMS diffuser vents, of Kolumbo submarine volcano, Hellenic volcanic arc [hereafter "Kolumbo CO_2 diffusers" ("KCO_2Ds")]. These rare actively forming Sb- and Au-rich polymetallic (As, Ag, Tl, Pb, Zn, Hg) SMS SMS deposits comprising pyrite, marcasite, sphalerite, chalcopyrite, galena, Pb-Sb sulfosalts, stibnite, orpiment/realgar and barite (Kilias *et al*., 2013). The KCO_2Ds display a distinct mineral zonation, grading from a pyrite-dominated, barite-polymetallic sulfide inner part (ISSC), through a thin sphalerite-dominated sulfide zone, to a barite-sulfide outer layer, and finally to an orpiment-dominated exterior (OAsL) locally covered by $Fe3^+$-(hydrated)-oxyhydroxides (SFeC) (Kilias *et al*. 2013). Importantly, pyrite occurs erratically within, and throughout, the KCO_2Ds, and occurs as compositionally zoned colloform pyrite 1 (Py1) that is overgrown by aggregated anhedral pyrite 2 (Py2), and coarse-grained euhedral pyrite 3 (Py3) (see Fig. 1 and Kilias *et al*., 2022). Samples came from KCO_2Ds that vent nearly pure CO_2 boiling fluids at 265°C (Kilias *et al*., 2013; Zegkinoglou *et al*., 2023). Hence, the Kolumbo system represents an optimum natural laboratory to decipher the effect of boiling and cooling due to fluid-seawater mixing, on stibnite composition, and Sb hyper-enrichment associated with SMS mineralization.

Materials and Methods

- **Sampling**

Sulfide samples were retrieved with Remotely Operated Vehicles (ROVs) from the northern part of the Kolumbo crater. Detailed descriptions on sampling and preparation methods are presented in Kilias *et al*. (2013) and in HCMR's "SeaBioTech Report 2013".

- **Optical microscopy and Mineral Analyses**

All samples were petrographically examined via transmitted and reflected light microscopy. The quantitative analyses of the main sulfide-sulfosalt phases were conducted by Energy Dispersive Spectroscopy (EPMA-EDS) using a JEOL JXA-8600 Superprobe. The S contents were determined by EPMA analysis. Trace element analysis was performed by laser ablation-inductively coupled plasma-mass spectrometry (LA-ICP-MS) using a New Wave Research-ESI 213 nm laser unit attached to a ThermoScientific ICAP-Q quadrupole ICP-MS. Analytical precision and accuracy were monitored by the repeated analysis of FeS-1 and MASS-1 (United States Geological Survey-USGS). Trace element concentrations were processed by the Iolite software package (https://iolite-software.com).

- **Raman spectroscopy**

Raman spectroscopy was performed using a Renishaw inVia Raman confocal microscope. Spectra were obtained using the 785 nm laser and a grating of 1200 groves per mm, with a power range between 0.5 and 0.05 mW, due to the varying stability and fluorescence of the analysis spots. Samples were exposed to the laser through a long-focal distance, 50X objective lens with 0.55 numerical aperture, and with the measured spectral range extended from 100 to 3200 cm-1. The obtained spectra were then processed by the WiRE software for Windows. Background noise was reduced by the subtraction of a polynomial baseline, and cosmic ray removal corrections were performed for all spectra.

- **Synchrotron X-ray fluorescence (μ-XRF)**

Polished thin sections of selected representative samples were analyzed using scanning μ-XRF at the Nanoscopium hard X-ray CX3-scanning spectromicroscopy beamline of Synchrotron Soleil (France). A monochromatic X-ray beam, with an energy range of 11.8–20 keV, was focused on the sample area using a Kirkpatrick–Baez nano-focusing mirror. To achieve micrometer resolution in elemental mapping of mm²-sized sample areas, the fast-continuous scanning (FLYSCAN) technique was employed.

Results

- **Mineralogy, textures and paragenesis of stibnite (Sb_2S_3) and Sb-sulfosalts**

Antimony phases include thin, needle-like stibnite crystals mainly in the OBL (Fig. 1A) and OAsL and individual Sb-bearing sulfosalt phases, such as semseyite and meneghinite, throughout the KCO_2Ds (see below and Kilias *et al*., 2022). Sb-bearing sulfosalts, relatively abundant in the ISSC, mostly occur as dendritic fishbone-like crystals (Figs. 1B, C), as intergrowths with barite rimming pyrite successions (Fig. 1D), and as overgrowths on Py1 (Fig. 1E). Sb-bearing sulfosalts may also occur as colloform-like phases (Fig. 1F) rimming As-sulphides, such as orpiment. Replacement of Sb-bearing sulfosalts by orpiment has also been observed, resulting in a porous and inclusion-rich (Pb-Sb sus) As-sulphide. The As-sulfide overgrowth precipitates from hydrothermal solution, indicating boiling-induced Coupled Dissolution Reprecipitation (CDR) processes (Fig. 1G). Moreover, a progressive transition of Pb-Sb sulfosalts to orpiment-like As-sulfides resembling frutexites-like microstomatolites with branching and outgrowths formed by cyclic growth has also been detected. The alternating banding consists of Pb-Sb sulfosalts progressively transitioning to orpiment-like As-sulphides (Fig. 1H). Rare stibnite occurs as independent needle-like crystals in open space, as inclusions in prismatic barite, or as intergrowths with Pb-Sb sulfosalts and orpiment of the OAsL (Figs. 1I, J, K respectively). Stibnite has also been found as a tube-like core in orpiment filamentous structures (Fig. 1L).

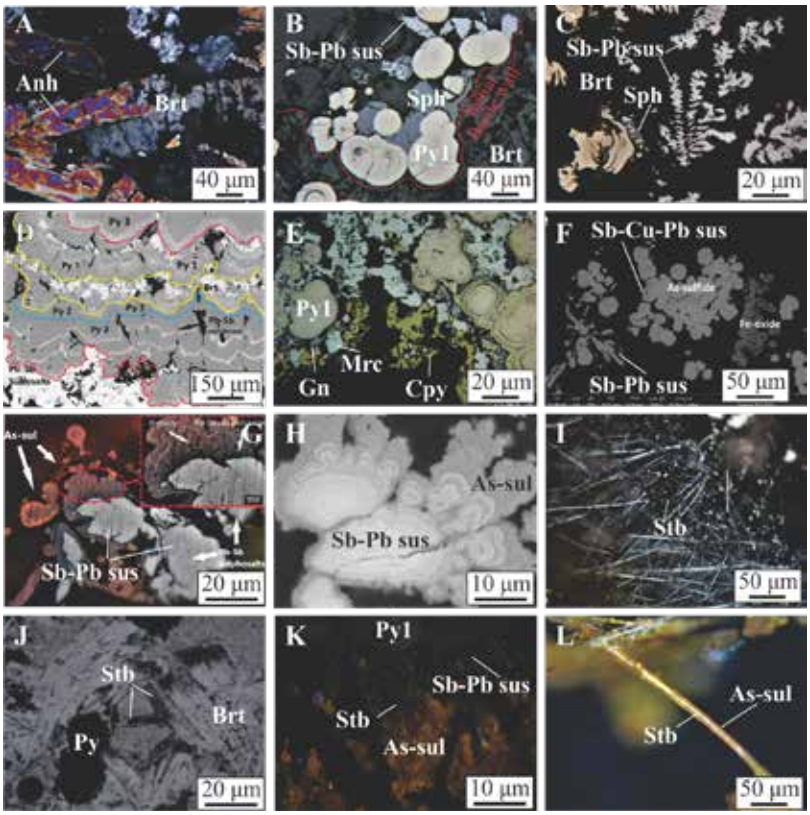

Figure 1. Reflected photomicrographs (A, B, C, F, I, G, K, L) and BSE images (D, G, H), showing textural features of stibnite, semseyite and meneghinite and other KCO2Ds minerals. (A) Replacement of anhydrite (Anh) by barite. (Brt) Colloform Py1 intergrown with sphalerite (Sph) and semseyire (Pb-Sb sus) on pore space of the barite "mound". (C) Dendritic texture of semseyite, with pyrite and sphalerite on barite substrate. (D) Repeated cycles (separated by colored dotted lines) of successive and subparallel colloform-crustiform micronscale bands of Py1, 2, and 3, interbanded with barite; semseyite is intergrown with barite (lower left). (E) Chalcopyrite lining channel edge, with marcasite, galena and Py1; (F) Colloform meneghinite (Sb-Cu-Pb sus) intergrown with As-sulfides, associated with semseyite and Fe oxyhydroxides. (G) Semseyite (Pb-Sb sus) sulfosalt partially replaced by orpiment (As-sul) with trace metal(loid)-rich Pb-Sb sulfosalt inclusions, indicating CDR processes; (H) Frutexites-like stromatolitic structure showing a CDR reaction of fine Pb-Sb sulfosalt laminae alternating with, and gradually replaced by As-sulfide laminae. (I) Needle-like, radiating stibnite (Stb) crystals, filling cavities and covering barite surface. (J) Radial and random needle-like stibnite crystals within transparent crystals of barite; (K) Intergrowth of barite, pyrite 1, semseyite (Sb-Pb sus), stibnite (Stb) and orpiment (As-sul). (L) Core-shell filamentous structure including core of stibnite and shell of orpiment.

- **Spectral characterization of Sb-bearing phases**

The majority of the obtained Raman spectra indicate that the dominant Sb-bearing phases in the KCO_2Ds are stibnite (Sb_2S_3) and semseyite ($Pb_9Sb_8S_{21}$). Stibnite exhibits sharp, characteristic Raman peaks, with decreasing intensity, at 312, 283, 240, 192, 156 and 129 cm^{-1}. Semseyite, presents a dominant Raman peak at 217 cm-1, with a broad shoulder at 176 cm^{-1}. Raman peaks of lesser intensity are present at 335, and 120 cm^{-1}. A less abundant, Sb-bearing sulfosalt that has been identified through Raman spectroscopy is meneghinite ($Pb_{13}CuSb_7S_{24}$), presenting a dominant Raman peak at 212 cm^{-1} with a shouldering peak at 248 cm^{-1}, and a secondary but intense peak at 328 cm^{-1}.

- **Mineral chemistry and Sb enrichment (LA-ICP-MS)**

LA-ICP-MS spot analyses show a unique enrichment in Sb in all the mineral phases present at the KCO_2Ds (Fig. 2). Galena exhibits a strong Sb enrichment with maximum concentration of 98000 ppm. Py1 is the most common sulfide mineral in the system and displays high Sb concentrations, up to 111192 ppm. The concentration of Sb in Py2 reaches up to 36100 ppm, whereas Py3 is the most depleted generation of pyrite, with maximum concentration of 79000. Sphalerite is also highly enriched in Sb concentration, reaching up to 98000 ppm. Marcasite and chalcopyrite are moderately enriched in Sb ranging up to 7730 ppm, and 16100 ppm, respectively. Lastly, the Sb concentration in orpiment is measured up to 16100 ppm.

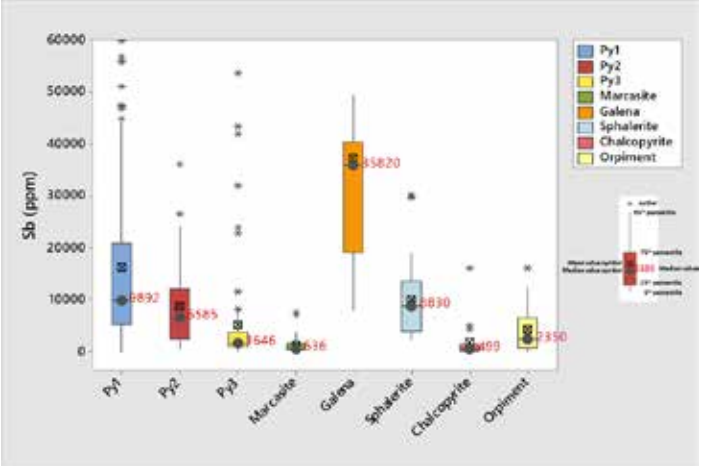

Figure 2. Box and whisker plots of Sb concentration in sulfide minerals present at the KCO2Ds analyzed by LA-ICP-MS. Mean values (black squares) are calculated using the entire dataset (including outliers), and might plot outside the respective box, whereas median values (gray dots, red numbers) are based solely on data within the box (25th to 75th percentile).

To better understand the sequestration of trace metals and especially Sb, in the main mineral phases, LA-ICP-MS depth profiles were thoroughly examined. The smooth parts of LA-ICP-MS time resolved spectra indicate structurally bound metal(loid)s while the irregular and spiky parts of the profiles signify the presence of micro/nanoparticles in the structure (George *et al*., 2019). The LA-ICP-MS depth profiles in stibnite display irregular parts for most trace elements (Zn, Ag, Au, Tl) implying that these elements are incorporated as nanoparticles in the structure of stibnite (Fig. 3A, 3B). The depth profiles for Sb in pyrite exhibit both smooth and spiky parts indicating that Sb precipitates both as nanoparticles along with other metal(loid)s and as lattice bounded in the structure of pyrite (Fig. 3C). Pb-Sb sulfosalts depth profiles appear spiky with respect to As, Cu, Ag, Zn and Au suggesting the incorporation of those metal(loid)s as inclusions (Fig. 3D).

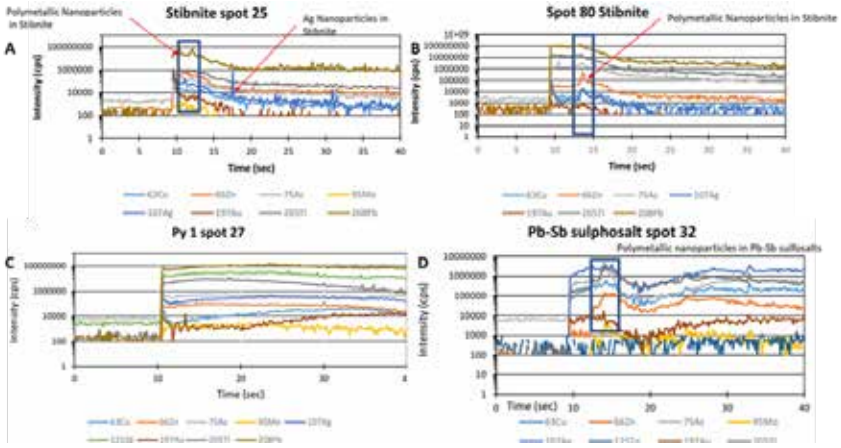

Figure 3. Time resolved spectra of metal(loid)s in pyrite and stibnite. A., B. LA-ICP-MS irregular depth profiles in stibnite. Note the presence of spikes in the same wavenumber for different trace elements, indicating the existence of polymetallic inclusions in stibnite. C. Smooth Sb LA-ICP-MS depth profile in Py1, signifying the sequestration of antimony in solid solution. D. Spiky depth profiles in Pb-Sb sulfosalts exhibiting polymetallic inclusions.

- **Synchrotron X□ray fluorescence (μ□XRF)**

Multi-scale length elemental maps on Py1 demonstrate that metal(loids) do not exhibit a homogeneous distribution, but rather a concentric chemical zoning. Elements such as Fe and Pb exhibit oscillatory chemical zoning at the inner part of the pyrite (Fig. 4A, E), whereas Zn, Cu, and As tend to enrich the outer zones of the crystal (Fig. 4B, C, F). Antimony, on the other hand (Fig. 4D) demonstrates oscillatory zoning rimwards. Core-to-rim traverse on Py1 indicates that the Sb, Pb and Tl concentrations have been affected predominately by boiling processes (Fig, 5A). The spatial distribution of Sb/Pb ratios with values less than 0.5, which are characteristic of boiling-induced precipitation (Falkenberg *et al*.,

2021) demonstrate an alternation of boiling-dominated, and likely seawater mixing-dominated regions (Fig. 5B), that coincide with the oscillatory chemical zoning of Sb (Fig, 4D).

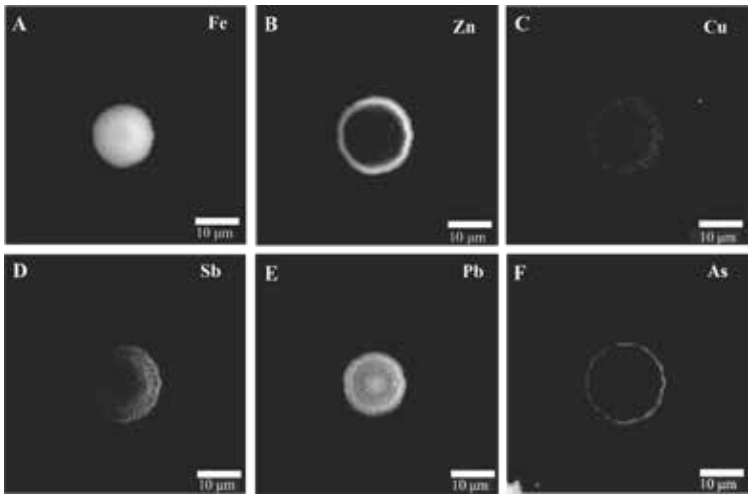

Figure 4. Synchrotron μ-XRF elemental maps of spheroidal pyrite from KCO_2Ds, illustrating the spatial distribution patterns of A) Fe, B) Zn, C) Cu, D) Sb, E) Pb, F) As.

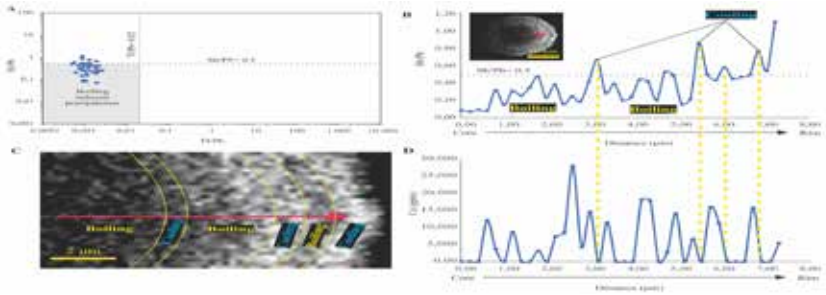

Figure 5. Synchrotron-obtained data from Py1 showing: (A) Sb/Pb vs. Tl/Pb (modified from Falkenberg et al., 2021) demonstrating boiling-induced precipitation, (B) a core-to-rim traverse in Py1 showing the alternation of boiling-dominated and likely non-boiling or fluid-seawater mixing (cooling) dominated regions

Discussion and Conclusions

Kolumbo is a submarine arc volcano that hosts a complex and dynamic magmatic-hydrothermal system with constantly evolving fluid chemistry through space and time (Zegkinoglou *et al.*, 2023; Patten *et al.*, 2024; Hector *et al.*, 2024. Geochemical and micro-textural evidence shows that the Kolumbo SMS mineralization has been formed by fluids undergoing multiple recurrent intense boiling and/or flashing or gentle and/or non-boiling events (Fig. 5); moreover, the high contents of Sb, along with As, Hg, and Tl in the KCO_2 Ds (Figs. 2 and 3) support boiling and zone refining processes, as these metal(loid)s are easily mobilized in the vapor phase (see Zegkinoglou *et al.*, 2023). The Kolumbo pyrite has recorded critical information related to boiling vs. non-boiling: The features displayed by Py1(±Py2) that occurs erratically distributed within the KCO_2Ds, reflect multiple episodes of vigorous boiling to flashing, whereas Py2 that occurs mostly in the inner KCO_2D parts, it is spatially concurrent with chalcopyrite lining narrow channels (Fig. 1E), has features that suggest precipitation from hot (>250°C) gently boiling to non-boiling fluids (Zegkinoglou *et al.*, 2023). Thus, pyrite can provide key information for the interpretation of associated Sb mineralization (stibnite, semseyite and meneghinite) forming conditions, and conditions of Sb incorporation in pyrite, during the 3-stage KCO_2Ds growth model (Berkenbosch *et al.*, 2012; Zegkinoglou *et al.*, 2023; Roman *et al.*, 2019; Falkenberg *et al.*, 2021). Vigorous boiling events have coincided with periods of intense magmatic degassing of volatiles and metal(loid)s (i.e., Cu, Au, Sb), and increase of the proportion of magmatic fluids into the Kolumbo hydrothermal system. In addition, the evolving Kolumbo magmatic-hydrothermal system could include periods of magmatic quiescence that results in a seawater-dominated hydrothermal fluid (Zegkinoglou *et al.*, 2023; Hector *et al.*, 2024).

At Kolumbo, textural (Fig. 1) and chemical variations of multiple pyrite (colloform, microcrystalline, crustiform banding, euhedral), chalcopyrite (linings), Pb-Sb sulfosalt (semseyite, meneghinite) (dendrites, colloform and subhedral crystals)

generations, are indicative for sulfide-sulfosalt precipitation during repeated cycles of progression from a young low-temperature <150–200°C) seawater-dominated, to a more "refined" system with a higher temperature (up to 300-350°C) upwelling of phase separated liquid-, or vapor-, dominated fluid flux and less seawater mixing (Falkenberg *et al.*, 2021). The close association of dendritic semseyite ($Pb_9Sb_8S_{21}$) (Fig. 1C), with adjacent concentrically layered colloform Py1, and anhedral sphalerite, occupying pore space of the Stage 1 barite substrate (Fig. 1B), suggests an early semseyite formation due to rapid precipitation and undercooling at temperatures <150–200°C, due to mixing of upwelling boiling, liquid- or vapor-dominated fluids, with seawater, in seawater-dominated inner KCO_2Ds (ISSC) zones (Berkenbosch *et al*., 2012; Falkenberg *et al*., 2021). In addition, semseyite that is interbanded with barite layers associated with colloform-crustiform banded Py1 (Fig. 1D), suggests that semseyite was synchronous with the development of barite and Py banding, and resulted from rapid precipitation due to boiled off hydrothermal fluid-seawater mixing-cooling cycles (Berkenbosch *et al*., 2012; Roman *et al*., 2019). Similarly, semseyite associated with orpiment [highly enriched in Sb (≤1.23 wt%)-unpublished data)] (Fig. 1F,G,H), on the outer chimney wall (OBL, OAsL), indicates a genetic linkage to low-temperature (≤100 °C) As and Sb-rich boiled off vapor input and vapor-seawater mixing (Dekov *et al*., 2013). The replacement and recrystallization of massive, or stromatolite-like, semseyite to colloform As-sulfides (i.e., orpiment) (Figs. 1G, H) probably represent a low-temperature (100 to 150°C) overprint and coupled dissolution and reprecipitation (CDR) processes based on zone refining (Berkenbosch *et al*., 2012; Falkenberg *et al*., 2021).

The trace element incorporation mechanisms in the Kolumbo stibnite, semseyite, and pyrite, also depends on variable degrees of fluid-seawater mixing and fluid boiling precipitation. For example, intensity spikes in time-integrated LA-ICP-MS spectra (Fig. 3D) are likely related to microscale polymetallic inclusions in stibnite and semseyite (Fig. 3A,B). Such inclusions may well reflect hydrothermal fluid supersaturation in Cu, Ag, Sb, and Pb, caused either by abrupt cooling because of abundant fluid-seawater mixing, or boiling that caused destabilization of metal(loid) complexes (Falkenberg *et al.*, 2021). These notions are supported by chemically zoned Py1 spheroids that exhibit low Sb/Pb and Tl/Pb ratios, and decoupled zoning between trace metal(loids), indicating boiling-induced precipitation (Fig. 5A). In this paper, we have documented that additional to magmatic volatile degassing, boiling- and seawater mixing-induced processes, may be responsible for hyper-enrichment of Sb in the Kolumbo SMS mineralization.

V_{S30} Estimation from P-Wave Seismograms: Exploring a Frequency-Domain Approach for Stations Located in Sedimentary Basins

Pappa E[1]., Papazachos C[1]., Chatzis N[1].

[1]*Geophysical Laboratory, Aristotle University of Thessaloniki, P.O. Box 352-1, GR-54124, Thessaloniki, GREECE*

Introduction

Earthquakes are natural phenomena, often with significant impacts on the human infrastructure. Understanding the factors that influence seismic motion at a specific location is crucial for reducing earthquake risk. These factors include the earthquake source (e.g., magnitude and rupture mechanism), the propagation path (e.g., geometrical spreading and anelastic attenuation), as well as local site effects.

The later factor, local site effects, can play a critical role, as they can amplify seismic motion and significantly influence the level of ground shaking. One of the most common approaches to assess local site effects involves calculating the time-averaged shear wave velocity down to 30 meters, V_{S30}, (e.g., EN1998-1, NEHRP97, etc.). However, reliably estimating V_{S30} is not always straightforward. Traditional methods such as borehole drilling, or geophysical measurements, including refraction, MASW (Multichannel Analysis of Surface Waves), and microtremor measurements (e.g., Chatzis et al., 2018, Chatzis et al., 2022), require significant time, human resources, and funding. Meanwhile, proxy methods, like those based on slope or terrain (e.g., Wald and Allen, 1997) often introduce significant errors. This highlights the need for simple, cost-effective, and reliable methodologies.

Ni et al. (2014) proposed a promising approach, the P-wave seismogram method, to estimate the time-averaged shear wave velocity down to a depth z (V_{SZ}) at a station's location using seismic records. This methodology has been extensively validated using small to moderate magnitude earthquakes (**M**2–4) across various regions, including Central and Eastern North America (Kim et al., 2016), Texas, Oklahoma, and Kansas (Zalachoris et al., 2017), California (Li and Rathje, 2023), Japan (Miao et al., 2018, Kang et al., 2020), and Korea (Kim et al., 2020). It has also been applied to larger earthquakes (**M**4.0–5.5) near the Anchorage Basin in Alaska (Skarlatoudis et al., 2022) and microearthquakes ($-1.1 \leq M_L \leq 1.7$) in the Pohang Basin, South Korea (Lee et al., 2022). In all cases, the method demonstrated a good correlation between estimated and reference (*in situ*) V_{S30} values, verifying its potential as a reliable tool.

Greece, one of Europe's most seismically active countries, has a dense seismic network covering both inhabited and remote areas. However, reliable V_{S30} data is unavailable for many of the stations' locations, making it a critical area of study. Pappa et al. (2025) applied the P-wave seismogram method to two accelerometric arrays in Greece and found a strong correlation with reference values, after employing a standard bandpass filter (0.2–40 Hz) and making appropriate corrections for the effect of the ray parameter and earthquake magnitude on V_{SZ}. In this study, we applied the same methodology to test its applicability at seven stations, those with the most extensive datasets, from the arrays already used by Pappa et al. (2025). However, we deliberately chose not to apply the bandpass filter to assess whether the method performs reliably without it. Our findings revealed that the results were not satisfactory, with all stations showing a bias with respect to reference values, typically exceeding 50%, especially in basin areas (low V_{S30} sites). To address this issue, we explored an alternative approach, by considering the same data in the frequency domain instead of the time domain. This modification significantly reduced the method errors, offering a potential pathway to improve the reliability of the P-wave seismogram method in estimating V_{S30} values for noisy sites, especially for stations located in basin sites.

The P-wave seismogram Method and its Frequency Domain Adapting

Most earthquakes originate within the crust, where seismic waves travel with relatively high velocities. In contrast, seismic stations are often located on near surface, lower-velocity media. Due to Snell's law, the incident angle of incoming P and SV waves at the free surface is smaller than their takeoff angle at the source. This phenomenon results in a stronger P wave on the vertical component and a weaker P wave on the radial component (Figure 1a). The softer the medium, the weaker the P wave contribution to the radial component. Consequently, the ratio of the radial to vertical component amplitudes increases as the soil becomes stiffer. Conversely, the SV reflections from an surface impinging P-wave are generally stronger on the radial component, even in softer sites, as the SV polarization is perpendicular to the ray path. Theoretical arguments (Aki and Richards, 2002; Ni et al., 2014) have shown that the amplitude ratio of the radial (U_R) to vertical (U_Z) components of the incident P wave is reliable indicator of the near surface shear-wave velocity (Vs):

$$\frac{U_R}{U_Z} = \frac{-2V_S\, p\, cosj U_R}{1-2p^2{V_S}^2\, U_Z} = \frac{-2V_S\, p\, cosj}{1-2p^2{V_S}^2} \quad (1)$$

Where, p, is the ray parameter for plane waves:

$$p = \frac{sinj}{V_S} \left(= \frac{sini}{V_P}\right) \quad (2)$$

By combining equations (1) and (2) to eliminate the angle j, the time-averaged shear wave velocity down to a depth z, V_{SZ}, can be estimated as a function of U_R/U_Z and p (Li et al. 2014):

$$V_{SZ} = \frac{1}{\sqrt{2}p}\left[1 - \left(\frac{1}{1+(\frac{U_R}{U_Z})^2}\right)^{\frac{1}{2}}\right]^{\frac{1}{2}} \quad (3)$$

The depth z to which the estimated V_{SZ} corresponds is roughly equal to the dominant wavelength of the S-wave:

$$z = \tau_p V_{SZ}^{Pseis} \quad (4)$$

where τ_p is the duration of the source time function, e.g. duration of the P-wave pulse.

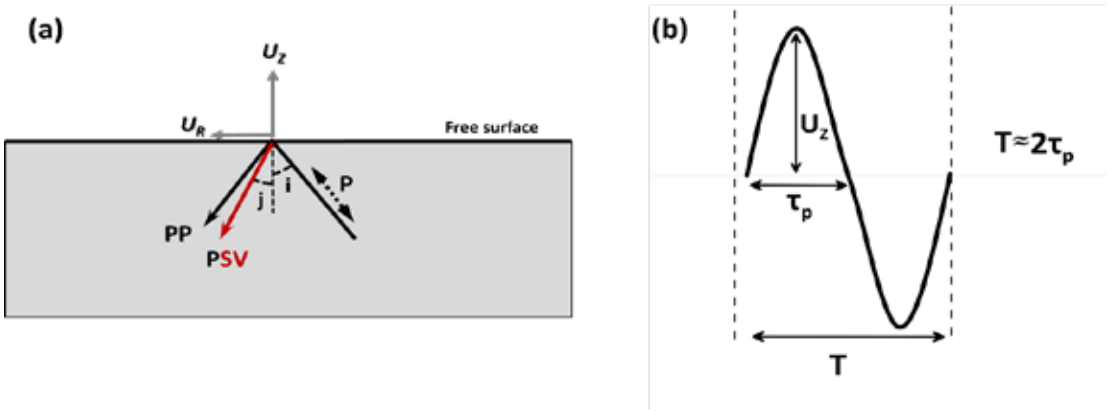

Figure 1. (a) Interaction between an incident P wave and a free surface. The vertical and horizontal components of the P wave result from the superposition of the incident P wave, the reflected P wave, and the S wave generated at the free surface. (b) Schematic representation of a simplified single wave time series, illustrating the source time function (τ_p), the period (T), and their durations.

The application of Fast Fourier Transform (FFT) analysis for the U_R/U_Z estimation section offers several advantages over traditional time-domain analysis, allowing for a more detailed investigation of signal characteristics. In the frequency domain, a signal is represented by independent frequency components, whereas in the time domain, the signal is described by a single waveform that contains the sum of all frequency-dependent contributions.
Figure (1b) presents a schematic first P wave pulse. The source time function used in equation (4) corresponds to the duration of the first pulse, τ_P. If we consider that this waveform is dominated by a characteristic frequency, the duration of this wavetrain should correspond to this dominant wave period. Thus, the period of the first P wave should be approximately twice the source time function, τ_P. The Discrete Fourier Transform (DFT) of the signal shown in Fig.1b includes a minimum (first) frequency component after the zero-frequency, which is determined by the duration of the signal, since this first frequency component is the inverse of the total signal duration. By analyzing the DFT amplitudes, we can better understand the characteristics of the seismic signal, which may be less evident in the time domain. Additionally, this approach allows us to identify and retain only the records where the signal in both components (R and Z) is above the noise level.

Site Selection and Data Processing
Several previous studies have applied the P-wave method using hundreds of stations, with or without reliable reference velocity profiles. In contrast, we focused in two specific arrays and a total of seven stations, selecting those with the most extensive dataset. These arrays are located in sedimentary basins, which are of particular interest due to the significant amplification of seismic motion often observed in such areas. Additionally, the arrays are situated in earthquake-prone regions with well-established velocity profiles (Raptakis et al., 2000; Theodoulidis et al., 2018,

Cushing et al., 2020), making them ideal for testing the methodology.
The first array, EUROSEISTEST, is located in the epicentral area of the 1978 **M**6.5 earthquake in the Mygdonia Basin, which caused severe damage in the neighboring city of Thessaloniki (Papazachos and Papazachou, 2003). The basin spans 5.5 km in the NNW-SSE direction and consists of Quaternary deposits, with a maximum bedrock depth of 200 m, where gneiss was identified (Raptakis et al., 2000). The second array, ARGONET, is located in the Koutavos Basin on the island of Cephalonia, near the Cephalonia Transform Fault Zone (CTFZ). This array was established as part of the SINAPS project (Berg-Thierry et al., 2017). The basin consists of a range of geological formations, including Cretaceous limestones (below 90 m depth, as indicated by borehole data), Upper Pliocene marly sandy limestones and claystones, Pleistocene lithological clays, and Holocene clays and silty sands (Theodoulidis et al., 2018).
From the EUROSEISTEST array, we selected five stations (BUT, GRA, PRO, STC, TST), while from the ARGONET array two surface stations (CK0, CKWP) were chosen for further processing. Among these seven stations chosen, CKWP and PRO are located on bedrock sites, while the others are situated on soft sediments. We utilized all available data, i.e. records of regional earthquakes recorded by the two networks, spanning from 1994 to 2020. The only restriction applied to the dataset was to reject data with ray parameter values p<0.1s/km, as Pappa et al. (2025) demonstrated that the use of smaller p values leads to a systematic bias of the near-surface velocity results.
For the first P-arrival we manually picked the maximum amplitudes of both the radial and vertical components. We opted not to rely on automatic pickers, even though they could expedite the process, as they can introduce errors, especially in noisy signals. We also chose not to apply any filters (highpass, lowpass, or bandpass) in order to preserve the original information contained in the initial P-wave arrivals and examine the method robustness to noise, since we aimed to test the method without applying any a priori filtering. For each waveform, we performed baseline corrections and identified the maximum values of the initial P-wave pulse (indicated between the red dotted lines in Figures 2a and 2b) in both radial and vertical components to calculate the U_R/U_Z ratio.

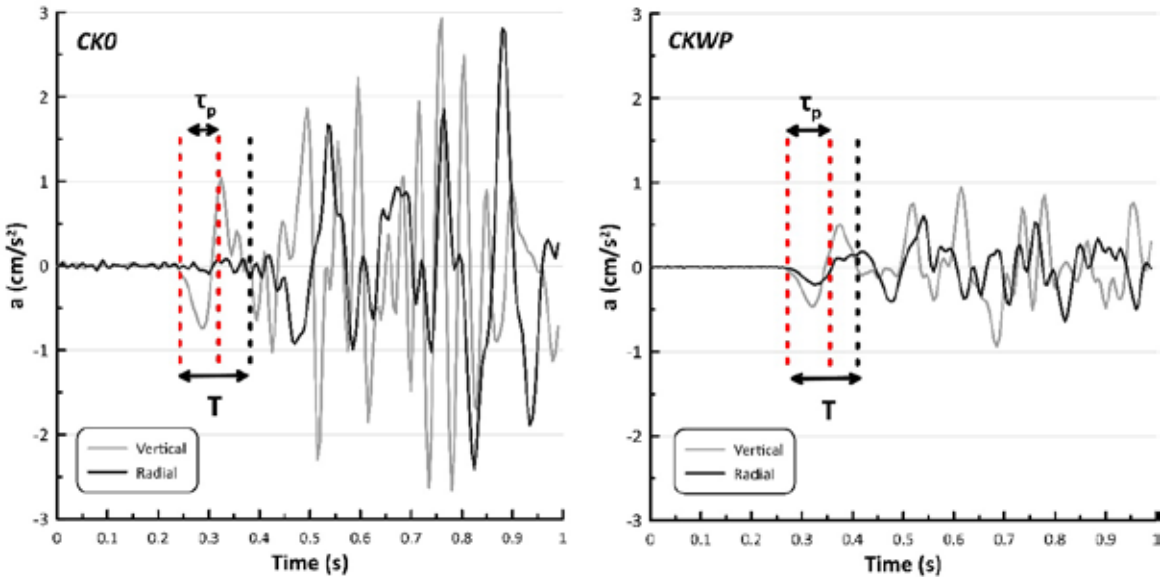

Figure 2. Example of a record at (a) CK0 and (b) CKWP stations for the arrival of the first P wave from the same local earthquake. The source time function, τ_P, and the duration, T, of the corresponding first period are also depicted.

We also extracted the arrival time of the earthquake at the station, the ending time of the first pulse, as well as the end time of the first period (see examples in Figures 2a and 2b). Figure 2a shows a waveform from station CK0, located in soft sediments, where the vertical component is much larger than the radial component. Figure 2b, from station CKWP (located on bedrock), shows a smaller difference between the radial and vertical components, which is attributed to the higher velocity of the near-surface structure.
Once the U_R/U_Z was estimated, we proceeded with the p estimation for each waveform using the TauP toolkit (Crotwell et al., 1999), implemented in ObsPy (Beyreuther et al., 2010). We used the epicentral distance, focal depth, and a local 1D P and S velocity model for each station, derived from the 3D tomographic model of Papazachos and Nolet (1997). As already mentioned, we kept only data with a ray parameter p≥0.1s/km. Since U_R/U_Z and p are known, we applied Equation (3) to estimate V_{SZ} for each record. However, since V_{S30} values are most widely used, we used the V_{SZ}-to-V_{S30} conversion equations from Boore et al. (2011) to assess V_{S30} values for each recording station. To apply

these equations, we first estimated the depth z corresponding to each V_{SZ} value using Equation (4). The duration of the first P-wave pulse was used as τ_p. Unlike Lee et al. (2022), who used an average value for τ_p, we opted to use the specific τ_p for each record to more accurately estimate the correspnding depth samples by the P-pulse wavetrain. The corresponding median V_{S30} values, noted as $V_{S30}^{Original}$, showed significant deviations, involving values with a ~ 50% relative bias (BUT, GRA, PRO, STC, TST) compared to the reference values, increasing to over 80% for stations CK0 and CKWP.

In an attempt to improve these results, we tested the possibility of computing the U_R/U_Z in the frequency domain, where we could more easily identify frequencies where the signal was above the noise level. This approach appears to be promising, especially since most of the stations used in this study were located in soft soil sediments, for which the radial components are more prone to noise compared to rock sites, potentially leading to erroneously larger U_R/U_Z values. For this reason, we applied the Fast Fourier Transform (DFT) to each waveform with a duration equal to the dominant period, T, and selected only those with an SNR in the radial component greater than or equal to 1.2 for the first (lower) frequency. This SNR threshold was applied to the radial component because stations in soft soil often exhibit weak P-wave arrivals, making them susceptible to noise. In the frequency domain, the U_R/U_Z ratio was calculated as the amplitude of the radial component divided by the amplitude of the vertical component at the first frequency. Figures 3a and 3b show examples of how the picking was done in the frequency domain for indicative records from the CK0 and CKWP stations, respectively. The subsequent processing steps, namely from the ray parameter estimation up to the V_{S30} calculation, noted as V_{S30}^{FFT} for this application, remained the same as in case of U_R/U_Z processing in time domain.

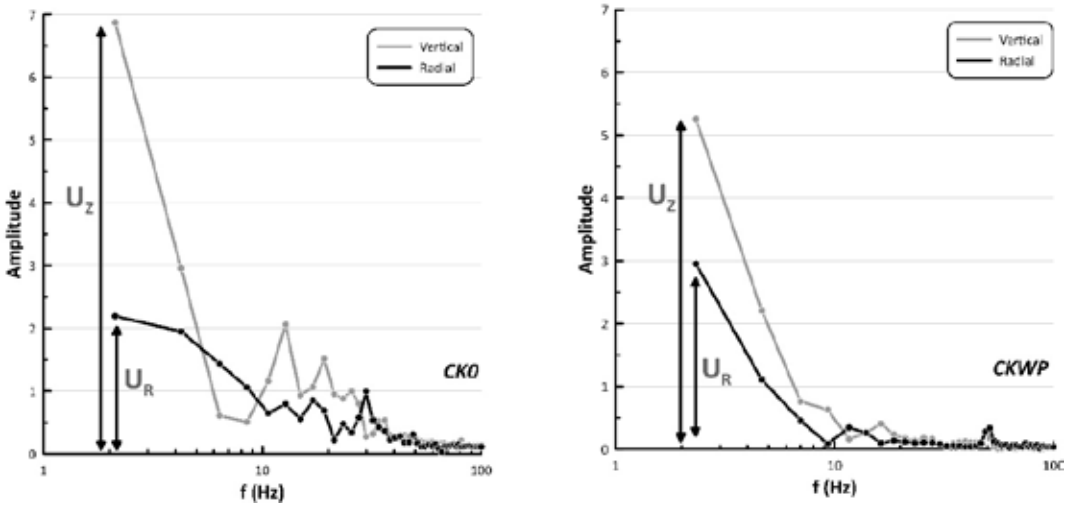

Figure 3. Example of waveform amplitude spectra at (a) CK0 and (b) CKWP stations for the first P wave and a duration equal to the dominant period (see Fig.2). The amplitude of the two components, used for U_R/U_Z estimation, is also depicted.

Results

The results of the V_{S30} estimations using both the time-domain and frequency-domain (FFT) approaches are summarized in Table 1. For stations CK0 and CKWP, the time-domain methodology ($V_{S30}^{Original}$) produced significantly overestimated values, with CK0 showing the largest deviation from the reference values (V_{S30}^{ref}). Applying the FFT-based approach reduced the overestimation across all stations, yielding lower V_{S30}^{FFT} values that were closer to the reference ones. Despite this improvement, all stations still exhibited some degree of overestimation with the FFT approach, except for station GRA, where the methodology failed to provide an improvement. The exclusion of waveforms due to low signal-to-noise ratio (SNR < 1.2) in the radial component has a different impact, depending on the recording station. CK0 had the highest exclusion rate (21%), while PRO and CKWP had no data rejections. Other stations, such as STC (2%), BUT (5.7%), and TST (6.7%), had minimal rejection rates, reflecting the overall improved data quality in the FFT-based analysis.

Figure 4 illustrates these findings: in Figure 4a we present the comparison of time-domain results with reference V_{S30} values, showing a pronounced overestimation compared to the reference, with most points lying far from the 1:1 line. On the contrary, the FFT-based results (Figure 4b) demonstrate a much better agreement with the reference values.

Table 1. V_{S30} median values, estimated from the P-wave Seismogram method with a time domain U_R/U_Z picking procedure, $V_{S30}^{Original}$, and frequency domain approach V_{S30}^{FFT} for SNR in the radial component greater than 1.2. For comparison, we also present the reference V_{S30}^{ref} values from local velocity profiles estimated from active and passive seismic methods.

Station	$V_{S30}^{Original}$ (km/s)	V_{S30}^{FFT} (km/s)	V_{S30}^{ref} (km/s)
CK0	1.05	0.48	0.24
CKWP	1.44	0.87	0.79
BUT	0.43	0.29	0.26
GRA	0.4	0.46	0.23
PRO	1.24	1.23	0.83
STC	0.54	0.52	0.35
TST	0.35	0.32	0.22

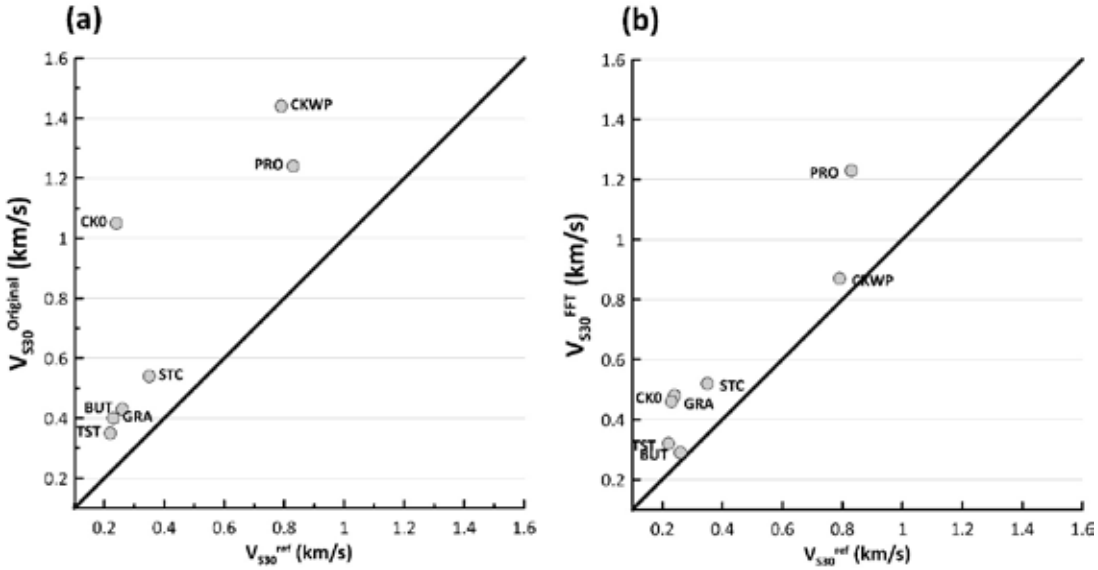

Figure 4. Plot of (a) $V_{S30}^{Original}$ and (b) V_{S30}^{FFT} as a function of V_{S30}^{ref} of each station, estimated from various active and passive seismic methods. The 1:1 line is also presented.

Conclusions

We have processed seven selected stations from two seismic arrays (EUROSEISTEST and ARGONET) located in sedimentary basins with well-documented velocity profiles and a large number of seismic records from regional earthquakes. These stations were chosen to test and refine the P-wave seismogram method for estimating V_{S30} values, focusing on both time-domain and frequency-domain approaches. Specifically, the use of FFT and imposing an SNR threshold on the radial component significantly reduced errors for most stations, bringing the estimated V_{S30}^{FFT} values closer to the reference values. However, the station GRA remains an exception, with noisy waveforms likely contributing to larger errors. This highlights the critical role of the picking process, which is particularly sensitive to noise, especially for stations in soft-soil conditions.

CK0, one of the noisiest stations, presented challenges in the time-domain approach, where its U_R/U_Z ratio was highly exaggerated. After applying the frequency-domain methodology, only 78 waveforms (less than 50% of the total dataset) were retained due to the SNR filter, leading to much better results. Similarly, other stations, especially those in ARGONET, benefited significantly from the frequency-domain approach, with notable improvements in V_{S30} estimates. The results also suggest that the softer the formation at a station's location, the lower the U_R/U_Z ratio tends to be, consistent with theoretical expectations. Stations such as BUT, which have a reference V_{S30}^{ref} value close to the V_{S30}^{FFT}, exhibited a median U_R/U_Z of ~0.11, whereas GRA, with noisier data, showed a higher median U_R/U_Z of ~0.16.

In conclusion, the proposed frequency-domain approach can enhance the reliability of V_{S30} estimations, particularly in noisy environments or soft-soil conditions. However, challenges are still present regarding the handling of noisy data, such as at GRA, where an additional refinement of the proposed approach may be necessary. The findings underscore the potential of frequency-domain analysis to improve site condition assessment, but additional investigation is needed to address the remaining discrepancies and optimize the approach for broader applications.

Research Highlights

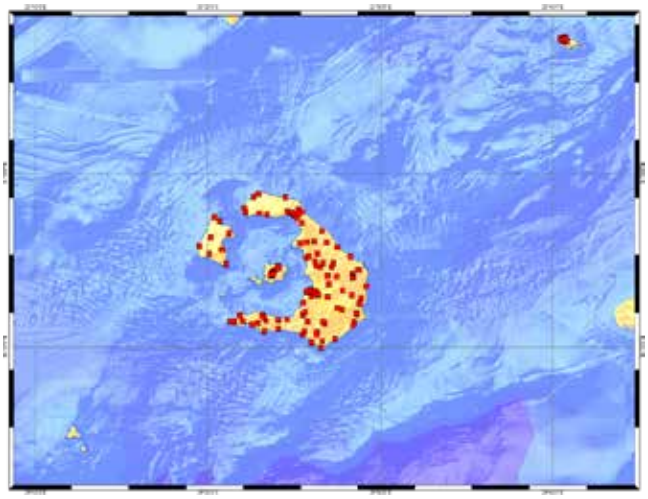
- Gravity changes during early 2025 suggest renewed subsurface activity in Santorini.
-Integrated microgravity and GNSS monitoring reveal localized mass redistributions.

Introduction

The Santorini volcanic complex is well known around the globe, largely due to the catastrophic Bronze Age eruption (~1600 BCE), possibly contributing to the collapse of the Minoan civilization (Bruins et al 2008, Friedrich 2000; Pyle 1990). The last eruption occurred in 1950, after which the volcano remained dormant. Between January 2011 and February 2012, significant unrest was recorded, characterized by seismicity, ground uplift of approximately 14 cm, and changes in fumarolic gas compositions (Newman et al. 2012; Parks et al. 2012; Tassi et al. 2013; Tarchini et al. 2019). After this unrest period, gravity surveys were conducted by the National Technical University of Athens (NTUA) in 2012 and 2014. The processing of these datasets indicated the injection of approximately 330 billion kg of basaltic magma at a depth of ~3 km, north of Nea Kameni, and highlighted concurrent changes in the hydrothermal regime (Paraskevas et al, 2023).
Beginning in August 2024, preliminary GNSS and InSAR observations indicated renewed ground uplift, marking the onset of a new phase of geophysical unrest (Paraskevas et al. 2023). Since late January 2025, Santorini has experienced a significant seismic swarm, centered primarily offshore between Santorini and Amorgos islands. Over 50,000 earthquakes have been recorded from January 31, 2025 to April 8, 2025 (Margarita Segou, British Geological Survey, pers. comm) , several exceeding magnitudes 4.0, with the largest event reaching M 5.3 on February 10, 2025(National Observation of Athens). These developments triggered a targeted gravity survey conducted from 7 to 13 February 2025.

Methods

Between February 7 and 13, 2025, a high-resolution gravity survey was carried out at Santorini, during which a total of 865 gravity measurements were collected at 137 established stations distributed across Santorini (96 stations), Nea Kameni (18 stations), Thirasia (8 stations), and Anydros (15 stations). All measurements were referenced to a fixed base station (ID 2000) located in Santorini, with a calibrated absolute gravity value of 979992.9261 mGal. Data processing was conducted using a least squares adjustment approach, incorporating 677 gravity observations to resolve 137 unknown station values, resulting in 540 degrees of freedom. The initial variance factor (σ^2) of 0.225 and the maximum residual of 0.0394 mGal indicated an overestimation of the observational errors. Consequently, a rescaling of weights and standard deviations was applied, yielding robust absolute gravity values for each of the 137 stations referenced to the Santorini base station. Following the derivation of these absolute gravity values, Free-Air and Complete Bouguer anomaly maps were produced according to the methodology thoroughly detailed by Paraskevas et al. (2024). Subsequently, offshore gravity measurements from the PROTEUS project (Hooft et al. 2015) were integrated with the new onshore data, enabling the generation of updated and comprehensive Free-Air and Complete Bouguer gravity anomaly maps for the Santorini volcanic complex and its surroundings



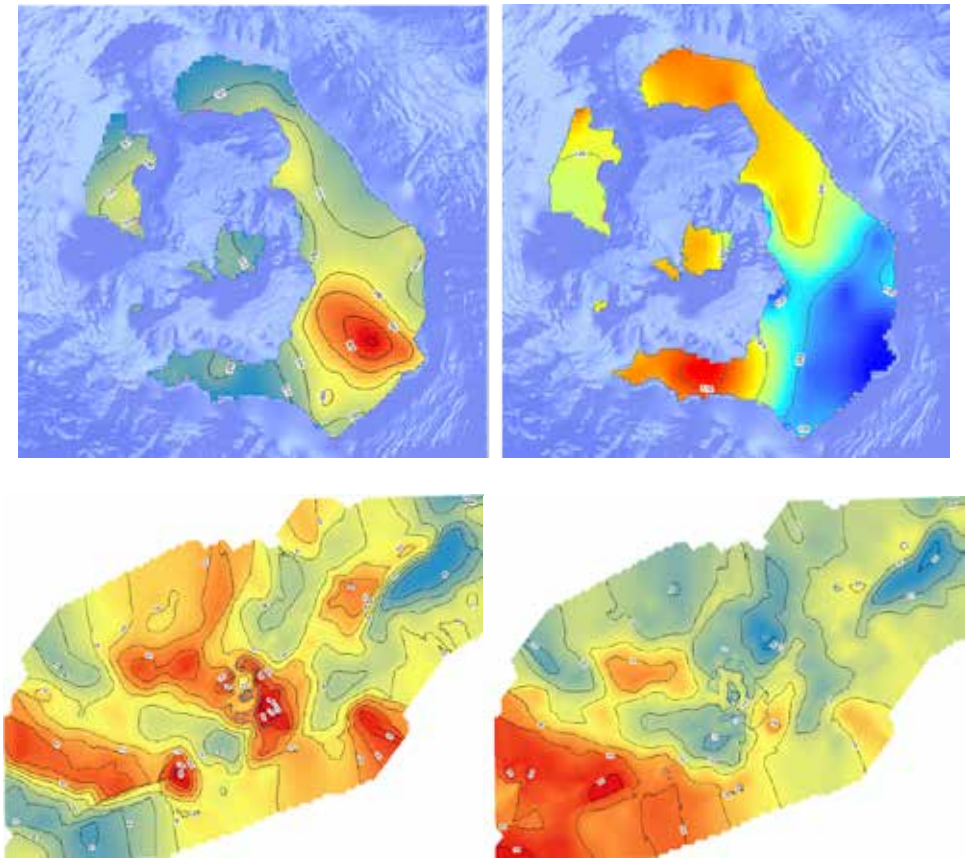


Figure 1 – 137 Gravity stations measured from 7 to 13 Feb 25

Data Analysis

Out of the 137 stations surveyed in 2025, 93 stations had previously been measured in either 2012 or 2014, providing a baseline for temporal gravity comparisons. At these 93 stations, absolute gravity values from the current study were directly compared with those earlier measurements. Subsequently, gravity effects associated with ground deformation were isolated and removed using GNSS and InSar-derived displacement data, allowing for the calculation of residual spatiotemporal gravity variations within the study area. The results of this comparative analysis are illustrated in Figure 4. These preliminary results indicate the presence of a subsurface mass deficit beneath the Santorini volcanic system during the period of measurements, primarily focused in the area of Nea Kameni and extending northwestward towards Kolumbo. Additionally, statistically significant gravity variations highlight a notable subsurface mass redistribution within the broader Santorini volcanic complex.

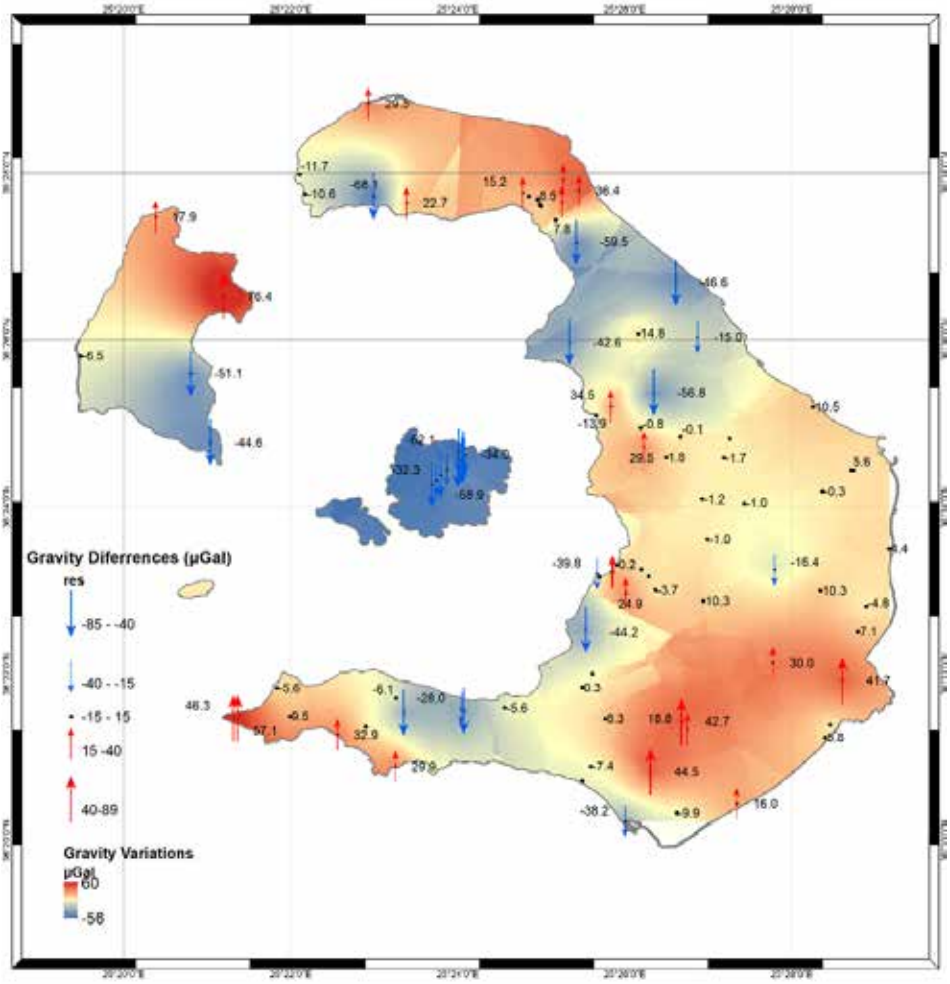

Figure 4 – Spatiotemporal Gravity changes from 2025 to 2012 or 2014

Conclusions

The high-resolution microgravity measurements conducted between February 7 and 13, 2025, provide critical insights into the ongoing geophysical unrest at the Santorini volcanic complex. The comparative analysis of gravity data collected in 2025 against previous measurements from 2012 and 2014 reveals statistically significant spatiotemporal gravity variations, indicative of substantial subsurface mass redistribution processes. The observed mass deficit, predominantly beneath Nea Kameni and extending northwest toward Kolumbo, strongly suggests changes in the volcanic and hydrothermal systems. These preliminary findings highlight the importance of integrating gravity monitoring with GNSS and InSAR deformation analyses, underscoring their collective capability to enhance our understanding and monitoring of volcanic unrest. Continued monitoring and multidisciplinary analyses are recommended to refine interpretations and provide timely updates on potential volcanic hazards.

Stone bridges. Resilience to catastrophic phenomena

Paschos Panagiotis
Dr Geologist
Hellenic Survey of Geology and Mineral Exploration (H.S.G.M.E.), Regional Branch of Epirus, Eleonas, 48100 Preveza. Greece

Introduction / Background

Epirus, being an integral part of Greece with the complex geodynamic evolution that remains active until today, is characterized by the diversity of relief elements, featuring a set of successive mountain ranges with rapid and abrupt altitude changes and a dense hydrographic network.

Numerous settlements, endowed with abundant natural resources (water, food) and protected throughout history, evolved within this environment. Due to the mountainous nature of the area, the construction of bridges was of paramount significance, as it facilitated the free movement of inhabitants from one place to another.

This presentation describes the results of the project: Recording stone bridges in the Region of Epirus that face problems from catastrophic phenomena. The project is implemented by EAGME, with funding from the Public Investment Program.

In the Region of Epirus, there are several stone bridges as a result of the intense relief and the multifaceted dissection of the hydrographic network. These bridges are architectural monuments of exceptional aesthetics and are part of the cultural identity of the region. However, the action of catastrophic phenomena (earthquakes, floods, landslides) but in some cases also human intervention result in the deterioration of these monuments. The fact of the collapse of the Plaka Bridge is an example to avoid similar incidents.

The bridges were constructed from blocks of limestone and sandstone, which are common building materials in the area.

The bridges' foundation positions were chosen so as to ensure their stability and durability against the flooding phenomena of the streams and rivers.

They were located at narrow passages where the cross-section of the stream was confined.

Stone bridges receive the entire volume of water during flood conditions, as well as large quantities of accumulated debris from mud, stones and wood, along with all sorts of objects/materials that were discarded on the slopes and the beds of torrents and rivers.

The hydraulic restriction regarding the amount of water that has to pass only through the bridges' arches creates an increase in water velocity that is accompanied, in some cases, by erosion of the riverbed and damage to the bridge pedestal.

High rainfall is a frequently occurring phenomenon in the area of Epirus. Sometimes recorded extremely high rainfall that takes place in the region

Considering that due to the lithology of the catchment area (flyschic background with limited infiltration) all these quantities of water accumulate abruptly and flow downstream, forming flood conditions.

With this specific project, the bridges that have been affected and are at risk from the ongoing action of the destructive phenomena are recorded in cooperation with Municipalities of Epirus and in collaboration with the Service of Modern Monuments and Technical Works of Epirus, North Ionian and West Macedonia.

The identification, prevention and minimization of the corrosive processes affecting the foundation platforms, especially during flooding conditions, as well as the submission of proposals for their mitigation, constitute determining factors as far as the bridges' protection is concerned.

The procedures and actions that will be launched, after the completion of the project, to remove the risk and restore the possible damage to the bridges, will require combined interventions and collaborations of several scientific specialties and specialized technicians. This will create, in addition to preservation, a turnover and the creation of jobs. Through this project, knowledge will be enriched for minimizing the consequences of the action of the destructive phenomena.

Stone bridges constitute part of the cultural heritage of Greece and most of them have been designated, by legislative regulations, as protected monuments. Responsible for their protection is the Service of Modern Monuments and Technical Works of Epirus, North Ionian and West Macedonia, whereas the local authorities play a crucial role in the implementation of protection measures and monitoring.

Abstract
The Clarion Clipperton Zone (CCZ), located in the Northeast Pacific Ocean between the Hawaii islands and Mexico, is a region known for its polymetallic nodules. These nodules are iron and manganese-rich concretions formed of concentric layers of hydroxides and are found on the ocean floor, at depths ranging from 3500 to 6500 meters. They contain valuable metals such as nickel, copper, cobalt, and rare earth elements, making them a potential resource for various high-tech applications. This study focuses on the mineralogical and geochemical analysis of polymetallic nodules collected from the eastern part of the CCZ. X-ray Diffraction (XRD) and Scanning Electron Microscopy (SEM) with EDS techniques were used to investigate the mineral composition, morphology and textures of these nodules. Special attention is given to key minerals such as manganese oxides, todorokite, and birnessite, which serve as indicators of growth processes as well as concentric layering patterns and compositions to identify the specific environmental and geochemical conditions under which these formed.

Introduction
The existence of manganese (Mn) or polymetallic nodules has been known since the early 19th century but it was during the Challenger expedition of 1873–1876 that they were recognized for their significance as metal resources. It was only after World War II that the nodules became focus of detailed research, due to their unique ability to absorb important metals from seawater and form valuable ore deposits. However, the exploration and interest in their potential economic use diminished, due to technical, economic and environmental challenges. In recent years, the interest in the polymetallic nodules has revived, as they can be important source of nickel, copper, cobalt, and rare earth metals. These elements are essential for the continuous advancement of high technologies, the transition to green energy systems, and the development of efficient energy storage systems.
Manganese, ferromanganese and polymetallic nodules are metal-rich concretions found on the deep ocean floor, in depths ranging from 3500 to 6500 meters. Their size ranges from a few millimeters to several centimeters and exhibit irregular shapes. Structurally they consist of multiple, concentric micron-thick layers that form around a core, growing in an extremely slow rate over millions of years. The central core, may either be of biogenetic origin such as shark tooth, or of sedimentary origin such as sand grains, and rock fragments.
Manganese nodules form over millions of years through two main processes: hydrogenetic and diagenetic growth. In the hydrogenetic growth process, the minerals precipitate directly from oxic seawater and their mineralogy is dominated by vernadite (δ-MnO□) and amorphous δ-FeOOH phase (Halbach et. al., 1988). Their composition is characterized by low Mn/Fe ratio (≤3) and relatively low concentrations of Ni and Cu. Hydrogenetic nodules are found commonly in seamounts and on their slopes. When nodules grow diagenetically, the metals precipitate from the sediment pore water under oxic conditions. The Mn/Fe ratio is between 3 and 10 and Ni and Cu concentrations are significantly higher. Todorokite, -a phyllomanganate mineral, and birnessite are the most common Mn-minerals. Nodules that form through the influence of both processes are named as mixed-type nodules and are characteristic of the CCZ (Halbach et al., 1981).
This research work investigates several polymetallic nodules from the CCZ with focus on their internal structures, mineralogy and mineralogical textures in micron-scale. The primary objective is to classify the nodules based on their formation processes (hydrogenic or diagenetic).

Geological Setting of the Clarion Clipperton Zone
The Clarion Clipperton zone is a vast segment of the Pacific Oceanic Plate located in the northeastern Pacific Ocean. It covers an area of approximately 5 million square kilometers, which is equivalent to the size of continental Europe.

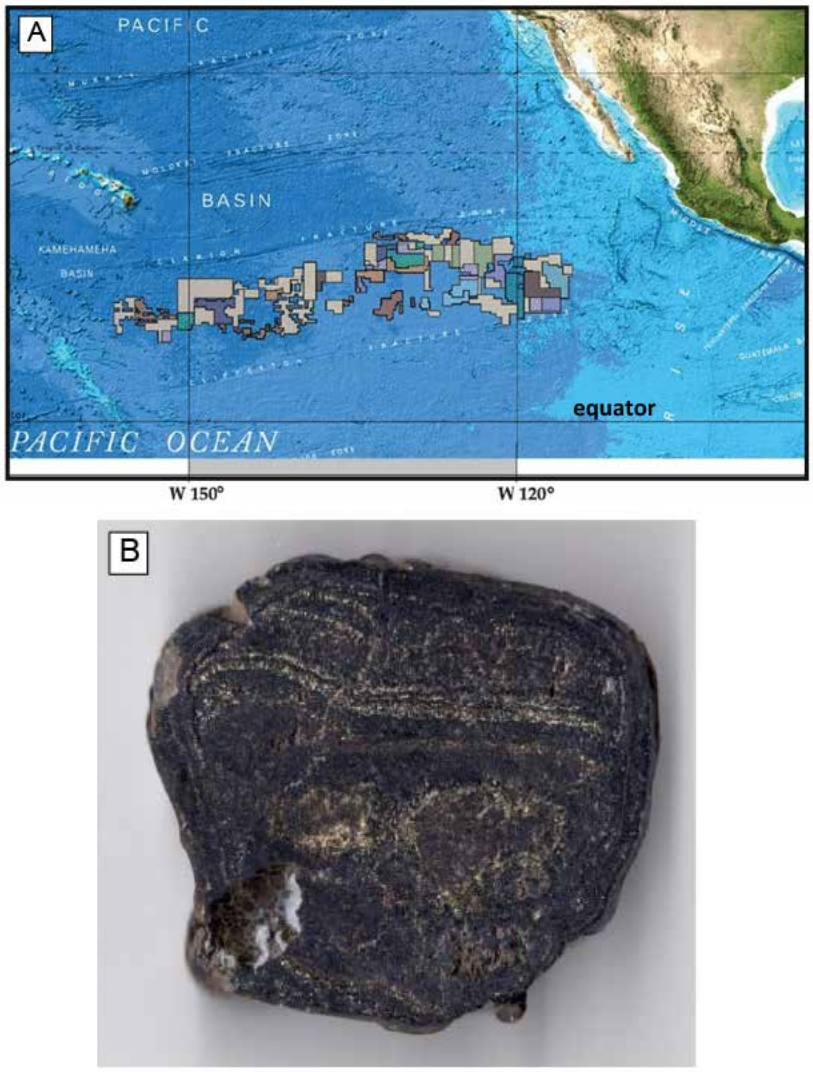

Figure 1. A) Map showing the location of the Clarion Clipperton Zone and the numerous exploration areas (Abramowski et al., 2021). B) Polished slab of a typical polymetallic nodule from the CCZ studied in this work.

The depth is relatively uniform and ranges from 4000 meters to the southeast up to 5000 meters in the northwest. The CCZ lies between of two major fracture zones: The Clarion to the north and the Clipperton to the south. The seabed of the CCZ is predominately composed of basaltic abyssal hills covered by layers of siliceous and calcareous sediments (Parianos et al., 2021). The abyssal hills are the result of normal faulting at mid-ocean ridges, that formed horst and graben structures, indicative of the extensional tectonic regime during opening of the Pacific Ocean. Other occurring geomorphological features include volcanic knolls, seamounts, and lava outcrops.

Samples and Methodology

Approximately 3 kilograms of individual polymetallic nodules were made available for this study by the AllSeas Group S.A. X-ray Diffraction (XRD) was used for the identification and characterization of mineral phases based on their crystallographic structure. The nodules were first heated at 140ºC for 24h and then crushed powdered in homogenous samples and finally pressed into holders. The X-ray Diffractometer used is D8 ADVANCE BRUKER. Polished thin sections were prepared for microscopic examination using a Zeiss Axioscope 40 Pol, and by backscattered electron imaging with a JEOL JSM-6390LV scanning electron microscope (SEM) equipped with INCA 300 energy-dispersive X-ray Spectroscopy (EDS). All sample preparation and analytical procedures were carried out in the laboratory facilities of the Mineralogy-Petrology-Economic Geology at the Department of Geology, Aristotle University of Thessaloniki.

Results

Nodule mineralogy: The XRD analysis revealed that the main mineral phases found in most samples are a) todorokite $Mn_6O_{12}(H_2O)_4$, b) birnessite $MnO_2(H_2O)$, c) manganese dioxide MnO_2 or vernadite (and/or hydroxide), d) goethite FeO(OH), e) quartz SiO_2, f) baryte $BaSO_4$, and, g) ilmenite $FeTiO_3$ (Figure 2). Other aluminosilicates observed are illite $(K,H_3O)(Al,Mg,Fe)_2(Si,Al)_4O_{10}(OH)_2\ nH_2O$, smectite (and probably zeolite), and detrital anorthite $(Ca,Na)_x(Al,Si)_xSi_2O_8$.

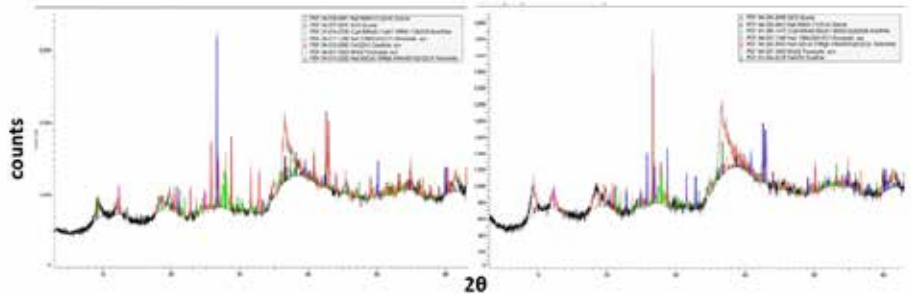

Figure 2. Typical X-ray powder diffractograms from two samples (No.205, No.104). Peak positions indicate the main minerals identified as listed in the legend box.

Manganoan mineral textures and chemistry:

a) MnO_2 and $Mn(OH)_2$: In BSE imaging vernadite is the brightest mineral after barite and ilmenite found as finely crystalline, botryoidal, or in dendritic structures (Figure 3, 4). It contains > 70 wt % MnO_2 and significant amounts of Fe, Ni and Cu as well as impurities of Si, Al, Na and Mg.

b) Todorokite and Birnessite: These form concentric zones where todorokite is slightly brighter than birnessite because it incorporates higher levels of heavier metal cations (Ni, Cu) in its structure. However, these are difficult to distinguish because of the incorporation of various amounts (or impurities) of clay minerals. They both contain commonly more than 40% MnO_2, Fe, Ni and Cu up to 10% in total (oxides), and locally very high amounts of Si and Al.

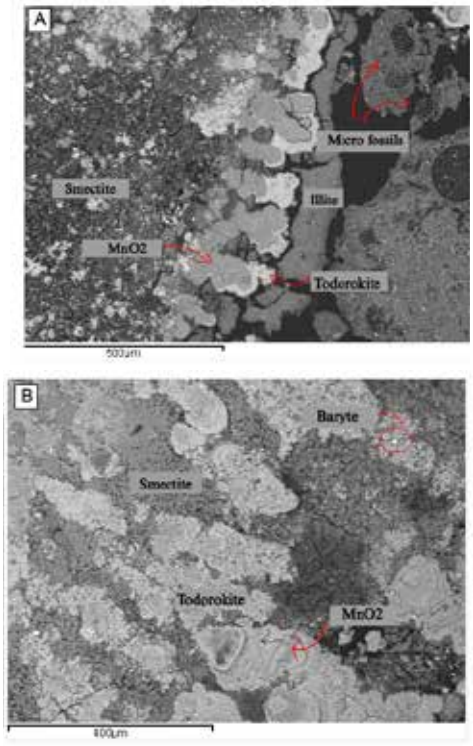

Figure 3. BSE high resolution images of: A) sample CCZ101 showing the different layers and microfossils (possibly radiolaria). B) sample CCZ206 showing the dendritic structures of the manganoan oxides, bright white are baryte crystals.

SEM analyses revealed three distinct types of layers based on texture and composition (labeled as 1-3):
Layer Type 1: These layers exhibit low reflectivity and appear dense with columnar growth. Energy Dispersive Spectroscopy (EDS) spot analyses show Mn/Fe ratios ranging from 0.53 to 4.24, and Ni+Cu contents between 0.16 and 2.55 wt %. These layers are indicative of the hydrogenetic growth process.
Layer Type 2: These layers show high reflectivity and are the most dominant in the nodules, with characteristic dendritic, porous growth patterns. These dendritic zones contribute to the high porosity of the nodules. EDS spot analyses reveal Mn/Fe ratios ranging from 1 to 30, with Ni+Cu contents averaging 3.9 wt %, reaching a maximum of 6.5 wt %. These layers are characteristic of the diagenetic growth process.
Mixed Layer Type 3: These layers have low reflectivity and a columnar growth pattern, with Mn/Fe ratios ranging from 3 to 11 and Ni+Cu contents ranging from 1 to 4.6 wt %. These layers represent a transitional type from Layer Type 1 to Layer Type 2.

Elemental Distribution:
The element map shown in Figure 4 illustrates the distribution of the critical metals in different layers of the nodule. Iron, Ni, Cu, and Mg show a similar distribution pattern to Mn, indicating that these metals are absorbed by the layered and tubular structure of the phyllomanganate minerals, such as birnessite and todorokite, respectively. Areas enriched with Si and Al correspond to the non-crystalline aluminosilicates (e.g., smectite).

Aluminosilicates:
The chemical composition of the aluminosilicates in the nodules varies widely, including smectites, illite, and their manganous varieties. These aluminosilicates are primarily deposited directly on the seafloor or form through early diagenetic processes.

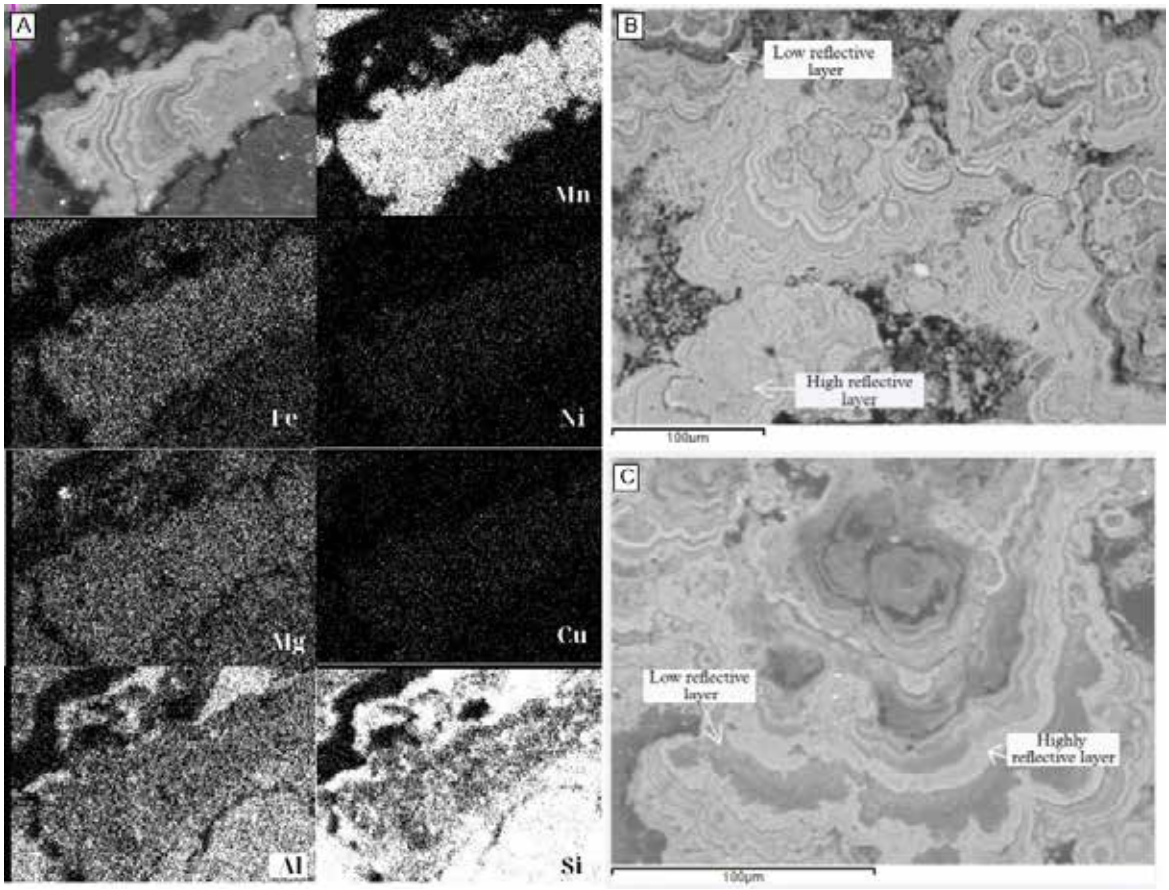

Figure 4. A) SEM-EDS elemental mapping images showing the distribution of metals in the high-manganese layers (sample CCZ203). B) BSE images of concentric layers of types 1 to 3. The higher the reflectivity intensity, the greater the manganese content.

Discussion and conclusions

The polymetallic manganese nodules of the Clarion-Clipperton Zone (CCZ) consist of macroscopically distinguishable layers, which include fine-grained, partially crystallized clays (e.g., smectite, illite) containing detrital quartz, plagioclase, ilmenite, and abundant visible microfossils. These layers alternate with metal-rich layers primarily composed of vernadite, todorokite, and birnessite. Baryte, in the form of small acicular crystals, is a common accessory mineral.

The phyllomanganates are not present as pure phases; rather, they incorporate significant amounts of substituted cations such as Fe, Ni, Mg, and Cu, as well as impurities from surrounding sediments. These impurities result in elevated concentrations of SiO□, Al□O□, and trace metals (e.g., Ti), contributing to the complex compositions of the manganese minerals. Additionally, manganese-rich clays, most likely Mn-smectite (e.g., Mn-nontronite), were identified in the nodules.

These aluminosilicates are typical clay minerals, primarily deposited directly on the seafloor (e.g., smectite) or formed through early diagenetic processes (e.g., illite). The detrital material, such as quartz and ilmenite, accumulated from the erosion of basaltic rocks and was transported by deep ocean currents. Based on the mineralogy and textures observed, the manganese minerals in the nodules formed through both hydrogenetic and diagenetic growth processes. The presence of dendritic todorokite, enriched in Ni, Cu, and Mg, suggests these metals are concentrated within its tunnel structure, while the higher Mn/Fe ratios (compared to birnessite) indicate a diagenetic origin. The Ni, Cu, and Mn metals may have originated from multiple sources, including terrestrial influx and hydrothermal activity associated with the East Pacific Rise (Piper et al., 1981).

Minerals such as vernadite (MnO□) and birnessite, which contain higher Fe, Ca, and Na, likely precipitated directly from oxic seawater during hydrogenetic growth due to their layered structure. The presence of baryte in the nodules further supports the diagenetic processes involved, likely precipitating from sulfate-rich pore waters enriched in barium released from biogenic material (e.g., radiolarians) or organic degradation. Baryte formation may have occurred alongside todorokite. In conclusion, the nodules from this part of the CCZ exhibit a mixed-type hydrogenetic-diagenetic growth pattern, consistent with the observations of Halbach et al. (1981).

Acknowledgements

We express our sincere gratitude to AllSeas S.A. and particularly Mr. Wouter Duijnstee for their generous provision of the samples used in this study.

EXTENDED ABSTRACT 255

A Pilot Study of Erosion in the Mavro Lithari Beach, part of the Highly Urbanized Coastal Zone of the Eastern Saronic Gulf, through the use of drone technology

Introduction

On the basis of aerial photographs collected from seasonal drone flights between May and November 2023, a shoreline retreat of 1-2 m in the central part of Mavro Lithari beach was observed, which can be characterized not very significant in comparison to other places of the Saronic Gulf.

Beaches are dynamic geomorphic systems that are in constant evolution and can be affected by a number of human and natural factors leading to erosion. Specifically, the increase in coastal population, combined with climate change, have disturbed the annual balance of erosive and reserve processes (it has become negative in the majority of cases), so that erosion is now a permanent regime even within an annual cycle of beach evolution, especially when human populations occupy the active part of the beach and create conditions of 'coastal squeeze'. Such conditions are now the norm in highly urbanized coastal areas.

In Greece, coastal erosion threatens more than 30% of its coastlines, making it one of the country's most important environmental problems. In particular, the coastal areas of Attica face significant environmental and aesthetic degradation due to excessive urbanization, due to the artificial transport of sediment from the hinterland to the coast (with the transported sediment subject to erosion) and due to the development of facilities and structures to serve tourism and trade (Belibassakis and Karathanasi, 2017). Human interventions and coastal erosion lead to ecosystem degradation and the destruction of shorelines that are important paleo-indicators of a beach's changes while protecting it from further erosion (Koutsomichou et al, 2009).

Regarding the Saronic Gulf and the phenomenon of its coastal erosion, this seems to be linked to human interventions, to climatic factors, to the change in sea level and at the same time to the tectonics that characterizes the Gulf. The Gulf is characterized by moderate seismicity, with the northern and western Gulf margins exhibiting high magnitude historical and recent earthquakes, associated with the presently active N-S extensional tectonic regime (Foutrakis and Anastasakis, 2020). The basin of the Gulf forms a complex neotectonic structure in the NW edge of the inner, modern, Hellenic volcanic arc, while a relatively shallow underwater ridge at its central portion demarcates the eastern from the western part of the basin (Kolaiti and Mourtzas, 2016). This central platform implies the existence of a NNE–SSW trending rupture zone, which is probably the offshore extension of a large thrust belt dominating the adjacent onshore areas (Drakatos et al., 2005).

For the study of erosion and the short- and long-term assessment of changes in a coastline, drone technology has become particularly effective. According to Joyce et al. (2023), drone technology is well suited to providing data in coastal environments and offers flexible timeframes that sequentially cover continuous changes in coastal dynamics; it can be applied to a variety of data types while offering better spatial resolution than that offered by other modes of survey (such as aircraft and satellites), as drones move at lower altitudes and therefore closer to the area of interest. In addition, their data can be combined with free satellite data to produce high fidelity images, which can then be used to build digital terrain models (DEMs and DTMs) and surface models (DSMs). Of course, drone technology presents its own challenges when using it in research, a topic that is beyond the scope of this research.

Objectives

The aim of this research is to investigate, using drone technology, the extent of erosive processes in the highly urbanized coastal zone of the Eastern Saronic Gulf, by determining the extent of horizontal shoreline displacement at the touristic beach of Mavro Lithari within two consecutive seasons - spring and autumn - of 2023. Understanding the size and dynamics of the active part of a beach is crucial for the sustainable environmental management of the wider coastal zone, although each beach due to its particular physiographic features may show smaller or larger deviations from the general morphological trend of the wider coastal area.

Methods

The collection of high-resolution images from the beach of Mavro Lithari in the two different seasons of 2023 (spring and autumn) was carried out using a rotor-wing UAS, the 'DJI Matrice 210 RTK' model series (Figure 1). This drone is one of the most suitable for coastal monitoring, and thanks to its RTK antenna equipment it shows great stability in flight, even in conditions with strong winds. Moreover, this type of drone can support different types of sensors and, therefore, can be applied in a variety of research fields (Vandarakis et all., 2016). At the same time, 14 Ground Control Points (GCPs) were selected for the georeferencing of the

collected aerial photographs, 7 points for the flight that took place in the spring season and additional 7 points for the autumn flight. In general, the use of GCPs (these are black and white targets of 25 cm × 25 cm., see Figure 1) plays an important role in maximizing the positional accuracy of the collected aerial photographs.
Therefore, the methodology followed was based on the use of drone technology for the collection of high-resolution aerial photographs and their processing through the Pix4D Mapper software in order to compose two orthophoto maps, one for the spring period (early May 2023) and one for the autumn period (late November 2023). Thus, the overall processing of the recorded data, led to the conversion of the orthophotomosaic into a format of two maps with all the necessary elements (such as orientation, scale, background and description of details), using ArcGIS Pro software. At the end, a combined, also, map was created that included both seasonal orthophotos in order to achieve a comparison of the results of the two flights performed (Figure 2).

Figure 1: The DJI Matrice 210 RTK drone and one of the seven GCPs

Results

Based on the acquisition and processing of the data collected, the orthophotos and the corresponding maps that were produced, the combined map showed the shoreline change between the two seasons (Figure 2). The comparison of the two seasonal orthophoto maps indicated an obvious shoreline retreat in the central part of Mavro Lithari beach, by the end of autumn, of 1-2 m. This calculation has not been influenced by the negligible error values (absolute and relevant), as showed in the comparative data of Table 1. The retreat of 1-2 m is an expected seasonal (probably) temporary retreat of the shoreline, as the physiography of the Saronic Gulf does not favor the development of frequent extreme wave conditions, while Mavro Lithari beach has not been subject to much human intervention in the active sedimentation zone, as the case is in other coastal areas of the Saronic Gulf (e.g. Ormos Faliros, Alimos, Glyfada), which present much more significant erosion processes.

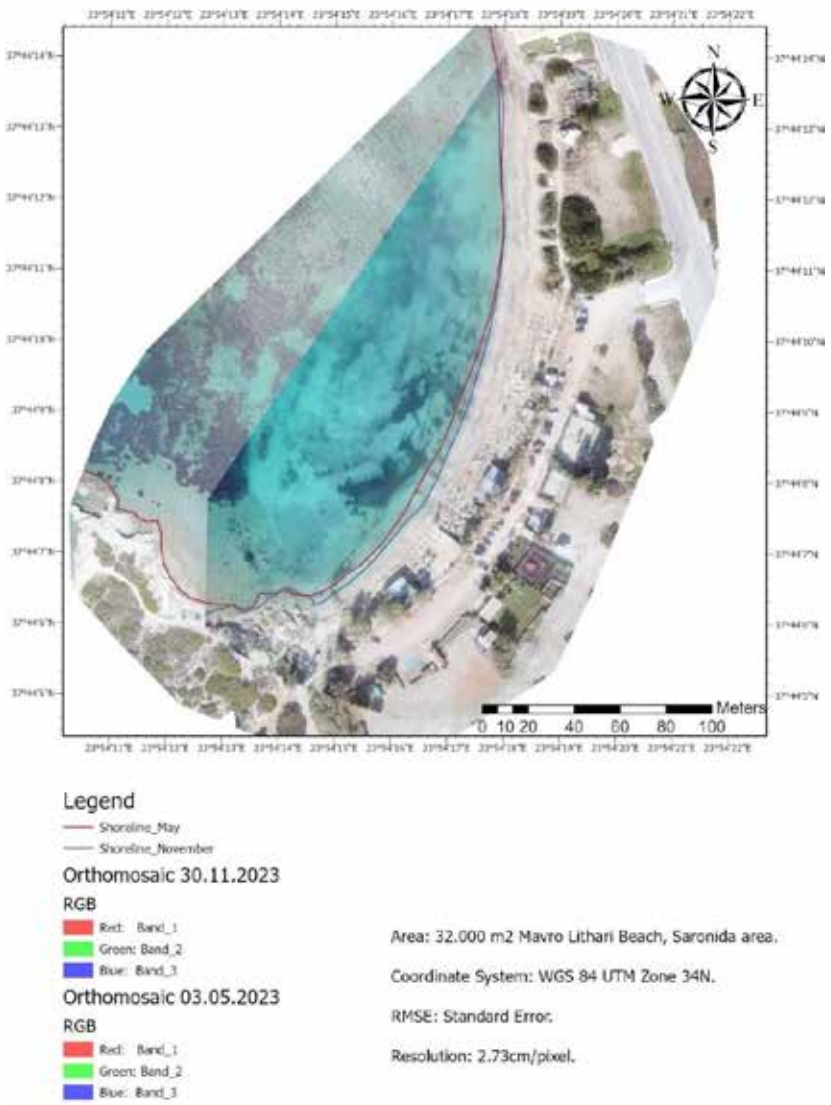

Figure 2: Combination of the two seasonal orthophotomosaics for the beach of Mavro Lithari

Discussion and Conclusions

The orthophotos produced by the two flights of the DJI Matrice 210 RTK drone showed that the shoreline in the central part of the study area receded by 1-2 m. It is considered that this shoreline shift probably represents a seasonal, temporary situation, as the beach of Mavro Lithari has not been subjected to significant human interventions (which are an erosional factor), while at the same time it is part of a bay whose general physiography favors only a small frequency of extreme wave conditions. Regarding the uncertainties of the determined erosion amplitude at Mavro Lithari beach, as calculated by the relevant Pix4D software of the two flights, they show very low error values, so the 1-2 m shoreline retreat is realistic and indicative of the degree of receding of a natural beach in the Eastern Saronic Gulf, albeit probably seasonally.

These results seem particularly interesting if we compare them with other studies for the Saronic Gulf. For example, Skilodimou et al. (2021) state that in the last 76 years the coastline has been enhanced by 40% in terms of extension (e.g. through earth filings, technical works, artificial structures) and the 60% of its total length is artificial, 29% includes rocky shores and the remaining part consists of beaches. The largest interventions have been made in Ormos Faliro (287%), Alimos (256%) and Glyfada (194%), areas with a higher coastal erosion. For comparative purposes, Figure 3 shows the artificial extension (tens to hundreds of meters) of various shorelines in the Eastern Saronic Gulf, which is the main factor of coastal erosion in the region. In our case, with the measurements showing a much smaller erosive area compared to the above-mentioned areas of the Saronic Gulf, this can be interpreted due to the physiography of the Mavro Lithari beach and the fewer human interventions (or absence of them).

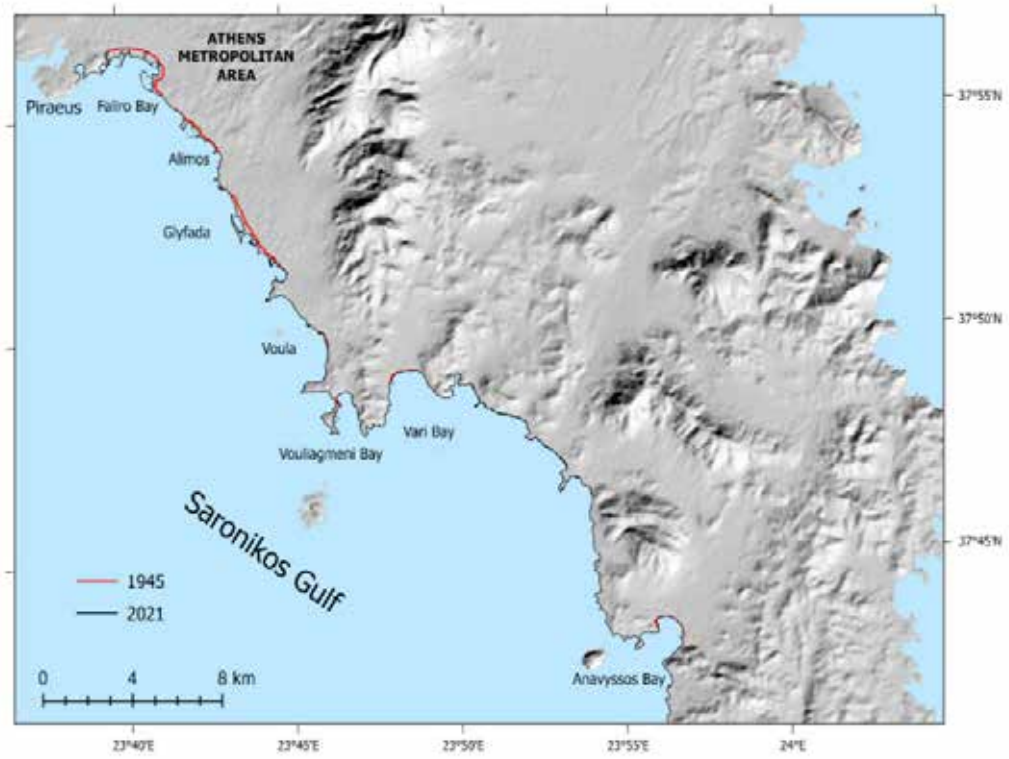

Figure 3: Shoreline changes in the northwest of the studied beach of Black Lithari (red arrow) which has undergone intense changes over the last decades (from Skilodimou et al., 2021)

The results of the research also highlight that drone technology is a very useful and versatile tool, which can produce very high resolution orthophotos and thus accurately capture the changes of coastlines in different regions of the planet at regular intervals, thus contributing significantly to the study of the phenomenon of coastal erosion, which is critical for humanity.

To conclude the discussion, our research has some limitations: a) the measurements were made between 3 May and 30 November 2023, so they cannot capture inter-annual changes; b) the research would be more complete if there were data related to the quality of sediments and rocks in the area as well as wave and wind data.

Active Faulting in Santorini and the recent intra-caldera (2024-2025) seismic activity along the Kameni-Fira Fault line

This paper presents certain elements of the neotectonic and active structure of the Santorini island complex. The active structures consist of sets of primarily normal fault systems with right-lateral component in an *en échelon* pattern, trending at or around N30°E (Mountrakis et al., 1998). Another important and common feature on Santorini is the feeder dykes that are related with those faults. Along the major Columbo fault line, which appears to start at the southernmost tip of Therassia Island (Cape Trypiti) and stretch up to the Columbo submarine volcano and Anhydros Islet, they are primarily concentrated on the northern narrow part of the island, north of Mikros Prophitis Elias ridge.

The Fira normal fault is another active structure that is visible in the caldera walls. Significant tectonic evidence of recent activity may be seen on the Yialos Caldera cliff, including fractured and tilted late Quaternary volcanic layers, as well as new on-land tectonic scarps. A syn-depositional normal fault, it is a significant structure that deforms various volcanic lava layers, scoria, and pyroclastic flows. As evidenced by the microseismic activity during the 2011–2012 crisis and the one ongoing since the end of 2024, this fault is classified as active.

A large scarp of the same strike affects the relief along the fault-line and continues farther to the northeast on the island, even though volcanic material near the topmost part of the fault appears undeformed. It is thought to be a longer, seismically hazardous structure that follows the tectonic line of the Kameni volcano. The fault was modelled by using data from a UAV campaign, that allowed for the construction of a precise DTM (Figure 1, Pavlides & Chatzipetros, 2018). It shows that fault throw episodically declines upward on the caldera's highly steep inner escarpment, from 22 m at sea level to nearly 2 m at the highest point (Pavlides et al., 2025, this volume).

Two extensional contemporary stress phases have been documented, implying that the first is attributed to the tectonic stresses related to the well-established Aegean motion towards SSW, whereas the second, which gives rise to recent microseismicity of the area, is a local stress regime attributed to buoyancy forces relating to magmatic processes of the area (Pavlides & Tranos 2014). Therefore, the combination of these two stress regimes reflects the competition between the tectonic (lithospheric) and magmatic (local volcano-tectonic) forces, in a fault-dynamic regime that could be characterized as extensional-transtentional field.

During the 2024-2025 volcano-seismotectonic crisis, the Fira fault ("Kameni line") is activated producing a shallow sequence which slowly initiated in the beginning of late September 2024 and is still in progress. More than 200 eventst were recorded within the study region for this period and their hypocentres were calculated using the NonLinLoc earthquake location algorithm (Lomax et al., 2000) along with the local 1D velocity model proposed for the region by Dimitriadis et al. (2009). The NonLinLoc algorithm utilizes the equal-differential-time (EDT) likelihood function (Zhou, 1994; Font et al., 2004), which uses travel-time differences between observed and synthetic travel times for pairs of stations, resulting to a more robust calculation of the optimal hypocentral location, due to the fact that the 4-D problem (x,y,z, t) is reduced to a 3-D search over space (x,y,z). Furthermore, mispicked phase data can be identified by the methodology and excluded from the solution. Due to the large number of local seismographic stations at a very close proximity to the sequence, for most of the located events the horizontal error was as low as 0.5km, whereas the vertical (depth) error was between 0.8-1.2 km. The majority of the sequence's hypocentres is located at shallow depths (3-8 km). The strongest earthquake (ML 3.6) occurred on January 25, 2025. The moderately linear horizontal trend of the epicentres is main the characteristic of the sequence.

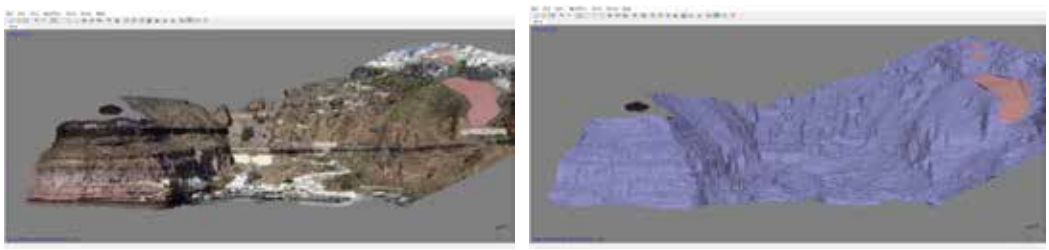

Figure 1. Digital Terrain Model of the Yialos cliff face, where the Fira fault is observed deforming the layers of lavas and pyroclastics. It was obtained through a targeted UAV campaign (Pavlides & Chatzipetros, 2018). Left image shows the outcrop photomosaic draped over the 3D model, which is shown at the right one.

The majority of earthquakes are thought to be caused solely by tectonic forces, specifically the Fira fault. If we additionally consider the estimation of the volume and depth of the magma intrusion, some of them are most likely caused by the volcanotectonic activity. More specifically, the Fira fault likely both facilitates the magma chamber's upward progress and marks it off to the south.

All evidence, both geological and seismological, indicate that the Fira fault is an active tectonic structure. Its activated length is estimated to about 6-8 km, corresponding to a moderate expected earthquake magnitude of Mw 5.5-6.0, as calculated from known empirical relationships (Wells & Coppersmith, 1994). The fault probably extends bilaterally, i.e. toward the NE, as shown by the seismic activity of the beginning of 2025, and toward the SW as well. Northward onward intracaldera tectonic structures formation example elucidates a swelling of the volcanic edifice.

The Fira fault, Santorini (Thera): morphotectonic, geomorphological and seismological evidence of fault activity

Pavlides S.[1], Sboras S.[2], Lazos I.[2], Mouzakiotis E.[2], Karastathis V.[2]

(1) School of Geology, Aristotle University of Thessaloniki, Thessaloniki, Greece, pavlides@auth.gr (2) Institute of Geodynamics, National Observatory of Athens, Athens, Greece

Introduction

The volcanic island of Santorini, *aka* Th(i)era, is located in the central part of the Hellenic Arc (or Hellenic Subduction Zone), in the South Aegean Sea, where the Nubian (African) and Eurasian tectonic plates converge (Figure 1; Pavlides *et al*., 2024 and references there in). Santorini has a rich geological history including recent tectonic and volcanic activity, particularly in the last century. The Fira Fault (*aka* Phera) is one of the most prominent active faults in Santorini (Figure 2). It outcrops on the eastern rim of the Caldera crossing the capital town of the island, in a NE-SW direction. Santorini's fault system includes numerous faults and fractures that contribute to its seismic activity, particularly around the caldera, which has been the focus of volcanic activity for thousands of years. The Fira Fault plays a key role in the ongoing geodynamic processes of the island. In addition to this fault, there are several other active faults around the caldera, including the "Kulumbo (or Columbo) line" and the "Kamenes line" (Pfeiffer, 2001), and others that create a complex tectonic pattern in the region (Figure 2; Mountrakis *et al*., 1998; see also Nomikou *et al*., 2021; Sakellariou *et al*., 2021).

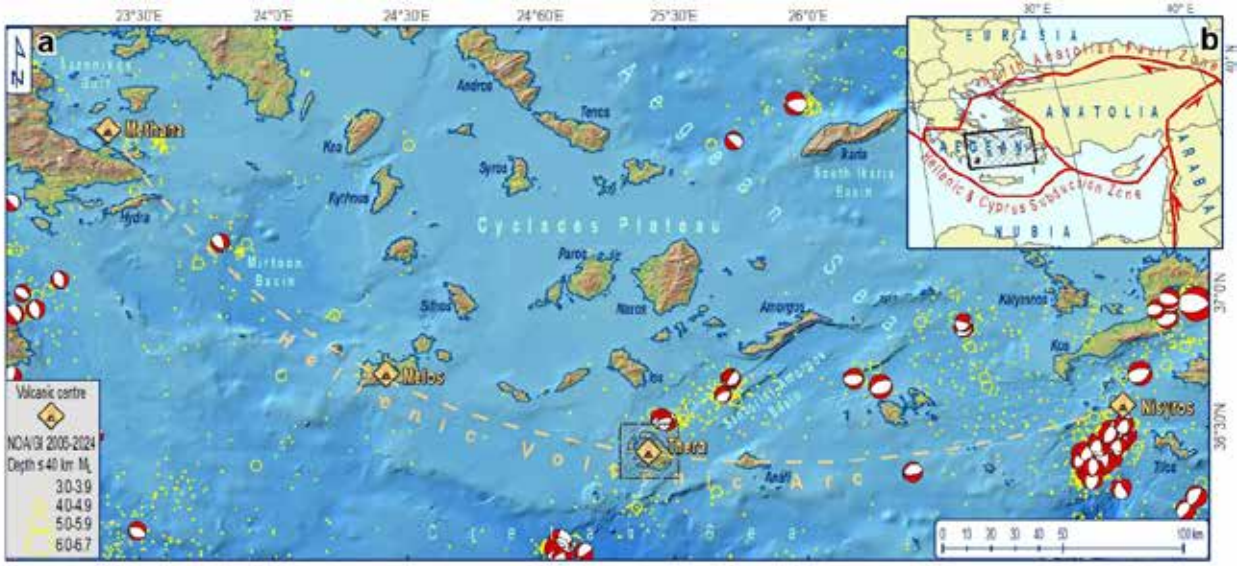

Figure 1. (a) Map of the South Aegean Sea showing seismicity (yellow circles; NOA/GI revised catalogue since 2006 for depths ≤ 40 km) and RCMT's focal mechanisms for depths ≤ 40 km (Pondrelli, 2002). The Hellenic Volcanic Arc is marked by an orange dashed line. Hatched frame indicates location of Thera as shown in Figure 2. (b) The tectonic plates boundaries in eastern Mediterranean Sea according to Bird (2003). Hatched frame indicates position of map (a).

Geodynamic & seismotectonic setting

The recent tectonic regime of the Aegean Sea is characterized by a regional extension deriving from the subducting slab's roll-back and retreat as the Hellenic Arc has been migrating southwards during the last 80 Myr (*e.g.* Le Pichon & Angelier, 1979; 1981; Jolivet *et al*., 2013; Barbot & Weiss, 2021; van der Stoel *et al*., 2024). This extension generates normal faults in the upper crust and rifting in the shallower part of the lithosphere (Jolivet *et al*., 2013). The extensional thinning of the crust facilitates the magma intrusion from the melting of the subducting slab and the emergence of the Methana, Melos, Santorini, Kolumbo and Nisyros volcanic centres which comprise the volcanic arc. The Santorini–Amorgos offshore basin is a crustal weakness zone in an overall right-lateral oblique-slip transtensional regime, representing a major structural boundary *(e.g.* Sakellariou & Tsampouraki-Kraounaki, 2019; Tsampouraki-Kraounaki *et al*., 2021).

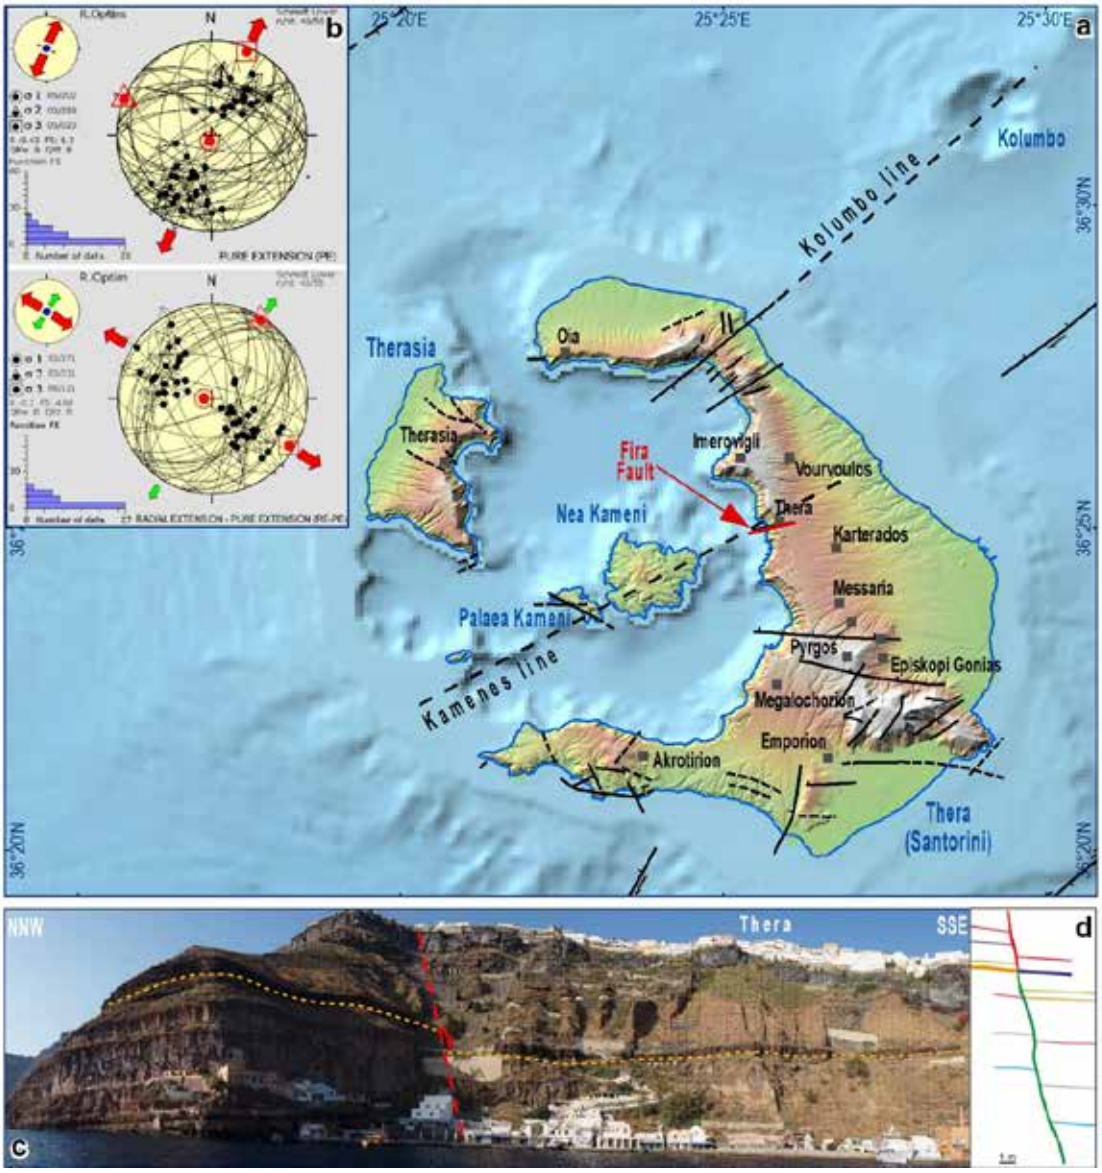

Figure 2. (a) Morphotectonic map of Santorini Island after Mountrakis *et al*. (1998). The "Kulumbo line" and "Kamenes Line" are modified from Pfeiffer (2001). (b) Meso-structural analysis of active faults on Santorini and surroundings showing two co-existing extensional stress fields: one (upper) due to pure tectonic forces (typical of the Aegean back-arc), and the other (lower) probably due to magmatic (local volcano-tectonic) forces (more radial extension). (c) Snapshot of a 3D image obtained from UAV depicting the inner caldera flank and the Fira fault cutting and downthrowing toward the SSE the lava layers (the most distinguishable layer is marked by a dashed orange line). (d) Sketch of the Fira fault and the displaced lava layers as shown in (c).

Santorini Island is an emergent remnant on the central and eastern flanks of a collapsed caldera. Its summit is preserved with over 50 active tectonic structures of the Middle Pleistocene to Holocene. Seafloor topography and subsurface fault data show a complex system of faulting from Christiana island to Amorgos island, with mainly NE trending normal and oblique faults in a right-stepping en echelon arrangement. A tectonic model demonstrating the occurrence of the volcanic centers at the fault segment boundaries is presented. In the case of Santorini – Amorgos Fault System, volcanic centers of Christiana Island, Thera – Kammeni and the submarine crater of Columbo are positioned in the boundaries of the right-stepping en echelon segments of normal and oblique faults. Fault segment boundaries comprise low strength multi-fractured parts of the upper crust, enabling insertion and ascendance of magma dykes. Possible interaction between volcanic activity and fault activation is also investigated based on the

early 20th century eruption activity in Kammeni islands and the 1956 double-earthquake event, as well as the 2011-12 volcanotectonic crisis. Dykes and fault swarms are the two main modes of brittle tectonics in the area. The active tectonic structures mainly consist of normal fault systems often in an *en-échelon* pattern. Reverse and right-lateral, or oblique-slip, faulting also occur in the area. Meso-structural analysis reveals the three main stress axes acting on Santorini and surrounding islets (Tranos & Pavlides, 2012; see also Tranos 2012): σ_1 in a NE–SW direction, σ_3 in a normal direction, and σ_2 in the third leading σ_2 direction. Santorini's tectonic structures are then probably the result of this stress field (Manning *et al*., 2020). Basaltic dykes, associated with neotectonic faulting, are another common feature in Santorini. They are aligned along the axial zone of the submarine caldera and are exposed on the marine cliffs, forming up to a 100-m wide rail on the caldera wall, concentrated on the northern narrow part of the island. The N30°E-trending arc (?) of Santorini and its orientation guide the spatial correlation in the dyke-fault system. This system is expected to be connected at depth because tensional fracturing is expected to occur in fissure eruptions and in the effects of ascending magma within the surrounding rocks (Mountrakis *et al*., 1998; Ruch *et al*., 2016). The orientation of the N30°E-striking structures, comprising mostly of normal and a few reverse faults restricted in the alpine basement, represent the local σ_3 axis. Northward, in the inner flank of the caldera, tectonic structures document a swelling of the volcanic edifice. The neotectonic map of Santorini in Figure 2 (Mountrakis *et al*., 1998) indicates the more recent tectonic structures and the active processes shaping the island's landscape. It shows the fault systems, including the Fira Fault and other fractures, which have been active in recent geologic and historical times. This map also highlights the zones of volcanic activity and deformation, which are critical for understanding the island's seismic hazards.
The faults that control the eruptive history of Santorini and changes of the magmatic chamber produce characteristic earthquake swarms. The 2011-2012 seismic crisis on Santorini is a typical example.

Morphotectonic study of the Fira fault

Neotectonic field studies on Santorini started in 1992-94 and were completed during 2016-22 (Figure 2; see Mountrakis *et al*., 1998; Pavlides & Chatzipetros, 2018). Among the on land mapped faults, the less studied is the Fira fault, named after the capital town of the Island. The fault has been a prominent feature of Fira cliff (Yalos harbour), and it has been described as a simple tectonic structure since the early French "Expédition de Morée (1829□38)". New airborne (UAV) and terrestrial (LiDAR) images were used to produce 2D and 3D photomosaics with photogrammetric methods so as to detect the location and map the Fira fault.
Meso-structural analyses, where the fault outcrops in accessible locations, indicate a normal dip-slip sense of movement with a right-lateral strike-slip component on an ENE-WSW (N60°E to70°E) striking fault. According to our 3D terrain model obtained from UAV images, on the very steep inner escarpment of the caldera, fault throw episodically decreases from 22 m at the sea level down to almost 2 m at the highest elevation where the Nomikos Conference Centre is built (Figure 2). At this point, the uppermost lava layer is affected suggesting a syn-depositional normal fault that deforms even the most recent volcanic lava layers and pyroclastic flow strata. This lava layer, which is also the last, 40-60 ka old, volcanic flow, documenting typical cooling fractures and tectonic open joints outcrop, has been vertically displaced. The episodic pattern of displacement can be interpreted as intermittent periods of possibly volcano-tectonic activity rather than simply tectonic. A non-typical fault scarp affecting the volcanics is detected in the urban area of Fira running subparallel to *i)* a longer "fault zone" which includes the known volcanic centres of Kamenes (Kamenes line), and *ii)* the large Amorgos-Thera seismic fault which produced the 1956 M7.5 earthquake (Kolumbo line). Due to its proximity to the "Kamenes line", the Fira fault can be considered as part of this line.
The Fira fault is classified as active, as it is documented not only from field observations, but also from the microseismic activity during the 2011□2012 volcano-tectonic crisis. Its activated length has estimated about 6 km, corresponding to moderate earthquake Ms 5.5 +_ , as calculated from known empirical relationships, while it is possibly extended both towards NE and SW.

Seismic Activity and the Volcanic Crisis of 2011-2012

During the 2011-2012 volcano-seismotectonic crisis, the Fira fault of the "Kamenes line" was activated producing a shallow sequence which slowly initiated in the beginning of late February 2011 and outburst in October of the same year (Kaviris et al., 2015). The strongest earthquake (M_L3.3) occurred on January 9, 2012; Five (5) earthquakes with $M_L \geq 3.0$ preceded and one followed the strongest shock.
The local seismicity for the period of interest was accurately located with the use of a local 1D velocity model proposed for the region by Dimitriadis *et al*. (2009), by applying the NonLinLoc -linear location algorithm (Lomax *et al*., 2000). The NonLinLoc algorithm utilizes the equal-differential-time (EDT) likelihood function (Zhou, 1994; Font *et al*., 2004),

which uses travel-time differences between observed and synthetic travel times for pairs of stations, resulting to a more robust calculation of the optimal hypocentral location, due to the fact that the 4-D problem (x,y,z, t) is reduced to a 3-D search over space (x,y,z). Furthermore, mispicked phase data can be identified by the methodology and excluded from the solution.

The majority of the sequence's hypocentres is concentrated at very shallow depths (2-6 km). The spatial distribution shows a quite well-formed cluster (cluster A in Figure 3 *left*) on the SW continuation of the Fira fault which moderately aligned along a NE-SW axis, *i.e.* parallel to the fault's strike. Two transverse profiles show the vertical extent of the sequence from ca. 1 km to 12 km depth (Figure 3 *right*). However, the density differs in the two profiles (Figure 3 *right*): in the profile B-B' it is much more concentrated than in profile A-A'. This also explains the moderately linear horizontal trend of the epicentres. In profile B-B', the density of hypocentres is much higher at depths shallower than 6 km. From this depth and deeper (down to 12 km), a much more linear, SSE steeply dipping trend can be observed, the upward continuation of which also marks the southern limit of the cluster. Thus, two sub-clusters can be distinguished: the shallow one, cluster A_1, down to the depth of 6 km, and the deeper one, cluster A_2, at depths between 6 and 12 km. Cluster A_2 is attributed to purely tectonic causes, and more particularly to the Fira fault. Cluster A_1 is probably due to the combined tectonic and volcanic (magmatic) activity if we also take into account the estimation of both volume and depth of the magma intrusion (Newman *et al*., 2012; Feuillet, 2013; Parks *et al*., 2012; 2015; Druitt *et al*., 2016). In more detail, the Fira fault probably restrains the magma chamber to the south and, at the same time, facilitates it movement.

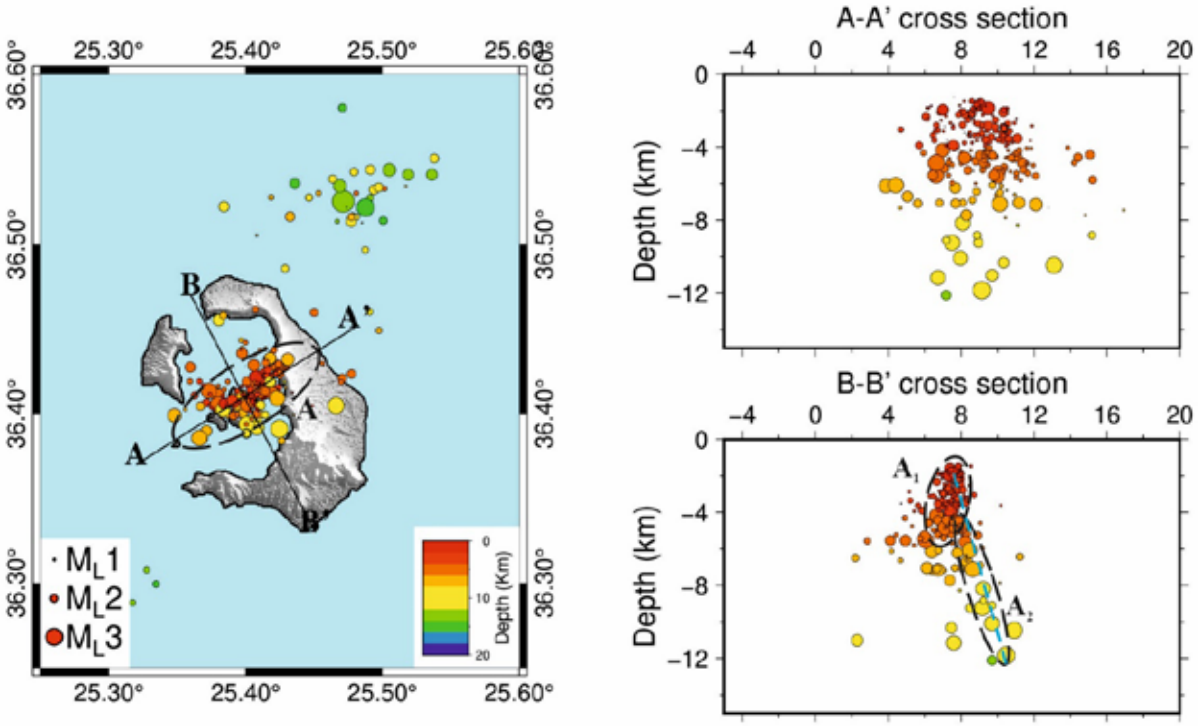

Figure 3. (Left) Relocated epicentres of the 2011-2012 crisis. The main cluster A is marked by a dashed ellipsis. A sparse concentration NE of Santorini Island is located under the Kolumbo submarine volcano. (Right) Vertical profiles of the 2011-2012 main cluster which is divided into two more sub-clusters (A_1 and A_2). The blue dashed line represents the Fira fault. The profile traces are shown on the left map.

The 2011-2012 volcanic crisis in Santorini was marked by increased seismic activity, volcanic unrest, and noticeable ground deformation. This period of volcanic crisis also involved:

- Ground deformation: There were reports of ground uplift, which is often associated with magma intrusion or movement beneath the surface (e.g. ISMOSAV, 2013). GPS measurements and InSAR images show both lateral extension and uplift, clearly suggesting inflation (Newman *et al*., 2012; Foumelis *et al*., 2013; Papoutsis *et al*., 2013; Saltogianni *et al*., 2014). This is typical in volcanic regions where magma rises and causes the earth's crust to stretch or deform.
- Magma intrusion: A magma intrusion of 10–25 million m^3 is estimated (Newman *et al*., 2012; Parks *et al*., 2012;

2015) at a depth of ca. 4 km (Druitt *et al*., 2016). This magma is suspected to be linked to the dyke systems beneath the island, contributing to the seismic events. A dyke system refers to a network of vertical or steeply inclined fractures filled with magma, often causing crustal deformation and triggering earthquakes.

Conclusions

The Fira normal fault shows significant tectonic evidence of recent activity such as fresh scarps and faulted and tilted late Quaternary volcanic strata. It has not been studied in depth.

- The Fira fault is a typical normal tectonic structure trending ENE-WSW, with a right-lateral oblique-slip sense of movement. It shows decreasing downthrow from the sea level to the top lava layer, indicating a syn-volcanic deposition fault growth.
- It is an active fault in the western part of the Santorini caldera rim, contributing to seismic hazard.
- It is a "segment" of sub-parallel, left stepping faults belonging to the larger fault zone of "Kamenes line", including the known volcanic centers. It is also subparallel to the 1956 earthquake great Amorgos-Thera fault. Its internal structure is complex (under investigation).
- The 2011-2012 volcanotectonic crisis was characterized by increased seismicity and ground deformation, linked to magma intrusion and fault activity, associated with the Fira fault. It was a segment of 6 km that was activated by a series of small-magnitude earthquakes, along the Kamenes volcanic line. It is believed to be longer.
- This known fault length corresponds to a minor or moderate earthquake.

Understanding these elements is crucial for monitoring and assessing the potential volcanic and seismic hazards in the region.

Acknowledgements

Bathymetric DTM data used in figures are obtained from the EMODnet Bathymetry (2022). On land DEM data derive from ALOS World 3D, 30-m DEM, v3.2 (Japan Aerospace Exploration Agency, 2021) and the National Cadastre and Mapping Agency S.A. (5-m resolution).

EXTENDED ABSTRACT 258

Geological routes on Ammouliani Island, northern Greece

Pegioudi E.[1], Chatzipetros A.[2]

(1) University of the Aegean, Mytilene, Greece, pegiou@hotmail.com (2) Department of Structural, Historical and Applied Geology, School of Geology, Aristotle University of Thessaloniki, Greece, ac@geo.auth.gr

Introduction

The study area is an island located west of Agio Oros (Mt. Athos) peninsula. It consists of basement rocks of Kerdilia and Vertiskos Units (Kockel et al., 1977), intruded by younger magmatic products. Ammouliani Unit is suggested as a new Unit, between Kerdilia and Vertiskos Units (Plougarlis & Tranos, 2015). Published geological maps featuring the island are: (1) Geological Map of Chalkidiki peninsula and the surrounding region, scale 1:100,000 (Kockel et al., 1977), (2) Geological Map of Greece, Ierissos Sheet. Scale 1:50,000 (Kockel et al., 1978), (3) Geology of Ammouliani Island (Northern Greece), scale 1:10,000 (Plougarlis & Tranos, 2015), (4) Geological Map of Greece, scale 1:500,000 (IGME). The pre-alpine basement rocks are characterized by a general ENE-WSW strike and generally intermediate to large angles of dip, mainly towards the WNW. The northern part of Ammouliani is characterized by the rocks of Kerdilia , Vertiskos, and Ammouliani Units. The southern part of the island consists of Ammouliani's granitoid, which is considered to be part of the Sithonia/Ouranoupoli-type granite (Papapavlou, 2021).

Objectives

The aim of this paper is to propose georoutes on Ammouliani Island, targeted to both the scientific community, as well as the general public. This enhances the potential of an alternative form of tourism in this area and suggests a different approach to the economic and cultural development of the island. It promotes geology as a multidisciplinary scientific field accessible to everyone. It encourages people to become familiar with this science and cultivate curiosity for their surroundings. The island's geology contributes to its unique character and beauty, which has been valued by tourists and the scientific community.

Methods

Pre-existing studies of the island and the wider area were collected and, their description of general geology was unified. Also, this work utilizes the 1:12.000 topographic map of the area from the Ierissos Sheet (1:50,000) of the Hellenic Army Geographical Service using the Quantum Geographical Information System (QGIS). A detailed geological study was carried out and confirmed the evidence of previous researchers who studied this island. Based on the most recent 1:10,000 scale map (Plougarlis & Tranos, 2015), the geological sections of the same scale, and visitor accessibility, decisions were made about possible geopaths that could be mapped and documented. Fieldwork along these geopaths was conducted and original structural data were acquired. They were exported and analyzed using the appropriate software for each product. A digital topographic map of the area and a Digital Elevation Model (DEM) were created, as well as digitized detailed geological maps. All data, as well as the results of the quantitative structural analysis of faults, folds, schistocity etc., were incorporated into an integrated GIS database, of which any query can produce various outcomes. Three geological trails were selected for presentation, the technical information of which is shown in Table 1. Their profile is generally gentle, with occasional small irregularities (Fig. 1). They are shown in the summary map of Fig. 2.

Table 1. Technical details of georoutes

Georoute	Max Altitude	Average Duration	Max Incline	Average Incline	Existing Road
1.1-1.5	74 m	1:05 h	32.6%	7%	Yes (1.1-1.2), No (1.2-1.6)
1.7-1.11	23 m	1:15 h	22.5%	6.2%	Yes
2	67 m	2:00 h	31.1%	7.3%	Yes
3	65 m	2:30 h	31.5%	7.4%	Yes

Figure 1. Georoutes elevation graph.

The purpose was to cover the geology of the entire island, showcasing specific sites, and ensuring convenient visitor access to existing roads. The rocks mentioned in each area are based on the already existing geological map of 1:10,000 scale (Plougarlis & Tranos, 2015). An effort was made to categorize them in geotopes according to the geology they highlighted.

Results and Conclusions

Georoute 1 focuses on Sithonia-type granite intrusions into the existing bedrock. Georoute 2 refers to the gneisses of the Kerdilia and Ammouliani Units. Georoute 3 focuses on the biotite-mica gneiss of the Vertiskos Unit, however, geosites of the Ammouliani Unit have also been chosen to be presented, so a comparison of the two types of lithology and their characteristics is achieved. Additionally, two locations of structural interest have been selected as Geosites 4.1 and 4.2 on Karagatsia Beach. The study refers to all the rocks mapped on the previously mentioned 1:10,000 scale geological map, except for the marbles of the Kerdilia Unit, which had limited outcrops in areas that are currently under building construction.

Georoute 1 (Fig. 3)

This route is 4.5 km long, crosses Ammouliani's gneissic granite and is divided into two branches in the middle of the hiking path, southeast of Agionissi Resort. The first branch (Georoute 1.1) passes from the southernmost part of the island and moves along Psili Rachi, reaches 74 m altitude, and ends before Turkolimano beach. The second branch (Georoute 1.2) continues the road in the northern part starting from Agionisi Resort, reaches an altitude of 24 m and has direction to the north-east part of the Island. The granite of this area is mentioned by Plougarlis (2011) as the Eocene granitoid of Ouranoupolis and Sithonia.

The route starts from Ormos Glastri (location 1.1). In this location, the separation of the granite body, which is a typical plutonite structure, is evident. The granitic bodies are produced by magma in its cooling stages. The exposure of a granitic body at its surface causes corrosion, disintegration, and deformation associated with the creation of the plutonite. The structure that develops in the igneous masses is shaped during its cooling conditions and the process of intrusion of the magmatic body from the moment it is finally consolidated. These later forms non-tectonic rock separations (Vidal Romaní, 2008). Those form outcrop along Georoute 1.1. At Georoute 1.2 the fault and the crustal-deformation phenomena are firstly presented at Plougarlis & Tranos (2015) map.

Georoute 2 (Fig. 4)

Georoute 2 is approximately 3.7 km long and crosses the rocks of the Kerdilia Unit, including the plagioclase-microcline gneiss, and the Ammouliani Unit. It represents an attempt to trace the path along cross section A-A', as outlined by the most recent geological mapping (Plougarlis & Tranos, 2015).

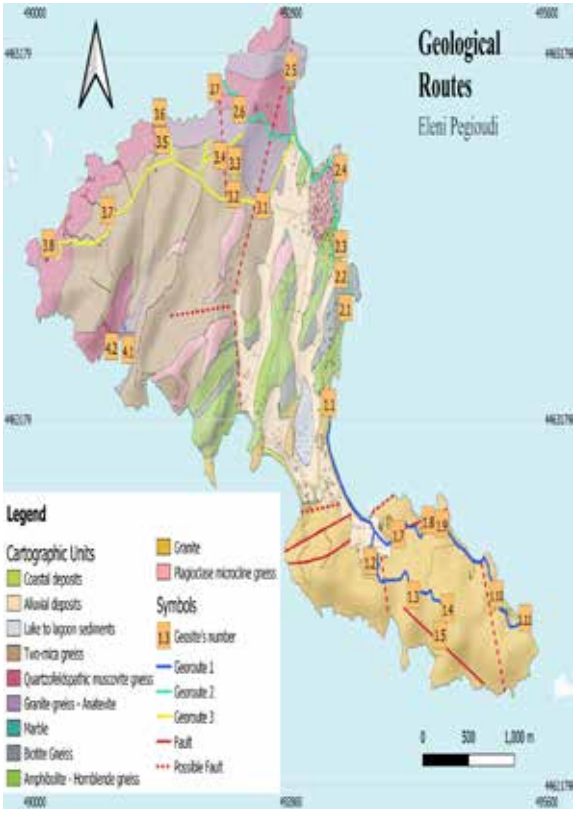

Figure 2. Geological Map of Ammouliani Island (modified from Plougarlis & Tranos, 2015) with the proposed georoutes and geosites

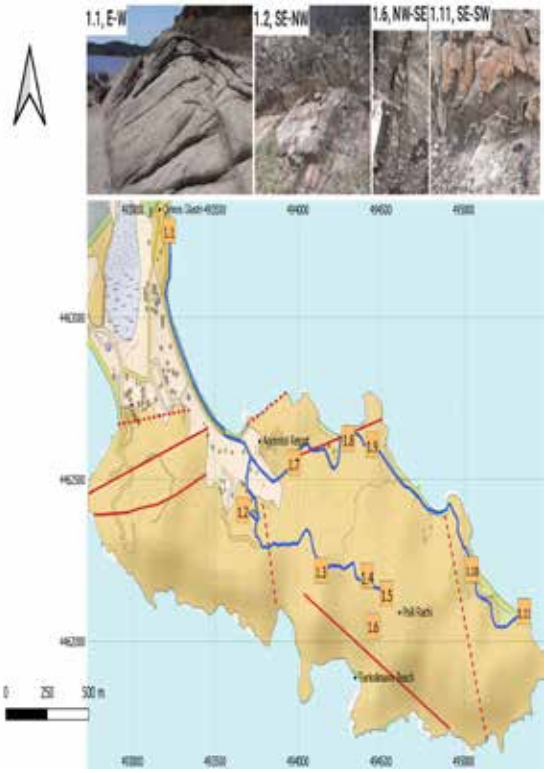

Figure 3. Georoute 1 at the southern side of the Island. Photos show a selection of geosites along the georoutes as well as the viewing orientation

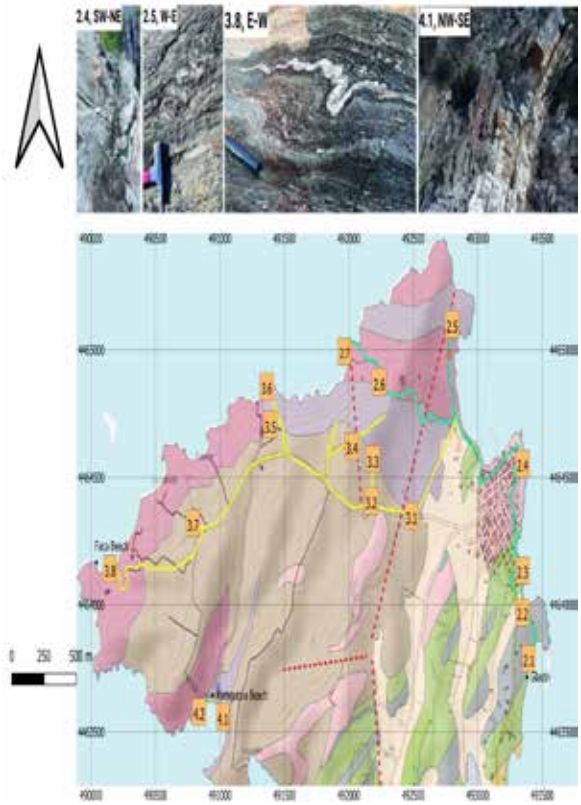

Figure 4. Georoutes 2,3,4 at the northern side of Ammouliani Island. Photos show a selection of geosites along the georoutes, as well as the viewing orientation.

Georoute 3 (Fig. 4)

This geological route is 5.2 km long and primarily features two-mica gneiss and its geological contacts with the Ammouliani Unit. The brownish two-mica gneiss belongs to the Vertiskos Unit and consists of quartz, plagioclase, muscovite, and biotite, with rare garnet, chlorite, and epidote occurrences. These gneisses are often interbedded with quartzofeldspathic muscovite gneiss of light brown-beige color, consisting of quartz, plagioclase, and muscovite. Additionally, muscovite-garnet gneisses appear as layers a few meters thick within the two-mica and quartzofeldspathic muscovite gneiss. Within the two-mica and quartzofeldspathic muscovite gneiss, augen gneisses with a variety of thickness that extending for several kilometers are observed, often showing features of intense shearing and mylonitization. Mineralogically, they consist of quartz, plagioclase, K-feldspar, muscovite, biotite, and in smaller amounts, hornblende and epidote.

Georoute 4 (Fig. 3)

An attempt was also made to trace two additional geological routes in the northwest part of the island; however, the flat geomorphology, the road network, cultivated olive groves, and vegetation inhibited exposure of rocks. However, there is information about Karagatsia Beach, which could be an interesting geological site, as its rocks belong to the Ammouliani Unit and are in contact with the Vertiskos Unit.

Discussion

The island, despite its small area, presents a variety of structures and lithological types. A multitude of kinematic indicators characterizes its entire range, while at the same time, it varies petrologically. Various types of rock deformation, such as faults, are quite new. Further studies of it may contribute to the disciplines of petrology, structural geology, stratigraphy, and neotectonics. Its small area and rich geology are suitable for developing geotourism for interested parties. Routes are easy to use for educational purposes, as they are short, have good accessibility, and are not physically demanding.

Acknowledgments

The first author would like to thank her family and friends for fieldwork assistance and georoute validation. The authors would like to thank an anonymous reviewer for their comments.

Introduction

Over the last decade, microplastics (MPs) have increasingly attracted the attention of both the scientific community and the public. Microplastics are usually defined as plastic particles <1 mm but in a broader sense as all particles < 5 mm. A large proportion of MPs form unintentionally, for instance through the decomposition of larger pieces of plastic waste (i.e., secondary MPs). However, tiny fragments of synthetic or chemically modified natural polymers are also produced to be used as such or added to products (i.e., primary MPs). In 2022, the European Chemical Agency (ECHA) estimated that more than 42,000 tons of intentionally present microplastics are eventually released into the environment each year. The widespread presence of MPs, both in the terrestrial and marine environments, also in surface and groundwater has only been recently demonstrated (e.g., Yu et al., 2020, Drummond et al., 2022, Perraki et al, 2024), Microplastics have also been detected in the food chain, and eventually enter humans (De-la-Torre, 2020), highlighting their pervasive impact. In this study, we analyze water samples collected from two caves at the Atzinolakkas area of Lefka Ori in Crete, a uniquely remote location, to determine whether the water is contaminated by (MPs). We performed water sampling at three locations using glass vials to minimize contamination from external sources such as equipment or clothing. The sampling sites were selected to ensure maximum spatial coverage of the caves.

Setting

Our study area is in Atzinolakas (or Atzines), on the northern side of the Lefka Mountains in the Chania Prefecture of Crete (fig.1), approximately 2 km east of the Agio Pneuma summit (2262 m). The broader area hosts more than 1000 caves (Adamopoulos, 2013) including the two deepest caves in Greece, the Gourgouthakas and the Lion caves namely. These caves are part of a larger hydrological system that composes the recharge area of the Koiliaris drainage area (Lili et al, 2020) and that most probably discharges at the Stylos spring.

The karst system of the White Mountains comprises an autochthonous geotectonic unit (Plattenkalk nappe) and two allochthonous units: the Western Crete unit (Trypali limestones and phyllites) and the Arna unit (metamorphic schists). Within the alpine nappes, the Plattenkalk nappe exhibits a stratigraphic sequence, from base to top, as follows: a)karstified unbedded dolomites, b) dolomitic marbles, c) thinly bedded calcitic marbles intercalated with chert layers and nodules, d) metamarls and limeschists.

Although the geological composition of the area appears to be quite uniform, it shows both spatial and deep changes. Based on the observations made during the visits to the cave, black dolomites with brecciated textures are predominant in the wider region, especially south-west of the entrance to the Gourgouthakas cave. Surrounding the Gourgouthakas cave entrance, partially recrystallized and locally brecciated white limestones are observed. This lithological unit persists within the cave to a depth of 522 m below the cave entrance, where transitions to thick bedded to platy limestones occurs, the same succession continues to 850 m below the entrance. Between 646 and 670 meters, interbeds of green schist are encountered.

In climatic terms, the western part of Crete, and particularly the Lefka Ori, is characterized by significant winter precipitation, estimated at around 2331 mm (Agou et al, 2019). The winter low pressure associated with the North Atlantic Oscillation (NAO) typically originates in the Atlantic near the Strait of Gibraltar. These systems exhibit a

northeastward trajectory, generally skirting the Adriatic Sea. Consequently, significant rainfall is primarily confined to western Greece. As these frontal systems approach Greece from the west, they induce predominantly southwest winds over the Ionian and Aegean Sea, thereby advecting maritime air masses eastward (e.g. Pennos et al., 2018).

Figure 1. Topographic map of the broader study area. Red rectangle highlights the Atzinolakas caves (basemap: Google satellite; GGRS87).

Methods

The water samples were collected at three different locations in Gourgouthakas, Lion Cave and LO23 cave systems in August 2024 Gourgouthakas-Liontari caving expedition. Glass vials of 30 ml were used as sampling containers. To minimise the risk of contamination from external sources such as equipment or clothing the sampling group performed the sampling in the beginning of the expedition. In the Gourgouthakas Cave, the Marcel Waterfall was designated as the sampling site (fig.3a&e). In Lion Cave, dripwater was collected (fig. 3b&d) from a location situated above the first hotspot, minimizing the potential for external contamination. In LO23 Cave, the spring utilized to supply the expedition's water requirements served as the sampling point and a small stream with continuous flow was selected (fig.3c). Unfortunately, the sample obtained from Lion Cave was lost during transport as the vial broke. Concurrently with the MP sampling, in situ measurements of the electrical conductivity (EC) were carried out on water samples from the same sampling sites.

Samples were filtered using a filtration device, a mechanical pump (-100kbar) and filter membranes (Macherey-Nagel, 47 Ø and 0.45 μm pore size, REF: 65300045047). Before filtering the samples, we performed a cleaning round with double filtered de-ionized water, to ensure that the apparatus was cleaned to proceed with blank samples. A negative blank sample (BL1) was prepared prior to analysis. All filters were covered with glass Petri dishes and stored in a controlled environment in a closed laminar flow hood for 24h to dry. After filtration a second negative blank (BL2) was prepared and intentionally left uncovered to measure possible air contamination inside the laminar flow hood. Each surface was cleaned with 95% ethanol prior to analysis and cotton labware, and glassware were used during the whole procedure. No pretreatment protocol was applied.

Particles were quantified using a Leica Ivesta 3 stereoscope (x40-x63 optics) with a Leica Flexacam C3 attached at the Laboratory of Mineralogy and Geology, Department of Natural Resources Management and Agricultural Engineering, Agricultural University of Athens. The material was sorted based on its visual characteristics (size, color, shape, degradation degree) (Hidalgo-Ruiz et al., 2012) and classified as potential microplastics using the LASX image analysis software. The particle size was estimated based on the Feret min diameter.

Subsequently, μ-Raman analysis was performed on 10 suspect particles (24%) without further treatment, using a Renishaw inVia Reflex micro-Raman at the School of Mining and Metallurgical Engineering of the Technical University of Athens, Greece. The spectra were excited at room temperature with the 532 nm excitation wavelength of a diode laser, in the spectral range from 200 cm^{-1} to 2000 cm^{-1}. Spectra acquisition time was set to 10s, 1 accumulation cycle and laser power at 1%. The spectra were processed with the WIRE 3.4 software.

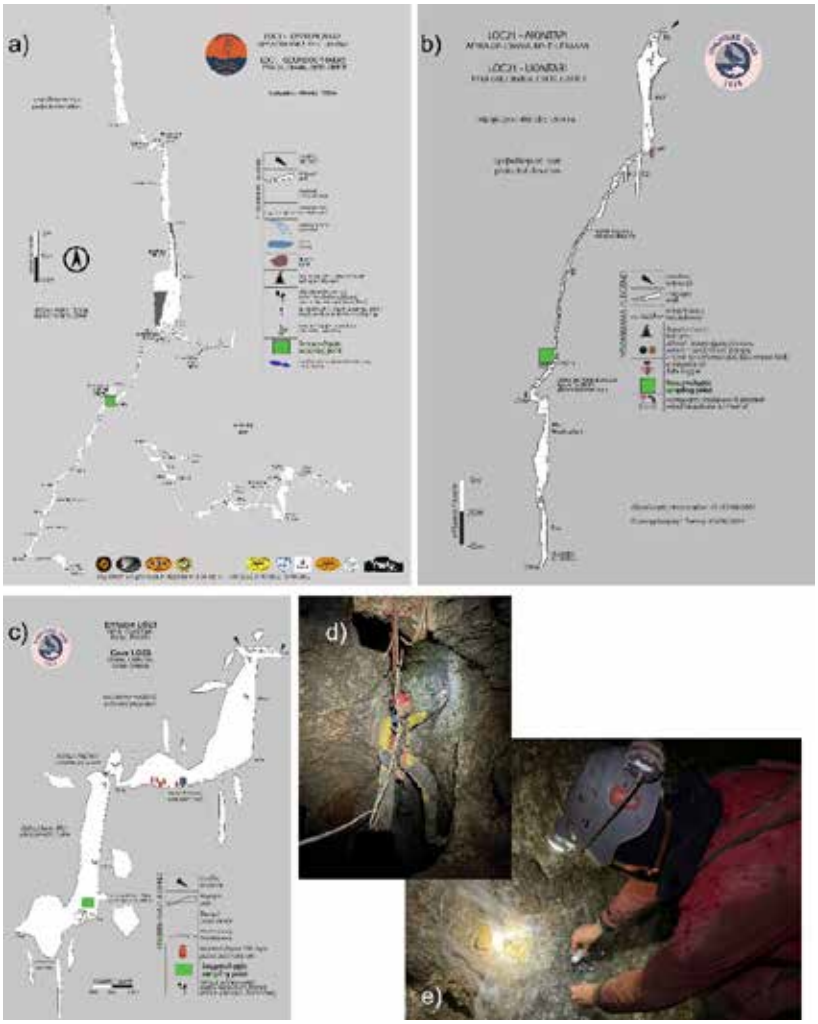

Figure 3. Extended projection of caves. a) Gourgouthakas cave, b) Lion cave, c) LO23 cave. d&e) collecting water samples in Lion and Gourgouthakas, respectively. Cave surveys are courtesy of Gourgouthakas expeditions.

Results

A total of 42 particles in the form of fibers and fragments were visually identified and classified as potential microplastics. Sample LOC1 contained 16 fibers and 4 fragments (fig.4). The predominant fiber color was blue (56.25%) followed by transparent (31.25%) and red (12.5%) (fig.5). Irregular fragments were only found in red color (100%). Regarding size, fibers in the LOC1 sample were distributed in 3 size classes namely, <500 μm (37.5%), 501-1000 μm (31.25%), > 1001 μm (31.25%), indicating a relative size homogeneity in their distribution. On the other hand, all fragments were measured with a size of <50 μm (100%). In the LO23 sample, a total of 22 particles were identified divided into 14 fibers and 8 fragments (fig. 6). Fibers were mostly transparent (71.43%) followed by blue (21.43%) and red (7.14%). Fragments were mainly blue (62.50%) but red, black and white colors were observed (12.5% each). Fibers were distributed in 3 size classes namely, <500 μm (50%), 501-1000 μm (35.7%), > 1001 μm (14.28%), with the <500 μm size class occupying 50% of the total fibrous material. Fragments were measured to be <50 μm (37.5%) and >51 (62.5%). Blank samples were also visually observed. BL1 had 2 fibers (transparent and black) and BL2 (opened Petri dish) had 2 white fragments and 1 blue fiber. Contamination was neither classified nor considered in the results. Raman spectroscopy of selected microplastic particles, revealed a very strong overlap of the MP peaks with the pigment peaks and in particular the indigo blue [547(s), 599(s), 939, 1010, 1147, 1252(s), 1297, 1310, 1365(vs), 1462, 1484, 1579(s), 1585, 1609, 1697 cm-1 (s)] and the copper phthalocyanine blue [peaks at 484, 594, 681(s), 748, 954(s), 1342(s), 1452(s) and 1529 cm-1 (vs)]. Besides, Raman peaks of polyethylene oxide (850, 1283, 1374cm-1) were also identified.

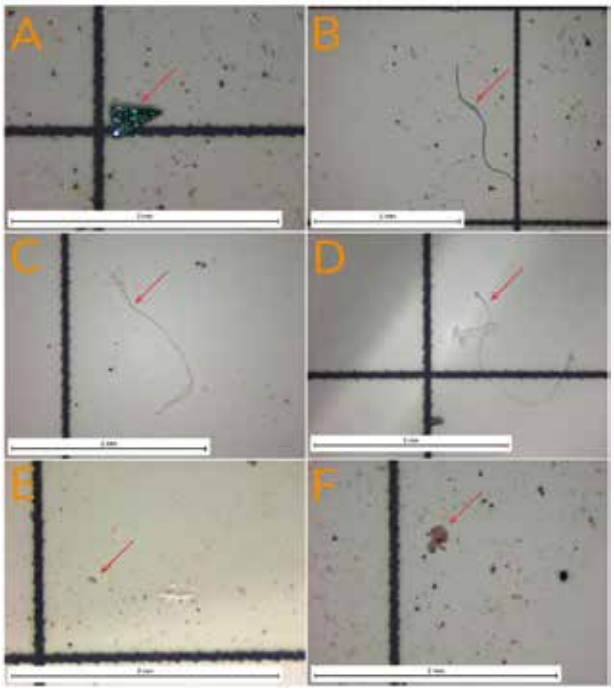

Figure 4. Particles identified as potential microplastics under the stereoscope in both samples: (A) black fragment, (B) blue fiber, (C, D) transparent fibers, (E, F) red fragments.

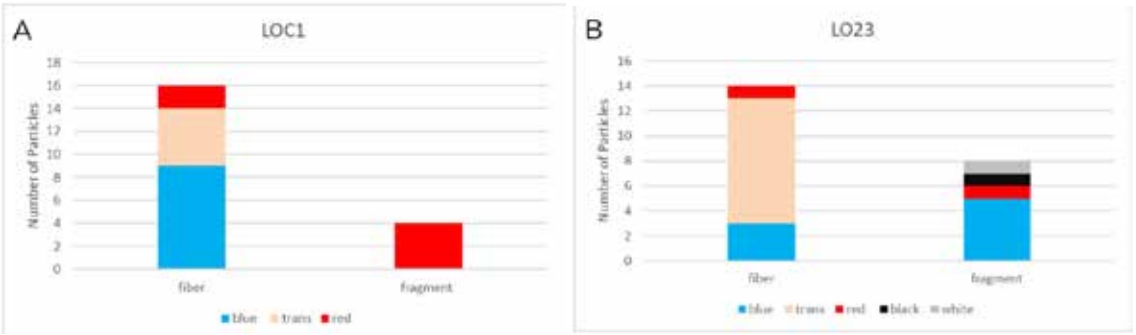

Figure 5. Total particle number of LOC1 (A) and LO23 (B) samples sorted by particle type and color, based on stereoscopical observations.

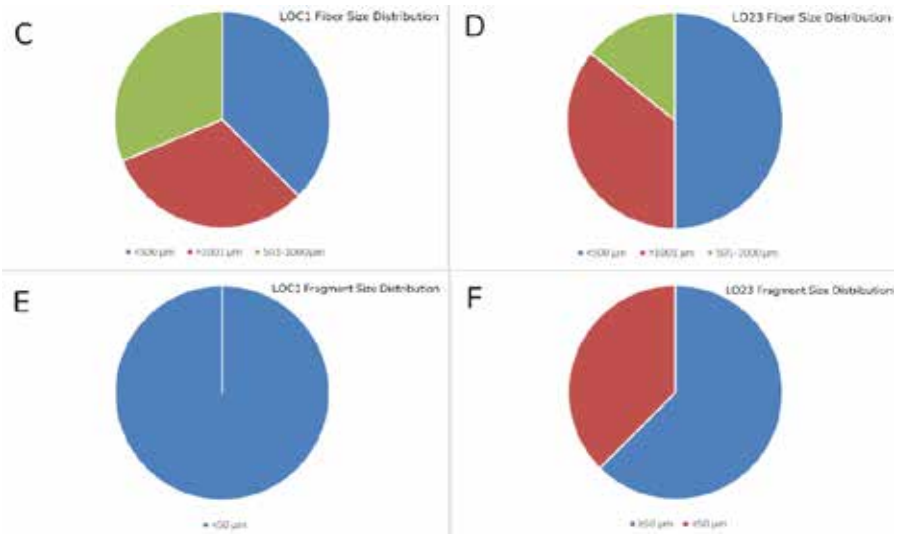

Figure 6: Distribution of fibers and fragments in LOC1 (C, E) and LO23 samples (D, F) based on stereoscopical observations.

The measurements on each sampling site showed similar EC values. In detail, in Gourgouthakas cave at the Marcel waterfall site the EC was 196 μS/cm at 9.6 °C, in Lion cave the EC of the drip water was 188 μS/cm at 9.3 °C. Finaly, the sample from LO23 exhibits EC of 180 μS/cm.

Discussion

Electrical conductivity measurements of the cave water samples exhibited values below the average reported for Greek karstic springs (Li Vigni et al., 2023). These low values of EC suggest a relatively short residence time within the karst aquifer and the recharge from the meteoric water. Despite the deep location of the sampling points within the karst massif, the observed low conductivity indicates rapid water percolation. This rapid flow likely occurs through high-permeability pathways, enabling swift infiltration and limited interaction with the limestone bedrock. Furthermore, the low water temperature recorded during mid-summer in the northern hemisphere strongly suggests a significant contribution from snowmelt, likely to originate from residual snow patches within the catchment area.

The presence of microplastics (MPs) in the collected samples suggests that it was transported to the sampling sites with infiltrating water. Given the remote location of the area above the caves and the minimal anthropogenic activities, a plausible transport mechanism for the MPs is proposed. Aeolian transport by westerly winds may have carried MPs from regions west of Crete, similar evidence was recorded recently to Mt. Tymfi's Alpine Lake (Salmas et al, 2024). These MPs could have subsequently precipitated snowfall during winter months. During summer, snowmelt would have introduced the MPs into the karst system, facilitating their rapid transport to the sampling points (fig. 7).

While this interpretation is based on limited data, it highlights the potential environmental hazard posed by aeolian-transported MPs and warrants further investigation.

Introduction / Background

In recent years, the Acoustic Emission (AE) method has seen significant advancement and usage in the field of rock mechanics for monitoring the gradual fracturing process and stress-induced damage due to crystal or grain sliding, crack growth and coalescence. The AE technique has been used both in laboratory and in-situ applications, especially in tunnels for studying the elastic wave propagation characteristics and acquiring parameters that can reflect the rock fabric and damage evolution process before the macroscopic rock failure. Acoustic Emissions consist of elastic sound waves that are transmitted from the interior of a localized source (etc. rock sample) during crack development. These elastic waves are the result of stored accumulated energy that suddenly releases during external loading. The resulting AE waves propagate through the rock and then captured from specialized surface piezoelectric sensors. The sensors convert the mechanical waves into electrical signals and record them as AE events (Hits) in specialized acquisition programs. Several parameters can be extracted from the raw data such as hits, amplitude, frequency, duration and energy of the AE signals.
According to literature, the AE method has been used in the laboratory for the determination of various values and factors such as (1) the AE activity regions (Boyce et al., 1981) and their connection with the main cracking stages, namely the crack coalescence (σ_{cc}), the crack initiation (σ_{ci}) and the crack damage (σ_{cd}) stages in the stress-strain diagram (Martin C.D., 1993), (2) the B-value factor whose reduction during the loading process provides insight on the gradual failure and the stability of the rock (C. H. Scholz, 1968) and has been used as a risk assessment tool in various civil projects (Gerd Manthei et al., 2018) and (3) the Felicity ratio (FR) after several loading cycles that can be used as a rock's quality index (Kallimogiannis, 2023). Outside the laboratory scale and into the deep tunnel construction, the already complex in-situ stress environment is redistributed during excavation causing microcrack and later macrocrack generation if the crack initiation load is exceeded. As such, AE monitoring has been utilized together with numerical simulations and laboratory AE tests in several underground mining and tunneling projects to examine the size of the excavation-disturbed zone (EDZ) (Stephen D. et. al., 1996), determine the rock mass strength parameters through back-analysis (M. Cai et. al., 2006) and predict hazards such as rockbursts (A. Hirata et. al., 2006), thermal induced dilation (J Hesser et. al., 2015) and ruptures of not-persistent joints (Shuting Miao et. al., 2024).
The failure mechanism and consequently the acoustic emission (AE) activity is strongly influenced by the rock's texture, mineralogical composition, and formation history (Gramberg, 1989). In particular, fine-grained monomineralic rocks tend to fail abruptly as σ_{cd} and σ_c almost occur simultaneously. In contrast, more ductile or plastic rocks exhibit lower AE activity, partly due to the deformability of clay minerals. Additionally, factors such as porosity and lamination significantly affect the microcrack development mechanism.

Objectives

In this study, the AE method was implemented during Uniaxial Compressive and Cyclic loading laboratory tests* in several rock types such as a Limestone both in intact and karst form from Revithousa island, a tectonized Mudshale from South Crete and a Trachyandesite from Poros island. The scope of this study is to examine if the determination of the above factors with the Acoustic Emission method can be utilized as a basic monitoring tool both inside the laboratory and in underground construction projects, providing greater insight into the rockmass behavior from the standard rock mechanic tests.
*All the tests were executed according to the ISRM standards in the laboratory of Engineering geology and Rock-mechanics (NTUA) in the School of Civil Engineering

Physical parameters

Before proceeding with the Uniaxial Compression Tests (UCS), itis necessary to obtain the rocks' physical parameters. Particularly, the density (pd, psat) and porosity (n%) of every rock type was determined using the saturation and caliper technique in at least three specimens. The results are given in **Table 1**. Some noteworthy findings include 1) the high density (2.77) and the inversely proportional low porosity (< 1%) of the intact Limestone indicative of its very high strength (Koukis et al., 1998) and 2) the high porosity (n=19%) of Trachyandesite which depicts the vesicular, but otherwise homogenous texture with albite, anorthite and biotite phenocrystals. These rocks' characteristics were also confirmed by measuring the primary-P and secondary- S ultrasonic wave velocity. In general, higher rock density facilitates faster propagation of sound waves. Finally, petrographic (via stereoscope) and if necessary XRD- analysis was conducted to derive the exact mineralogical composition of every rock.

Table 1. Physical properties (density and porosity) and ultrasonic wave velocity of every rock type.

Rock type	pdry	psat	ps	γdry	γsat	n	VP	VS
	*10^3 kg/m^3			kN/m^3		%	m/s	
Limestone (L)	**2.77**	2.77	2.79	27.2	27.2	**0.63**	6549	3945
Karstified Limestone (KL)	**2.53**	2.59	2.68	24.9	25.4	**5.49**	4197	2328
Trachyandesite (A)	**1.99**	2.18	2.45	19.5	21.4	**19.00**	3033	1769
Mudshale (S)	**2.62**	2.63	2.66	25.7	25.8	**1.57**	3749	2228

Experimental set-up for UCT tests

A servo-hydraulic load frame with a built-in load cell was used for loading the specimens under a constant stress rate (MPa/s). Axial and circumferential strain gauge extensometers were used for the strain measurement. The AE activity was recorded by two AE sensors connected via a signal pre-amplifier in the specialized AE data acquisition system. Full contact between the specimen and sensors was achieved using an ultrasonic gel couplant. Finally, HRC58 steel discs were positioned between specimen and load platens for minimizing the friction's influence in the AE signal. The exact sensor arrangement is presented in **Figure 1**.

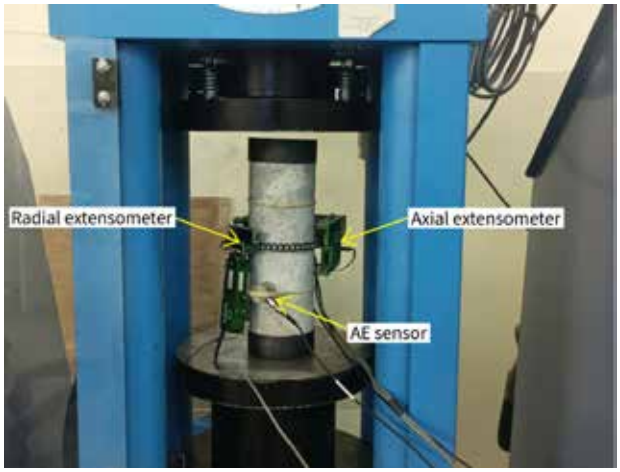

Figure 1. Experimental setup for the UCT-AE laboratory tests

Uniaxial Compressive Test with AE measurement (UCT-AE)

Before further examination, the first UCT results including strength, Young modulus and Poisson's ratio for every rock are presented in **Table 2**. Two sets of parameters (⊥ and //) were derived for Mudshale, based on the orientation of laminas with respect to the loading axis. The resulting stress-strain curves were divided into four microcracking stages, as presented in **Figure 2** (Martin CD et. al., 2001).

Table 2. Average values of strength and elastic parameters for every rock type.

Rock type	Limestone	Karstified Limestone	Trachyandesite	Mudshale (⊥ and //)	
σc (MPa)	106.5	31.0	20.2	54.6	23.8
E (GPa)	79.2	30.3	8.0	23.3	13.6
v	0.15	0.28	0.24	0.10	0.13

The brittle behavior of limestone is evident, as the elastic stage covers most of the loading range and is difficult to distinguish from the stable cracking stage. Also, the unstable cracking stage is presented just before failure within the final 5% and there is no post- failure stage. Karstified Limestone behaved similarly with a limestone breccia. The loading curve presents a clear distinction between the elastic and stable cracking stages, but from there the rock presents two different stages of severe cracking, the first one at around at 75% and the second at 98% of the total strength just before ultimate failure. In Trachyandesite, the microcrack coalescence was favored by the high porosity. Moreover, all failure stages are clearly visible. The Mudshale underwent the most significant deformation and failed by shearing along its laminations.

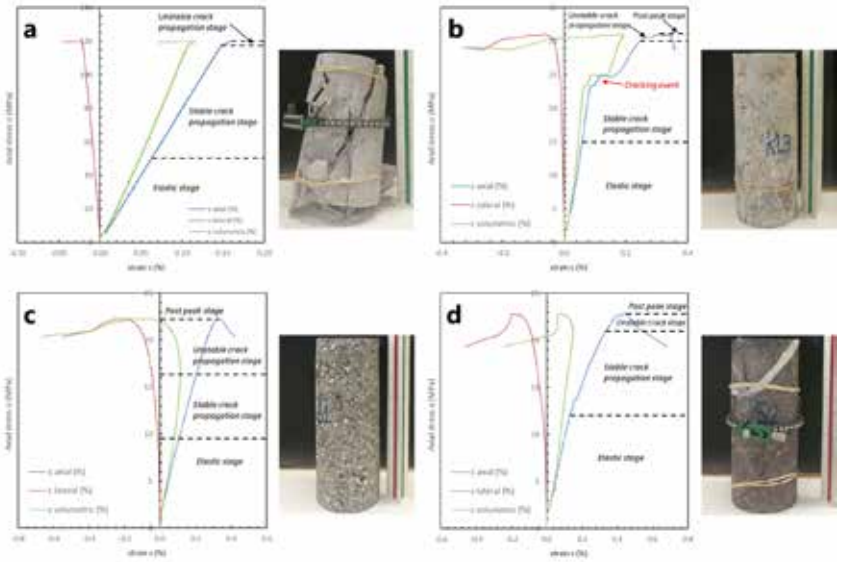

Figure 2. Distinction of microcracking stages along the stress–strain curve for every rock type. a) Limestone, b) karstified Limestone, c) Trachyandesite and d) Mudshale.

Microcracking stages determination with the AE method

Both microcracking stages (σci and σcd) were determined from the AE data by plotting the graph of the cumulative acoustic emission hits versus the axial stress (**see Figure 3**). Particularly, the microcracking stages correspond to the points of abrupt AE hit generation (i.e., where the slope of the curve suddenly increases). If the curve displays a continuous concave-up trend, precise determination becomes difficult. Therefore, the AE hit rate was employed as an alternative (Kallimogiannis, 2016). Moreover, AE activity is strongly influenced by the presence of pre-existing weak surfaces within each rock (e.g., veins, discontinuities). As such, it should be noted that the selection of the following values is subjective and relies on the user's experience.

Based on the results, the standard deviation for σ_{ci} is much lower (**see Table 3**), so it can be considered a more appropriate value for characterizing the mechanical behavior of the rock. The σ_{cd} is very close to the ultimate failure in the brittle rocks. On the other hand, the unstable cracking stage comes earlier in the porous or semi-plastic rocks, as they are slowly losing the ability to bear increasing loads. This microcrack generation and propagation is accompanied by increasing deformation (both axial and radial) and dilation.

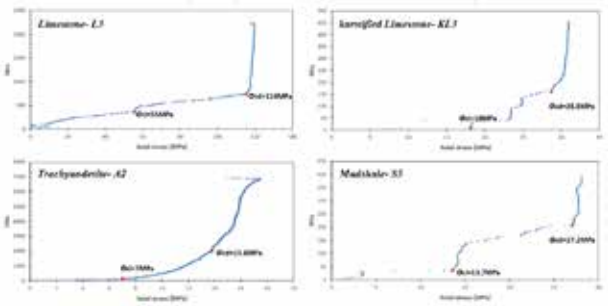

Figure 3. Examples of the produced AE hits vs stress curve for every rock type. The σ_{ci} and σ_{cd} values have been marked.

Table 3. Average values, % ultimate strength and St. deviation of the microcracking stages for every rock type.

Rock type (I.D)	σ_{ci}			σ_{cd}			σ_c	
	μ	% σ_c	St.dev	μ	% σ_c	St.dev	μ	St.dev
Limestone	55.7	52	9.0	97.8	92	29.8	106.5	37.9
Karstified Limestone	18.0	58	-	28.8	93	-	31.0	
Trachyandesite	9.5	47	2.3	15.5	77	2.1	20.2	2.5
Mudshale	15.9	49	3.6	27.5	84	11.7	32.8	18.9

B-value

Unlike the number of hits-stress relationship, the B- value accounts for the intensity of the AE waves (Hardy RH., 2003) and particularly it represents the relative proportion between weak and strong acoustic emission events that are produced under a specific load. B- values lower than one are indicative of intensive AE events that produce large-scale microfractures as the rock approaches failure. B- values larger than one mean that small-scale microfractures are dominant, so the rock has not experienced significant damage (Kallimogiannis, 2023).

All rocks display similar behavior (**see Figure 4**). Particularly, under low stress conditions, any microcracking event produce AE waveforms of low amplitude, resulting in higher B-values, ranging from 1.5 to 4. As the stress increases, crack propagation and coalescence occur, producing higher amplitude waves and therefore decreasing the B- value below one. The B- value decrement is more evident after the σci and σcd stresses are exceeded close to failure.

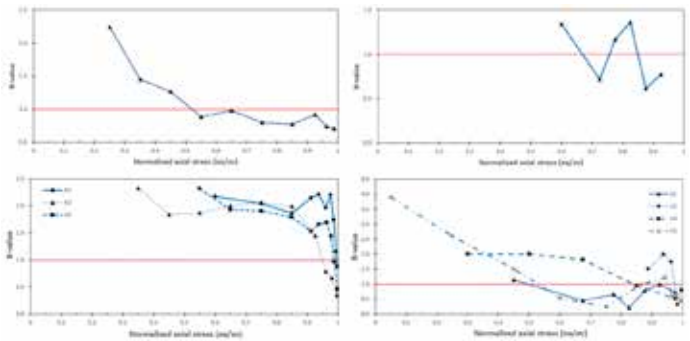

Figure 4. The B-value vs axial stress curve for every rock type. Notice that the B-value reduces after the main microcrack events. Limestone (top left), karstified Limestone (top right), Trachyandesite (below left), Mudshale (below right).

Cyclic Uniaxial Compressive Test with AE measurement. (CUCT-AE)

The rock specimens were repeatedly loaded, each cycle corresponding to a 10-20% increment towards the expected peak strength. The main objective was to study the rock damage accumulation in a damage “controlled” environment

(Eberhardt E. et. al., 1999). The results demonstrate that both axial and lateral strain curves move incrementally after each cycle (**see Figure 5**).

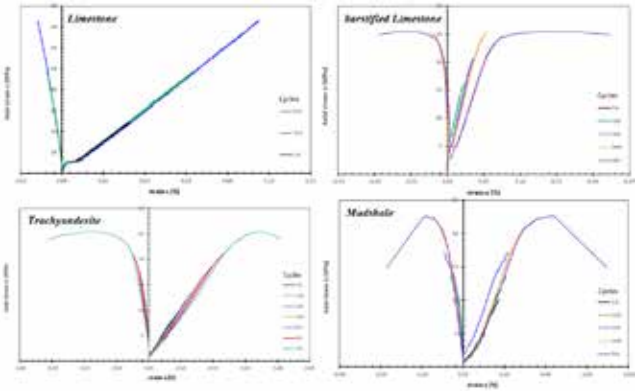

Figure 5. Combined stress–strain curves for every loading cycle.

This shift becomes more obvious as the stress approaches the σc and can be explained by microstructural damage accumulation. In particular, when microcracks generate in a preceding loading cycle, they partially close upon unloading. As such, during the following reloading phase, they extend at considerably lower stress level. Moreover, as most tensile microcracks generate along the specimen's length, lateral extension is the dominant deformation mechanism. The only exception belongs to Limestone in which the elastic phase has not yet passed, so no severe microcracking has yet occurred.

The acoustic emission (AE) method is employed in cyclic loading tests through the Felicity ratio. FR less than unity depicts the transition from the Kaiser effect (absence of AE events until the previously experienced stress on the material is exceeded (Lavrov, 2002) to the Felicity effect (presence of AE events before the previous cycle's peak stress) from which point, the damage that has been accumulated is irreversible. The Felicity ratio was calculated by dividing the stress in which the first AE activity was recorded, namely the AE onset stress with the maximum stress of the previous cycle. As illustrated in **Figure 6**, the FS value exhibits a gradual decline with increasing stress across all rock types.

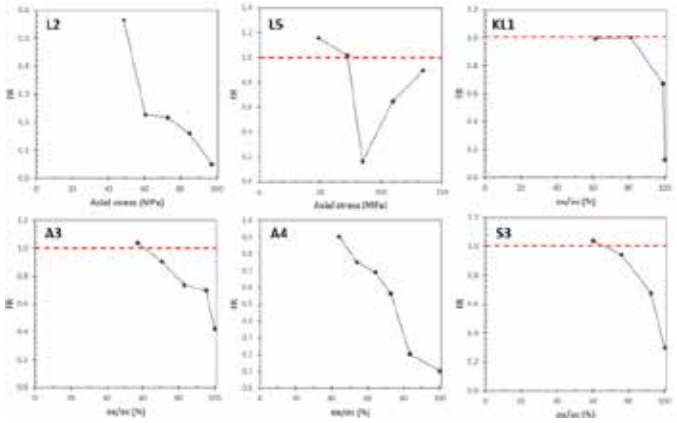

Figure 6. FR vs stress curve for every specimen. The red line marks the transition from the Kaiser to the Felicity effect.

Conclusions

This study highlights the application of acoustic emission (AE) monitoring across four different lithologies. Specifically, it was found that the crack initiation (σ_{ci}) and crack damage stress (σ_{cd}) occur earlier in porous and semi-plastic rocks and later in brittle rocks, relative to the unconfined compressive strength (UCS). Notably, σ_{ci} exhibits significantly lower variability, indicating its potential for use in estimating a more representative UCS through inverse analysis. Moreover, sudden reduction in the B-value reflects the intensity of microcracking activity which peaks near failure.

In damage-controlled UCS tests, the reactivation of microcracks is reflected in the progressive increase of deformation, irreversible strain and Poisson's ratio after each loading cycle. Furthermore, the Felicity Ratio (FR) emerges as a promising parameter for identifying both the onset and evolution of internal damage within the rockmass.
Consequently, the physical properties of rocks significantly influence both their failure behavior and their AE response. High-density rocks exhibit well-defined phases of intense microcracking, accompanied by elevated AE activity, while highly porous rocks tend to show continuous but less intense AE signals, indicative of a more distributed damage mechanism. In contrast, argillaceous rocks display limited AE activity, primarily due to the ductile behavior of their clay minerals, which inhibits microcrack formation. Collectively, these findings highlight the potential of the AE method to enhance understanding of rock failure processes and improve predictive modeling in geotechnical engineering.

Acknowledgements

The authors would like to thank the geotechnical company GeoTerra for providing the rock samples from various geotechnical projects in Greece and their support throughout the entire duration of the study. Special thanks to Geologists Tzivolias Efstratios, Varvadakis Manolis and Antoniou Anastasios.

Introduction

The majority of the first tools devised by Prehistoric men were made of stone; while it is reasonable to assume that a great many of these tools where made from rocks found lying around, at some point it seems inevitable that our ancestors would have to go about actively procuring the materials for their rudimentary tools and implements (Coulson, 2012). The oldest mine yet discovered is, most probably, that of Lion Cave in Swaziland, Africa, which is estimated to be about 30.000 years old (Dart & Beaumont, 1969). The first quarrying operation discovered is even older, and it is located in the Nile Valley, where numerous evidence for Palaeolithic flint and chert extraction is present (Vermeersch *et al.*, 1990). These are then the origins of mining and quarrying, an activity which grew steadily from the Bronze Age onwards (Coulson, 2012), and has influenced the course of history and civilisations (Periferakis *et al.*, 2019; Periferakis, 2021), being regarded as an integral part of the local heritage in certain places (Periferakis *et al.*, 2022).

However, neither mining nor quarrying are easy and danger-free tasks; in fact, they are rather laborious and potentially dangerous, especially in more primitive conditions. The recognition that mining is associated with specific pulmonary diseases has been made since the 16th century by Agricola (Ross & Murray, 2004). Since then, and especially after the 19th century, a systematic documentation of mining- and quarrying-related and induced occupational diseases is underway, revealing an ever-increasing number of pathologies and their associated mechanisms. Aside from increased awareness and potential of diagnostic techniques to identify such pathologies, the massive increase of the global mining and quarrying activities in the last two decades (Jasansky *et al.*, 2023) brings this problem even more to the foreground. Given that such occupational diseases represent a diverse and multifaceted issue, from the point of view of pathogenicity, diagnosis, and treatment, here we will focus on a brief overview of the radiographic evidence of pulmonary pathologies associated with coal and asbestos mining, and the associated diagnostic challenges. We have chosen coal and asbestos mining, as a wealth of data exist on the subject, and the relevant pathologies are associated specifically with these materials and are not generically caused by the mining conditions themselves.

Coal Miners' Pneumoconiosis (Black Lung Disease) and Other Pulmonary Pathologies

Coal deposits occur in coal-bearing strata, which can be found today in numerous locations worldwide. The Eurasia-China and the North America coal belts existing today were formed in the ancient supercontinent of Laurasia, while a third coal belt has formed across regions which were originally part of Gondwana. While coal from the Devonian age has been found, the majority of currently known deposits has formed during the Permian and Carboniferous ages; younger coal deposits from the Mesozoic and Cenozoic eras exist but there are fewer in number and less widespread (Wagner, 2020).

Ever since the industrial revolution, coal has been perhaps the most important source of energy, followed by oil as the 20th century progressed. Today, the major coal producing countries are China, the US, Australia, Indonesia and India, with a number of other countries also having significant resources (Wagner, 2020). Pneumoconiosis is most probably the oldest occupational disease, especially given the importance of mining and quarrying from a very early stage in human prehistory, as presented above. It is also the most prevalent occupational disease at a worldwide level (Wang et al., 2023). Coal mining-related pneumoconiosis has been identified since the 1830s, when miners presented with black sputa, breathlessness and coughing, and in autopsies, the lungs had a black pigmentation (Ronsmans & Nemery, 2022).

Pneumoconiosis is defined as a form of interstitial lung disease induced by particle inhalation, which leads to scarring and progressively diminished breathing capacity (Shekarian *et al.*, 2021). Regarding the pathophysiology of pneumoconiosis, this is determined by the interaction and deposition of the inhaled particles at the different levels of the respiratory system. As such, the smaller the particle, the more it will penetrate into the respiratory system, with

nanoparticles being the most dangerous and pathogenic

In coal mining the prolonged exposure to coal dust can lead to a particular form of pneumoconiosis, called coal workers' pneumoconiosis due to exposure to both coal and silica dust. The relevant forms of pneumoconiosis are anthracosis, silicosis and anthracosilicosis. In this context, particles with a 1-100 μm are characterised as dust, while particles below 1 μm are classified as the nano-sized fraction and are also damaging to the lungs when inhaled (Pan *et al.*, 2021); it is estimated that in mining enterprises, about 3% of the mined material will be converted to dust in the extraction process. About 40% to over 90% of dust in coal mines, at any moment, is pure coal. The particular characteristics of such dust and its relative pathogenicity depend both on the characteristics of the coal itself and on the mining methods and equipment used.

From a diagnostic perspective, the radiographic findings between the three forms are similar, with milder forms of the disease being confined to the upper parts of the lungs and presenting as small (< 1 cm) rounded opacities. The coalescence of these opacities into more massive forms is indicative of progressive massive fibrosis, a more severe form of this disease. Interestingly, in miners which are already suffering from rheumatoid arthritis, Caplan syndrome, i.e., rheumatoid pneumoconiosis, may occur. This presents as well-defined rounded nodules in the lung periphery, resembling rheumatoid nodules (Schreiber *et al.*, 2010). Anthracosis, in its mild and moderate forms, has COPD-like symptoms and a similar treatment scheme (Mirsadraee, 2014). Compared to asbestosis, it is usually less severe in the absence of comorbidities.

Other pulmonary pathologies, associated with dust inhalation in the context of coal mining are dust-related diffuse fibrosis, and some diseases of the airways such as emphysema and chronic bronchitis. Dust-related diffuse fibrosis is also, like pneumoconiosis, an interstitial lung disease, but radiographically appears as irregular opacities and presents difficulties in the differential diagnosis with idiopathic pulmonary fibrosis if an exposure history is not available (Petsonk *et al.*, 2013); it is more frequent in long-tenured coal miners compared to idiopathic pulmonary fibrosis prevalence in the general population (Laney & Weissman, 2014).

Notably, since the 1970s, due to legislation regulating the amounts of maximum permissible coal dust in mines, in major coal-producing countries, such as the US, and Australia, coal miners' pneumoconiosis incidence begun to decline. However, during the last decade, there has been an apparently unexplained increased in incidence, despite the improvement of working conditions and safety standards (Wang *et al.*, 2023). In the US, there also has been a constant incidence increase since the 1990s. In this resurgence, silica particles are implicated more than coal particles, and this may be attributable to a shift in mining methods as well as the stricter control of maximum allowed coal dust in mines compared to silica dust (Go *et al.*, 2023), although more research is required on this matter.

Pulmonary Pathologies Associated with Asbestos Exposure

The term asbestos is used to describe a group of silicate minerals, which form elongate thin fibers. These will release numerous microscopic fibers when tampered with or crashed. Their usual diameter is less than 1 μm and their length may range from several to hundreds of micrometres. Remarkably, even though the peak for asbestos demand is associated with the onset of the industrial age, such minerals have been known and used for over 5000 years (Ross & Nolan, 2003). Asbestos fibres have a number of very positive physicochemical properties, are especially durable to fire, and are very good insulators (Ross & Virta, 2001). From a mining and use perspective, chrysotile asbestos represents over 90% of the total mined asbestos (Ross & Virta, 2001).

From a mineralogical perspective, the term "asbestos" is used to refer to a family of fibrous silicate minerals, which occur in igneous and metamorphic settings. The asbestiform minerals can either be amphiboles or seprentines. The former group comprise grunerite $[(Fe_2^{2+})(Fe_5^{2+})(Si_8O_{22})(OH)_2]$, cummingtonite and its dimorph anthophyllite $[(Mg_2)(Mg_5)(Si_8O_{22})(OH)_2]$, crocidolite $[(Na_2)(Z_3^{2+}Fe_2^{3+})(Si_8O_{22})(OH,F,Cl)_2]$, tremolite, and actinolite $[Ca_2(Mg_{4.5-2.5}Fe_{0.5-2.5}(Si_8O_{22})(OH)_2)]$; anthophyllite is also known as amosite. About 90% of the total production of asbestos corresponds to crocidolite, with the rest comprising mostly chrysotile $[Mg_3(Si_2O_5)(OH)_4]$and amosite. All commercially exploitable asbestos minerals share a number of physical properties, i.e., (1) they occur as fibrous bundles, (2) these fibres have high tensile strength, (3) they have a high aspect (length:width) ratio, (4) they are flexible enough to be coiled. Due to their chemical composition, they are very stable in a variety of environments, have high thermal resistance, are not very biodegradable and are poor conductors of electricity. Other minerals which exhibit an asbestiform habit but do not exhibit all such properties are not classified as asbestos (Campbell *et al.*, 1977; Ross *et al.*, 1984; Hodgson, 1986; Skinner *et al.*, 1988).

Even though mining and use of asbestos have decreased in recent years, while safety standards and protective measures have gradually improved, there is a notable and quantifiable risk of development of asbestos-related diseases. A factor compounding the problem of correlating such pathologies with the original asbestos exposure is

the notable time lag between exposure and the manifestation of the pathology. This lag is commonly between 15 and 40 years (Luus, 2007). Exposure to asbestos can occur through a number of ways, via skin contact, ingestion, and inhalation; the first two are relatively harmless, or at least there is no significant evidence of severe asbestos-related pathologies in relation to these routes. Inhalation is the most dangerous avenue of exposure, being associated with severe pathologies (Luus, 2007).

Asbestos fibers, when inhaled, exhibit irritative, genotoxic and immunosuppressive properties. Respiratory mucosa irritation by asbestos fibers will lead to scar tissue formation, and finally benign fibrosis, effusions and plaques in the lung cavities (Pedley, 1930). Amphibole fibers are far more dangerous in that aspect given their chemical stability; chrysotile fibers can be removed relatively quickly while amphiboles may remain forever in their place of deposition (Bernstein & Hoskins, 2006). The induction of autoimmunity by asbestos fibers is not fully understood, although there is evidence indicating that they can suppress the activity of natural killer and pulmonary parenchymal cells, thus potentially leading to lung cancer (Sider *et al.*, 1987; Tsang *et al.*, 1988). Asbestos has also been found to damage the DNA and alter gene transcription and protein production (Sider *et al.*, 1987; Berry *et al.*, 2000); it seems that the genotoxic properties of asbestos fibers are proportional to their length, with the chrysotile fibers being longer and thus more dangerous (Keane *et al.*, 1999).

It is therefore clear that asbestos fibers can cause both benign and malignant lung pathologies. Regarding benign pathologies, there are asbestosis, effusions and plaques (Luus, 2007). Asbestosis represents one of the most characteristic pathologies associated with asbestos exposure and is, essentially, a bilateral interstitial pulmonary fibrosis, which preferentially affects the base of the lungs (Mossman & Churg, 1998). Amphibole fibers are the principal culprits in this case (Hessel *et al.*, 2005). The localization of asbestos-related fibrosis in specific lung regions leads to the development of plaques, which gradually limit lung functionality (Goldsmith, 1982; Cudgell & Kamp, 2004). The plaques themselves are benign but are associated with an increased cancer incidence (Sprince *et al.*, 1991). Effusions, i.e., lung collections in the lungs, which occur in association with asbestosis, plaque development and mesothelioma, can be either acute or chronic (Davies *et al.*, 1991) and can be potentially deadly. Amphibole fibers are again more responsible for this pathological aspect compared to chrysotile fibers (Davies *et al.*, 1991).

Clinical features of asbestosis comprise cough and dyspnea, while common signs are diminished breath sounds, limited chest expansion, finger clubbing, and cyanosis. The most severe complication and the usual cause of mortality is cor pulmonale (Kleinfeld, 1966). Localized fibrotic plaques may or may not impact lung function depending on a number of factors (Kerper *et al.*, 2015). In addition, the presentation of clinical effusions may vary from asymptomatic to difficulty in breathing, depending on its size and other comorbidities (Iyer *et al.*, 2019).

Mesothelioma is a type of cancer of the cell lining of the lungs and abdomen. It is often misdiagnosed as pneumonia (Peto *et al.*, 1999). Radiographically, mesothelioma presents as plaque-like or nodular pleural thickenings, which are concentric and unilateral. They may be associated with pleural effusions, with the tumor frequently extending into the lung fissures. Even though a simple chest radiograph is not enough to conclusively diagnose mesothelioma, it is highly suggestive in patients with a previous exposure history (Aziz, 2009). From a clinical perspective, most cases of mesothelioma present with chest pain and dyspnea; even with treatment, the prognosis is usually very poor (Berzenji & Van Schil, 2018). Asbestosis can subsequently lead to bronchogenic lung cancer (Luus, 2007). Bronchogenic carcinoma is the most frequently diagnosed pulmonary cancer and comprises a number of histopathological patterns. For its staging, a CT scan is necessary (Reddy & Reddy, 2022).

Discussion

As has been presented, both asbestos and coal mining are associated with a number of potentially severe pulmonary pathologies, which are mostly irreversible. While anthracosis and related pathologies are generally less severe than asbestosis and mesothelioma, they nevertheless correspond to a notable burden of disease (Lu *et al.*, 2021), especially given the prominence of coal mining relative to asbestos mining. The mortality and morbidity of such diseases is compounded by a frequent late diagnosis or misdiagnosis, especially if occupational exposure is not taken into account by medical personnel.

The diagnosis of occupational diseases associated with mining and quarrying, and their causative connection to these activities, is also important from a socioeconomic perspective, i.e., the possibility of workers to both demand safer working conditions and to claim compensation for such diseases from the owners of the enterprises where they work. While this may seem self-evident, it is not always the case. On one hand, in third world the countries working conditions in mines and quarries are not constrained by modern safety regulations and compensatory policies. But even in countries of the western world, there can be situations where the actual dangers are discounted. For example, in Britain in the early 20th century, anthracosis was considered eradicated in miners, thus leading to laxer safety regulations and the inability to claim compensation for this particular pathology; initial compensatory policies

of the period, both in the US and Britain were considered relevant only for miners suffering from silicosis (Ronsmans & Nemery, 2022). In the case of asbestos, exposure has rapidly decreased in countries where it has been banned, and it is only relevant in non-mining related contexts. In the EU, the first measures for reducing asbestos exposure were taken in the 1980s (Belackova *et al.*, 2022). Legislation to that effect has also been discussed and gradually implemented in the US around that time (Cohen, 1991). Even so, in spite of the known dangers inherent in asbestos mining and use, the global asbestos industry continues to thrive in certain countries, although globally the demand for asbestos has dropped after 2000 (Frank & Joshi, 2014).

For mesothelioma, a simple chest X-ray is a good screening test, but its non-specific findings may be confused with cases of lymphomas and metastatic carcinomas, or even benign asbestosis. Both CT and MRI scans are more useful in determining the disease and its extend, but the definitive diagnosis is always made after a biopsy (Aziz, 2009). A CT scan is also necessary for the staging of bronchogenic carcinoma (Reddy & Reddy, 2022), which in a chest X-ray usually appears as a peripheral mass (Sider, 1990). Likewise, screening for diseases associated with coal mining may be performed by radiography, although the fact that they may initially not manifest via specific signs and symptoms will most likely be associated with a delayed patient presentation, and thus diagnosis.

Even though coal miners' pneumoconiosis and asbestosis have histological differences, they both present as fibrotic pneumoconioses, and the differential diagnosis on imaging is not always simple. In principle, in pneumoconiosis we can identify diffusely distributed granular micronodules with a perilymphatic pattern, which may present central calcifications; these are often accompanied by hilar or mediastinal lymph node enlargement and may also associate emphysema. Conversely, in asbestosis we encounter dot-like opacities which are usually distributed to the inferior lobes with a reticular centrilobular pattern; it is usually associated with pleural effusions and plaques, as well as traction bronchiectasis and honeycomb fibrosis (Chong *et al.*, 2006).

Based on the aforementioned evidence, the particularities of coal mining and asbestos mining-related pulmonary pathologies, from a diagnostic perspective, have been briefly outlined. In considering the associated morbidity and mortality, and thus decrease in quality of life, it is evident that they represent a matter not only of medical, but also of socioeconomic significance (Yokoyama *et al.*, 2013; Deng *et al.*, 2022). Such aspects are highlighted also in other mining and quarrying-associated occupational diseases in scientific literature (Mandel *et al.*, 2016; Periferakis, 2020; Bonilla *et al.*, 2024). It is for these reasons that adequate enforcement of workplace regulations is necessary, along with the implementation of novel measures and technologies aimed at further improving the safety and hygiene of these occupational environments. Social support and financial assistance aimed at improving of the quality of life of affected miners must also be implemented, especially in communities where a significant part of the workforce is thus occupied. But, first and foremost, there is the need of timely diagnosis, of accurate and efficient screening methods, which will enable prompt diagnosis, therefore improving patient prognosis. Hopefully, future developments in imaging, surgical techniques and biomaterials (Nedelea *et al.*, 2024; Periferakis *et al.*, 2024) will improve care and treatment standards for such patients.

Research highlights:

The study focuses on Ni-Co sulfides and arsenides, highlighting their association with hydrothermal processes and ultramafic protolith alteration in the listvenite-hosted mineralization of the Rhodope massif.

Introduction / Background

Hydrothermal alteration of peridotites or serpentinites from ophiolite complexes, remnants of the Neotethys oceanic lithosphere has formed listvenites either mineralized or non-mineralized in many places, including Kosovo, Greece, Turkey, Oman, and Iran. In Greece, listvenites have been reported in Tinos Island, Mount Oeta in Central Greece, Gerakini and Vavdos at Chalkidiki, and in Vyrsini at Komotini (Iliadis, 2006, Hinsken et al., 2017 and references therein). The term listvenitization is used to describe the range of carbonization processes, from carbonate-rich to silica-rich phases, caused by hydrothermal fluids enriched in CO_2. These rocks are typically composed of quartz, Ca-Fe-Mg carbonates, fuchsite, serpentine, talc, chlorite, relics of chromite, magnetite, sulfides, and arsenides (Boskabadi et al., 2020). They commonly occur in shear or fault zones that serve as pathways for hydrothermal fluids, facilitating CO_2 infiltration and subsequent metasomatism. Listvenites are important since they are commonly associated with lode gold mineralization, as well as enrichment in other precious and critical metals, such as Ag, Hg, Co, Ni, As, and Sb that have been formed under low temperature conditions (Boskabadi et al., 2020).

The transformation of peridotite to listvenite involves multiple stages, beginning with hydration to form serpentinite, followed by carbonation and metasomatism through the influx of CO_2 rich fluids (Boskabadi et al., 2020). This transition is gradual, evolving with increasing CO□, and involves intermediate stages characterized by the progressive replacement of serpentine or talc, leading to quartz-carbonate assemblages. Based on the modal proportions of quartz and carbonate, three types of listvenite lithologies can be classified: carbonate listvenites, silica-carbonate listvenites, and silica listvenites (Boskabadi et al., 2020).

The objective of this study is to present preliminary data on the mineral composition of the listvenite occurrences in the Kato Vyrsini region in the Rhodope massif, and to document the mineralization they host, which has not been studied in detail so far.

Geology

The study area is part of the Kechros metamorphic core complex, which belongs to the Rhodope Massif in northeastern Greece. The Kechros complex is the lowermost tectonic unit of the Rhodope domain, exhumed against the Kimi complex by extensional deformation of the low-angle Kechros detachment fault during Early Eocene (36-32 Ma) (Mposkos et al. 2013, Kounov et al., 2024). This terrain consists of both continental and oceanic lithologies, represented by orthogneisses, pelitic gneisses, and high-alumina metapelites, intercalated with schists, amphibolites, boudins of eclogites, and scarce marbles. The oceanic affinity lithologies are tectonically intercalated and comprise serpentinized peridotites with dykes of gabbroic pegmatites, diabases, rodingitic gabbros, and blocks of trondjemites (Iliadis 2006, Mposkos et al. 2013). The antigorite serpentinite at Vyrsini spans approximately 95 km^2 and is considered one of the largest ultramafic bodies in the Greek Rhodopes. Its boundaries are defined by two major tectonic structures: the Smigada dip slip fault, and the Ragada-Esochi low-angle fault in the northern and southern parts, respectively. Over a large area, these rocks have undergone intense serpentinization and subsequent silica-carbonate alteration forming the listvenite zones. The largest listvenite body in the region extends from NW of the Kato Vyrsini village to Akritas occupying an area of approximately 2.5 km^2 (Fig. 1).

Methods

A preliminary investigation of the mineralization hosted in the listvenites of the Kato Vyrsini region was carried out on polished and thin sections. Observations were made using a Leitz LaborLux 11 Pol dual reflected-transmitted light polarizing microscope equipped with a Levenhuk M base series digital camera. The analysis was complemented by SEM back-scattered electron imaging, and the chemical composition of the ore minerals was determined by JEOL JSM- 6390LV scanning electron microscope (SEM) (JEOL Ltd., Tokyo, Japan) equipped with an OXFORD INCA 300 energy dispersive system (EDS). All the analyses were performed in the School of Geology at Aristotle University of Thessaloniki.

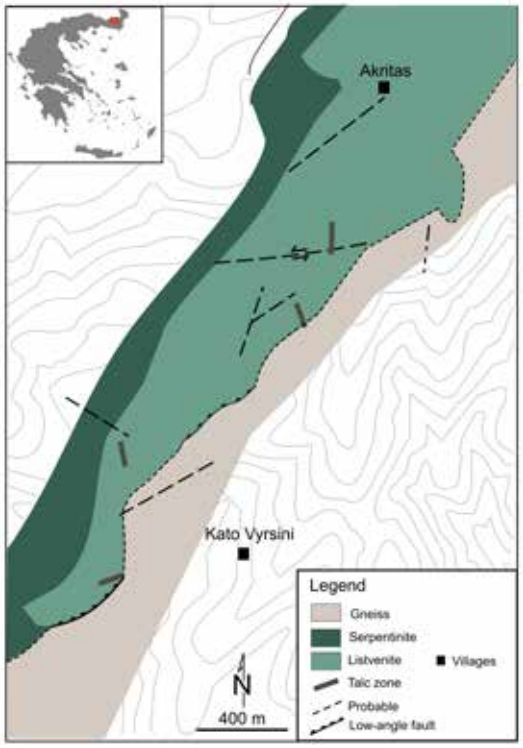

Figure 1. Simplified geological map of the area between Kato Vyrsini and Akritas (modified after Iliadis et al., 2006 and Kounov et al., 2024)

Results

In Kato Vyrsini, the listvenitization of serpentinite has resulted in the formation of three different rock types, each differing in mineralogy and the degree of metasomatism. These rock types include transitional rocks (Type I), carbonate-rich listvenite (Type II) and silica-rich listvenite (Type III) (Fig. 2a-c). Transitional rock types occur as lenses within the serpentinite body. They exhibit a greyish green color (Fig. 2a) and are characterized as magnesite-bearing serpentinite that contains over 70% serpentine along with magnesite and minor talc, chromite, magnetite, and hematite (Fig. 3a). Commonly, magnetite destabilized into hematite. Carbonate-rich listvenite is found adjacent to shear zones and is characterized by a green color (Fig. 2b). Its mineralogical composition is dominated by carbonate minerals, mainly dolomite, magnesite, with rare calcite, as well as quartz (Fig. 3b). It also contains chromite, which is often thinly rimmed by magnetite or ferri-chromite, and minor amounts of pyrite. Silica-rich listvenite, commonly referred to as “birbirite”, is formed along fault planes, indicating brittle deformation (Fig. 2c). It consists of a silicified mass with fine-grained quartz (Fig. 3c) and disseminated chromite, pyrite, marcasite, a Ni-sulfarsenide (gersdorffite), Ni-sulfides (vaesite, violarite), and minor rutile.

Figure 2. Hand specimen of different types of listvenite (a) Transition rock type (Type I), (b) Carbonate-rich listvenite (Type II), (c) Silica-rich listvenite (Type III) with mineralization

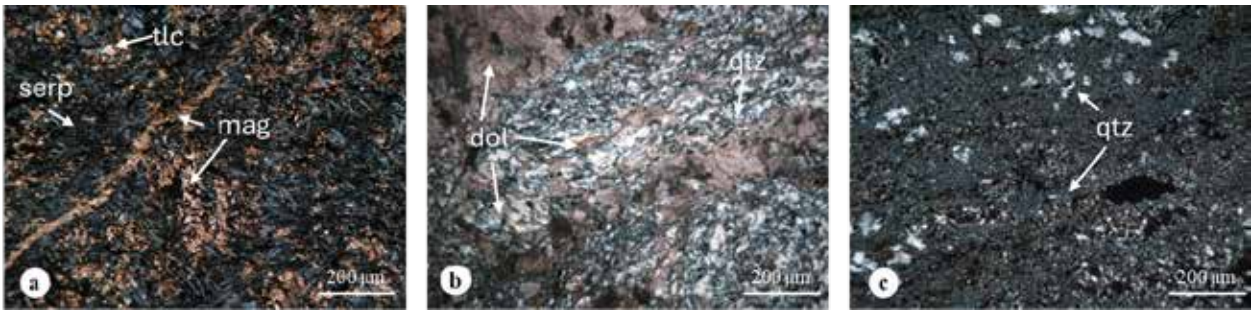

Figure 3. Microphotographs with closed-polarized light, of the different listvenite types (Type I-III) (a) Magnesite with fine-grained talc within a serpentine groundmass in Type I listvenite, (b) Dolomite with quartz in Type II listvenite, (c) Coarse- and fine-grained quartz in type III listvenite. Abbreviations: serp=serpentine, tlc=talc, mag=magnesite, dol=dolomite, qtz=quartz

Chromite appears with intense cataclastic texture in all listvenite types, with a decreasing extent from type I to type III, reaching sizes of up to 500 μm. In types I and II, chromite occurs within the carbonate mass and is commonly rimmed by magnetite or ferri-chromite (Figure 4a). In type III, it occurs as disseminated subhedral grains within the fine-grained matrix and appears more homogenous, without zoning. The chemical composition of chromite differs between the types II and III. When it is hosted in carbonate listvenites, it exhibits higher Cr_2O_3 contents, which decrease from the core to the outer rims, ranging from 45.98 to 49.56 wt.%. Similarly, MgO follows this trend, demonstrating contents of 6.67 wt.% in the core and 4.34 wt.% towards the rim. Conversely, Al_2O_3 ranges between 14.83 and 17.67 wt.% and increases towards the rims of the chromite crystals. Minor amounts of SiO_2 (up to 0.88 wt.%), V_2O_3 (up to 0.53 wt.%), ZnO (up to 0.96 wt.%) and NiO (up to 0.74 wt.%) are also present. Chromite in the silica-rich listvenites exhibits Fe content ranging from 24.6 to 52.01 wt.%, while Cr_2O_3 concentrations are lower compared to those in carbonate-rich listvenites, ranging from 40.74 to 44.05 wt.%. Additionally, there are minor contents in Al_2O_3 (0.7-0.91 wt.%) and MgO (0.66-1.16 wt.%). These chromites also contain TiO_2 ranging from 2.68-3.59 wt.%. Overall, the analyzed chromite grains in type III are characterized by a high chromite component, with a Cr# [Cr/(Cr+Al)] of 0.97, whereas those in Type II listvenites have a lower average Cr# of 0.67. Similarly, the average Fe# [$(Fe^{+2} / (Mg + Fe^{+2})$] value is 0.95 for chromites in silica listvenites and 0.72 for chromites in carbonate listvenites.

The abundance of magnetite decreases as the silica metasomatism increases, similar to chromite. Magnetite occurs as coarse- and fine-grained euhedral and subhedral grains, disseminated or massive, within the transitional listvenite and carbonate-rich listvenite. It commonly forms rims around chromite and occasionally it alters to hematite. It contains inclusions of Ni-bearing phases, such as violarite ($FeNi_2S_4$) (Fig. 4b). Variations in composition are observed within the same grains. In the cores, Fe content is lower and Cr decreases, while Ni is omnipresent (0.58–1.17 wt.%).

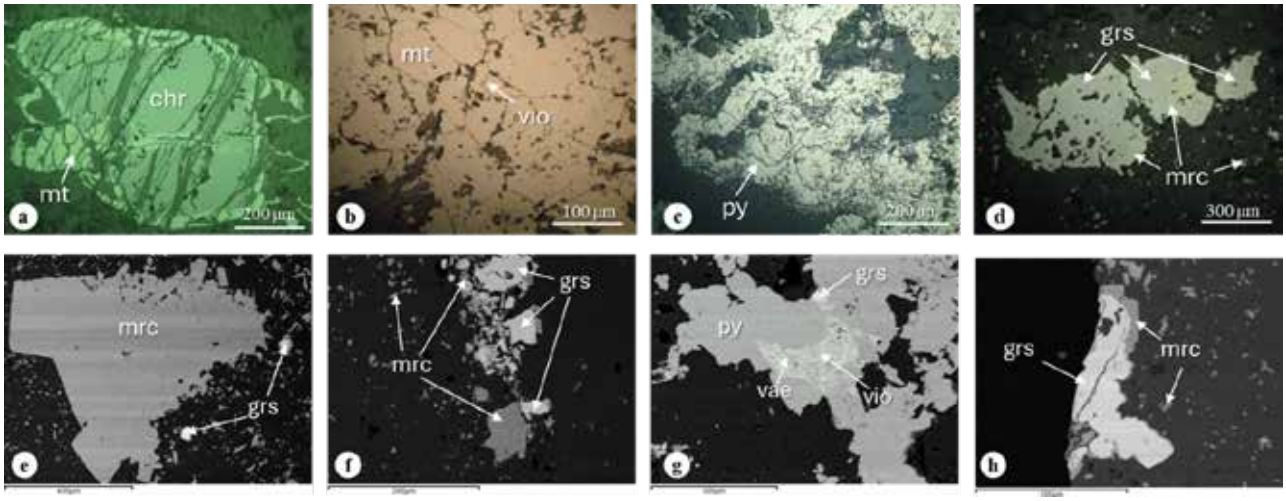

Figure 4. Microphotographs (a-d) and BSE images (e-h) of ore minerals in different listvenite types. (a) Chromite rimmed by magnetite. The microcracks are filled by serpentine (Type I listvenite), (b) Massive magnetite with violarite inclusion in Type II listvenite, (c) Oscillatory coarse-zoned pyrite in Type III listvenite, (d) Gersdorffite rimmed by marcasite in Type III, (e) Marcasite and gersdorffite with rims of marcasite in Type III listvenite, (f) Gersdorffite intergrown with marcasite in Type III listvenite, (g) Pyrite intergrown with Ni-phases (violarite and vaesite) in type III listvenite, (h) Gersdorffite with marcasite rim in Type III listvenite. Abbreviations: mt= magnetite, chr=chromite, vio=violarite, py=pyrite, grs=gersdorffite, mrc= marcasite, vae= vaesite.

Pyrite is present in listvenites of type II and III at Kato Vyrsini. Pyrite hosted within the carbonate-rich listvenites, exhibits a cataclastic texture and occurs as small subhedral to euhedral crystals, up to 20 μm in size. It is often oxidized to goethite while retaining the hexahedron crystal shape. In contrast, pyrite in the silica-rich listvenites forms significantly larger aggregates and is often associated with marcasite (Fig. 4c). The chemical composition of pyrite varies, with notable element concentrations. It contains up to 5.91 wt.% Ni, up to 1.91 wt.% As, up to 1.03 wt.% Ag and Zn, up to 0.87 wt.% Ti, up to 0.59 wt.% Sb, up to 0.47 wt.% Cu and up to 0.23 wt. % Co, many of which may be associated with micro-inclusions of other minerals. Iron content ranges from 35.48 to 43.09 wt.%, while S content ranges 54.82-59.16 wt.%. The average chemical composition can be expressed as $Fe_{0.87}Ni_{0.01}S_{2.11}$.

Gersdorffite is distributed within silicified listvenite (Type III) and occur as euhedral crystals up to 200 μm in size. These grains are often rimmed by marcasite or pyrite (Fig. 4d-h). Gersdorffite is the most widespread Ni-bearing phase of listvenites at Kato Vyrsini. The general chemical composition is NiAsS, with significant amounts of Fe and Co that can substitute for Ni, and minor amounts of Sb that can replace As. Gersdorffite from Kato Vyrsini contains 42.53-46.92 wt.% As and 27.89-36.01 wt.% Ni, 1.74-5.40 wt.% Fe, up to 3.28 wt.% Sb, 0.08-2.77 wt.% Co, and up to 0.53 wt.% Cu (Table 1). The average chemical formula is $(Ni_{0.9}Fe_{0.09}Co_{0.03})_{1.02}As_{0.99}S_{0.99}$.

Nickel sulfides are present in lower abundances and are represented by violarite and vaesite. Vaesite appears as anhedral grains interstitial to pyrite, alongside to violarite and gersdorffite in the silicified listvenites (Fig. 4g). Violarite is found in small grains associated with magnetite in the carbonate-rich listvenites. The average chemical composition of vaesite is $Fe_{0.2}Ni_{0.77}As_{0.02}S_2$, while violarite has a composition of $Fe_{0.99}Co_{0.01}Ni_{1.89}As_{0.03}S_4$. Violarite grains coexisting with magnetite are slightly richer in Ni and Co, contain no As, and exhibit a mean composition of $Fe_{0.75}Co_{0.06}Ni_{2.19}S_4$.

Table 1. Representative microanalyses (wt %) and calculated formulae of gersdorffite (1-6), vaesite (7-8), violarite (9-10) and pyrite (11-12) of the Kato Vyrsini listvenites

Discussion and Conclusions

The study of listvenites in the Kato Vyrsini area provides significant insights into their classification, mineralogical composition, and the associated mineralization processes. Based on mineralogical investigations, distinct types of listvenite were identified, differentiated by their dominant mineral assemblages. Serpentinization precedes listvenitization, as evidenced by the remnants of serpentine within the listvenite bodies, forming a transitional rock type (Type I). Type II (Carbonate-Rich Listvenites) forms during a subsequent phase of carbonation, characterized by the development of carbonate-dominated assemblages. Type III (Silica-Rich Listvenites) represents the most advanced stage, marked by intense silicification forming quartz-rich assemblages with disseminated Fe-Ni-S mineralization.

Most listvenites at Kato Vyrsini formed within or at the borders of serpentinized ultramafic rocks, along major tectonic zones (i.e. low-angle faults zones), which acted as pathways for hydrothermal fluids. However, some occurrences are associated with second order structures, such a small-scale cracks and high-angle faults, and also related to the porosity of highly altered serpentinized zones. A key aspect of listvenite-hosted ore formation in the study area is the role of a potential tectonic reactivation. Early-stage Mesozoic thrust faults were reactivated during Cenozoic

extension, and created low-angle detachment faults, enhancing fluid mobility and contributing to extensive alteration and mineralization, consistent with the tectonic regime observed in the Rhodope Massif (Melfos and Voudouris, 2017, Kounov et al., 2024). However, on the absence of age data, any genetic relationship between specific types of alteration and mineralization in the studied listvenites cannot be yet proven. We suggest here a scenario, where detachment faults facilitated deep circulation of CO_2-rich fluids, initiating carbonation reactions in the ultramafic protolith forming the transitional listvenite (Type I). As the system was uplifted the carbonate-rich fluids were substituted by silica-rich fluids and formed the carbonate-rich listvenite (Type II) and the silica-rich listvenite (Type III).
Chromite and magnetite occur in the least altered meta-ultramafic rocks. During listvenitization, these minerals are progressively replaced by newly formed mineral assemblages, especially sulfides, Ni-sulfarsenides, and Ni-arsenides. Pyrite and marcasite are the dominant sulfides, occurring in all types, and are accompanied by Ni-minerals, including gersdorffite, vaesite and violarite enriched in cobalt. The source of Ni and Co is attributed to the ultramafic protoliths, where they are hosted in silicates (primarily olivine or serpentine) or in magmatic sulfides that were destroyed during serpentinization and the subsequent hydrothermal alteration facilitated their leaching and mobilization (Kiefer et al., 2023). Although earlier studies in the Kato Vyrsini listvenites do not mention the presence of nickel minerals, they note attempts to explore nickel mineralization in the 1960s (Iliadis, 2006). This research shows that nickel mineralization is fairly common in the mineralization of the broader area.

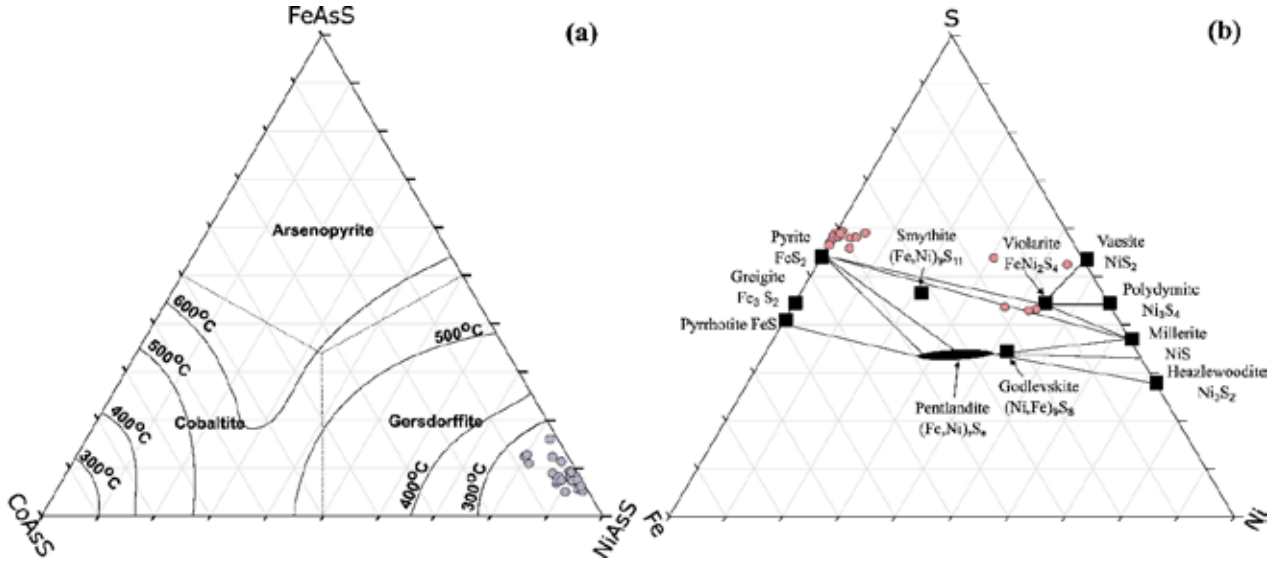

Figure 5. (a) Composition of gersdorffite in the FeAsS-CoAsS-NiAsS system. The solid lines contour the compositional fields of solid solutions in the system FeAsS-CoAsS-NiAsS at the specified temperatures (after Klemm, 1966), (b) Mineral stabilities in the ternary diagram Fe–Ni–S (after Schwarzenbach et al., 2014).

The ternary plot of gersdorffite analyses on the FeAsS-CoAsS-NiAsS system indicates formation temperatures between ~220-280 °C (Klemm, 1966, Mederski et al., 2021). Antimony, although not a common component of gersdorffite, was observed in grains coexisting with residual chromite within the listvenite mass. Correlation diagrams reveal a strong relationship (R^2=0.99) between Ni+Co+Fe and S+As+Sb (Fig. 6a), indicating that the elements behave in a coupled manner during mineral formation, transitioning to the gersdorffite-ullmannite series. Additionally, the substitution of Ni by Co is evident from the negative correlation between these elements in Fig. 6b. Iron, however, exhibits limited substitution for nickel (Fig. 6c), possibly due to the presence of a Fe-bearing phase intergrown with gersdorffite on a sub-microscopic scale, or due to the pyrite-marcasite rims around gersdorffite grains, creating observed irregularities. Figure 6d presents the correlation of R^2=0.67 of the couple substitution between Ni by Co and Fe.
Vaesite is intergrown with pyrite, gersdorffite and violarite. It typically forms at low temperatures through the replacement or remobilization of earlier Ni- and Co-bearing minerals. Vaesite is generally associated with the listvenitization of ultramafic rocks, where disulfides replace or overgrow older assemblages of sulfides (Schwarzenbach et al., 2014). Co- and Fe-bearing vaesite also contains more arsenic, while pyrite associated with vaesite exhibits higher cobalt concentrations. The same behavior is observed by the associated violarite. Violarite also forms intergrowths in magnetite with notable Ni and Co contents, suggesting formation at higher temperatures. Chemical analyses of vaesite and violarite indicate formation temperatures of ~230 °C consistent with phase relations in the Fe-S-Ni system (Fig. 5b) (Schwarzenbach et al., 2014).

The results of this study indicate that the Kato Vyrsini listvenites formed through complex processes involving hydrothermal fluids and tectonic activity. Further investigation is required to a more precise determination of the conditions that influenced their formation and mineralogical evolution.

Research Highlights

The previously unexplored geological structure of the Myrtoan Sea islets is briefly presented.

Myrtoan Sea stretches north to south between Spetses and Kithira Islands and east to west between Laconia Peninsula and Milos Island, comprising a subdivision of the Aegean Sea. It hosts a number of small islands (Antimilos, Ananes, Paximadi, Falconera and Velopoula) scattered on its marine territory, documenting the interesting, surficial geological structure of the area. With the scope of recording this local geology, the personnel of the Hellenic Survey of Geology and Mineral Exploration (HSGME) surveyed and mapped these islets in the framework of the project "Islets and rocky islets of the Aegean Sea" (2021-2025), supported by the National Funds Programme (NFP). This project attempted to shed light on the previously unexplored geological stratigraphy of the islets within the Myrtoan Sea, and place them in the context of the Hellenides belts.

The geology of the respective region can be distinguished in: a) the recent processes that took part at the northwestern segment of the active volcanic system of the South Aegean volcanic arc, b) the Mesozoic metamorphic basement of the Attic-Cycladic metamorphic complex and c) the Pelagonian realm. Each of these environments can be traced on the individual islets of the area. In the following sections, the stratigraphy description for each islet is given, starting from the most recent geological events and moving backwards in time.

Antimilos and Ananes Islets

Antimilos is situated almost 9 km northwest of Milos Island, whereas Ananes lies 22 km southwest of it. Both islets are part of the northwestern segment of the active South Aegean volcanic arc. The latter is comprised of a series of volcanic centers in a chain arrangement, that have produced a range of edifice-rich domes and lava flows with pyroclastic ejecta. The volcanic rocks vary from basaltic, through andesitic and dacitic, to rhyolitic compositions. They bear a typical calc-alkaline chemical composition associated with the active volcanic arc, triggered by the convergence of the African and Aegean plates. The volcanic activity initiated 3 million years ago (Ma) and remains active (Innocenti *et al.,* 1981). The tectonic regime of the area is characterized by a compressional phase during the Middle Miocene, followed by intense extensional stresses in the Pliocene (Angelier, 1979).

Antimilos Islet (Fig. 1) represents a large cone-shaped stratovolcano with steep-sided slopes, formed by an alternation of lava flow layers, composed mainly of dacite lava domes and subordinate andesite (Marinos, 1961) as well as pyroclastics. This volcano is characterized by explosive eruptions due to the high viscosity of the lava, suggesting a rhyolitic, dacitic and andesitic composition for the latter. The Antimilos rhyolitic activity (0.32 ± 0.05 Ma; Fytikas *et al.*, 1986) is coeval with the most recent eruptive phase on Milos.

Ananes Islets (Fig. 2) comprise a six-islet group, with the largest recording an altitude of 82 m, the intermediate 42 m, and the smallest ranging from 9 to a few meters. They consist mainly of highly-altered porphyritic andesitic lava flows, developed in dome structures, and their explosive and extrusive activities belong to the Milos Volcanic Field, dating back from 3.5 to 1.6 Ma (Late Pliocene-Early Pleistocene) (Fytikas *et al.,* 1986).

Paximadi Islet

Paximadi Islet is located 1,5 km southwest of Milos Island and consists of alpine and post-alpine lithologies. More particularly, Paximadi hosts the pre-volcanic metamorphic basement of the Attic-Cycladic Metamorphic Complex and on top of it, Neogene sediments lie unconformably. The metamorphic rock consists mainly of glaucophanitic schist and partly green schist, phyllite, metabasalt and quartz veins. It has undergone high-pressure (HP-LT) metamorphic facies in the Eocene and low-pressure (LP-LT) facies in the middle to late Miocene. Thus, it constitutes part of the Cyclades Blueschist unit (Grasemann *et al.,* 2018), and is identical to that of Milos Island.

Additionally, the Blueschist unit is subject to pervasive ductile deformation, possibly during the Paleocene-Eocene period, with a shearing direction towards south to southwest.

Falconera, Velopoula and Karavia Islets

Falconera, Velopoula and Karavia Islets occupy the southeastern sector of the Pelagonian sensus lato (s.l.) geotectonic unit. Karavia comprises two islets where the larger one is delimited by faulted surfaces trending NW-SE and NE-SW, resulting in steeper and more vertical cliffs compared to the smaller one, lying southwestwards. It consists of limestone rich in Upper Permian-age fossils (determination by J. Bizon in Tataris 1988).

The main characteristic of the larger islets of Falconera and Velopoula is the outcropping of the ophiolitic unit that could be palaeotectonically related to a back-arc environment, as the ophiolitic and flyschoidal materials that fed the mélange of the Argolis tectonic units (Photiades *et al.,* 2024a). Moreover, the ophiolitic unit can be regarded as representative of a back-arc basin opening during the Middle to Late Jurassic (?), analogous to that of Guevgeli and

Skra ophiolite complexes that occur to the east of the Paikon volcanic arc (Saccani *et al.,* 2008).

Falconera resembles an elongated Z in shape (Fig. 3) and has a steep coastline controlled by NW-SE and NE-SW trending faults. Its name derives from the "Black Hawk" due to the dark color of its surface owing to the lithological composition of gabbro. The ophiolitic complex of Falconera consists of the crustal section of the ophiolitic sequence, lacking the mantle rock remnants, probably due to the sequence's emplacement onto the continental margin, as in the case of the post-flysch Upper Tectonic Unit with serpentinite mélange in Argolis (Photiades *et al.,* 2024a). Therefore, it only includes (from base to top): a) the lower members of the ophiolitic complex that outcrop towards the NW basal part of the islet and they are magmatically characterized by a basic cumulate sequence consisting of stratified-layered gabbro, b) an isotropic massive gabbro, dominated by cumulate intrusive coarse-grained rocks of hornblende-bearing gabbro, c) a sheeted dyke diabase complex system which is interconnected and magmatically overlain by a submarine extrusion lava cover, without any presence of red radiolarian chert. The lava cover comprises horizons of massive vesicular to porphyritic lava flows with acidic volcanic veins, which are successively derived from multiple underlying feeder veins (see geological section in Fig. 3).

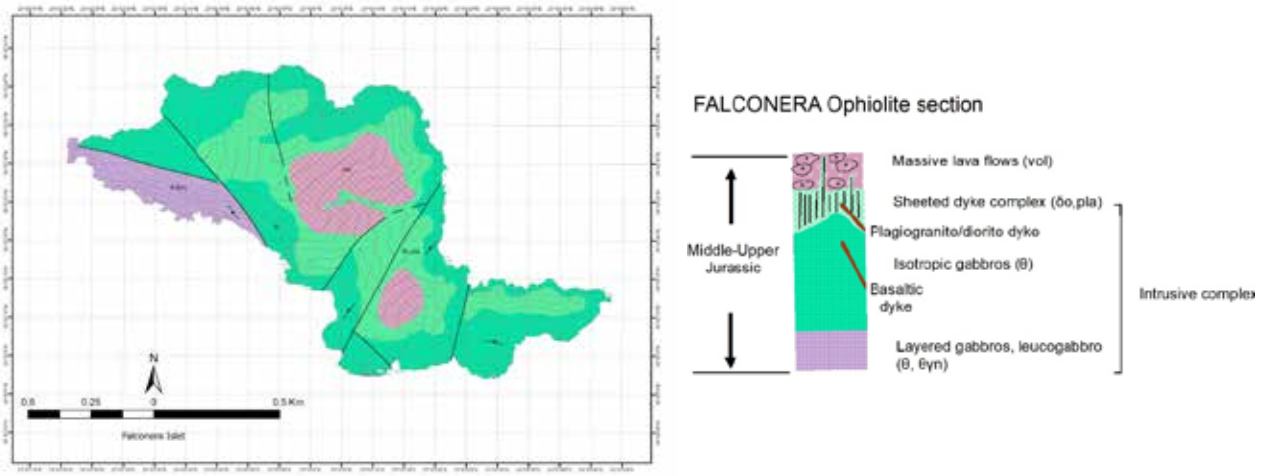

Figure 3. Geological map of Falconera Islet with its respective schematic stratigraphic column.

Velopoula is a 3-km long islet, bearing an elongated NW-SE steep ridge (Fig. 4). The presence of NW-trending faults contributes to the formation of its steep and weathered coasts. Ktenas (1924) mentions the outcropping of tuff, diorite, thick red jasper and Mesozoic carbonate at this islet.

Tectono-stratigraphically, Velopoula constitutes a nappe pile of the ophiolitic unit, thrusted on the Pelagonian continental margin, resulting from the compressional tectonic activity during the paleohellenic (eohellenic) phase as well as the post-flysch phase. The latter successively affected the neighboring Argolis Peninsula, too. Thus, from top to base, it comprises isotropic gabbro and tectonic slices of diabase intruded successively by quartz diorite, sub-ophiolitic mélange, red jasper succession, the carbonate platform and a basal volcano-sedimentary formation of Permo-Triassic age. Lithologically, the ophiolitic unit is homologous to the Falconera rocks. In general, Velopoula has undergone brittle deformation and low-grade, greenschist metamorphic conditions with recrystallizations.

The geological mapping of the above islets extending in the Myrtoan Sea between the Peloponnese and the Cyclades highlighted the following points: 1) The Upper Permian carbonate within the Karavia islets occurs as isolated blocks both in the Adheres-Argolis flyschoidal mélange of the internal Hellenides and in the imbricated Tertiary mélange unit between the Tripolis and Pindos Units in Peloponnese; 2) the Falconera and Velopoula ophiolite units can be regarded as representative as back-arc basin opening during the Middle to Late Jurassic (?), analogous to that of Guevgeli and Skra ophiolite complexes that obducted during late Jurassic-early Cretaceous times the continental margin of the internal Hellenides. Later, they were implicated by the post-Eocene continental collision of the Hellenides, leading to a non-metamorphic upper Cycladic Unit via a Miocene detachment over the Cycladic Blueschist Unit; and 3) Antimilos and Ananes volcanoes erupted during the Late Pliocene-Early Pleistocene, characterizing the Milos Volcanic Field on that subbasement.

The abovementioned geology of the islets at the Myrtoan Sea has been included in the geological sheet of Greece "Myrtoan Sea Islets", in scale 1:25000, edited by the HSGME (Photiades *et al.,* 2024b).

Introduction

Low-lying coasts such as beaches and lagoons are vulnerable to erosion and/or coastal flooding due to sea storms. A tool for the evaluation of the vulnerability of the coasts is the (CHW: Coastal Hazard Wheel), that is a universal coastal management framework (extended landwards to 200 m) for coastal classification, hazard information and adaptation guidance (Rosendahl Appelquist 2012; Appelquist & Halsnæs, 2015).

The coastal classification system is based on the bio geophysical components that are considered most important for the characteristics of a particular generic coastal environment; these are: (1) geological layout, (2) wave exposure, (3) tidal range, (4) flora/fauna, (5) sediment balance and (6) storm climate. Obviously, each generic coastal environment has a specific combination of these variables (Appelquist, 2012).)

The inherent hazard levels are defined as the hazards being an inherent part of the bio-geophysical properties of a coastal environment when exposed to the predicted changes in global climate over the coming decades. The inherent hazards covered by the CHW system are:

(a) ecosystem disruption that describes the possibility of a disruption of the current state of the coastal ecosystems under a changing climate

(b) gradual inundation, which describes the possibility of a gradual submergence of a coastal environment under a changing climate.

(c) salt water intrusion that describes the possibility of salty sea water penetrating into coastal surface waters and groundwater aquifers under a changing climate

(d) erosion and flooding, which describes the possibility of a sudden, abrupt and often dramatic inundation of a coastal environment caused by a short term increase in water level due to storm surge and extreme tides, under a changing climate

The purpose of the present study is to investigate the exposure of beach sectors from 4 different coastal areas of the Greek mainland The Kotychi lagoon, the Alfios River deltaic coast (north Kyparissiakos), the beach/dunes in the central Kyparissiakos coast and central part of the north coast of the Messiniakos Gulf, and four beaches from the coast of Attika (Figure 1).

Figure 1. **Beaches under investigation (a: West and Southwest Peloponnese, b: West Attica Coast)**

Methodology

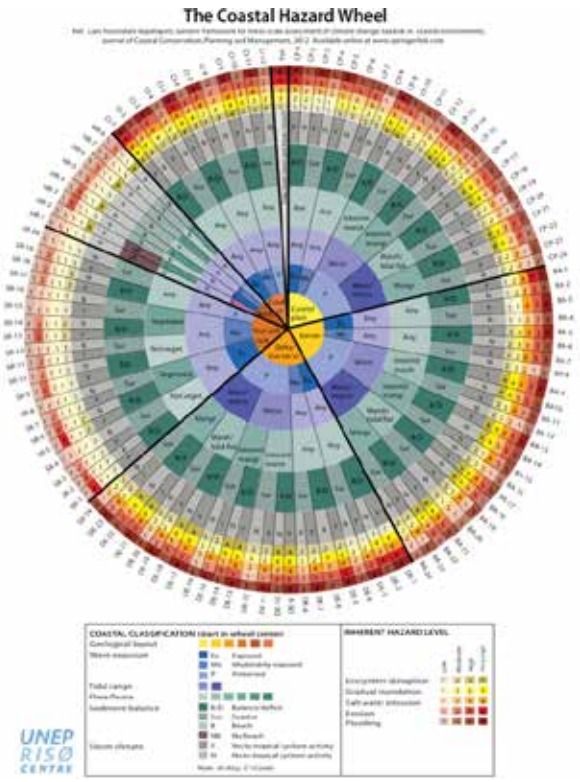
The application of CHW requires quantification/categorization of the bio-geo-physical components, as it is described below (Mangor, 2004).

The geological layout categories include (i) sedimentary plain; (ii) barrier; (iii) delta/low estuary island; (iv) sloping soft rock coast; (v) flat hard rock coast; (vi) sloping hard rock coast; (vii) coral island; (viii) tidal inlet/sand; and (ix) spit/river mouth (e.g., Davis and Fitzgerald, 2004).

Regarding wave exposure, coasts are classified as: (i) Exposed Coasts when fetches >100 km, (ii) moderately exposed, when fetches are 10–100 km and (iii) protected costs when fetches <10 km, but can also be seen along larger waterbodies with shallow nearshore zones or mild onshore wind climates (Mangor 2004).

The effect of tidal range includes 3 main categories: (i) microtidal <2 m; (ii) meso-tidal 2-4 m; and (iii) macro-tidal >4 m (Masselink and Hughes, 2003).

The flora/fauna component includes nine different categories; (i) intermittent marsh; (ii) intermittent mangrove; (iii) marsh/tidal flat; (iv) mangrove; (v) marsh/mangrove; (vi) vegetated; (vii) not vegetated; (viii) coral and (ix) any. Moreover, the vegetated category is applied when more than 25 % of the sloping soft rock coast is covered with vegetation while the not vegetated category is used when less than 25 % is vegetated (Appelquist & Halsnæs, 2015).



The sediment balance includes the two main categories: (i) balance/deficit; and (ii) surplus for the low-lying ssoft coasts and other two special categories (i) no beach and (ii) beach that applies to the hard rock coastlines (Haslett, 2009).

Storm climate differentiates between locations (i) with and (ii) without tropical cyclone activity, irrespective of their frequency. In areas identified as being under tropical cyclone influence (i.e., 5°–15°N and 5°–15°S), the classification system assigns a “yes” to tropical cyclone activity, while it assigns a “no” to locations outside these regions. (Appelquist, 2012).

The CHW hazard levels are divided into four categories ranging from 1 (low hazard) to 4 (high hazard). (Rosendahl Appelquist & Halsnæs, 2015). Each generic coastal environment is assigned a specific inherent hazard level for each hazard type. In the CHW, this information is presented using a combined number and color code, providing users with a clear and comprehensive overview of the hazard profile for a given coastal environment (Figure 2).

Results and Discussion

The results refer to: (1) The coastal zone of Kotyki, which extends in front of the homonymous lagoon, (2) The deltaic coastline of the Alphios River, (3) The coastal zones of the Central Kyparissia Gulf and the central part of the Messinian Gulf coastline, which include dunes and develop in front of a coastal lowland plain and (4) Four pocket beaches along the coast of the Athinaiki Riviera.

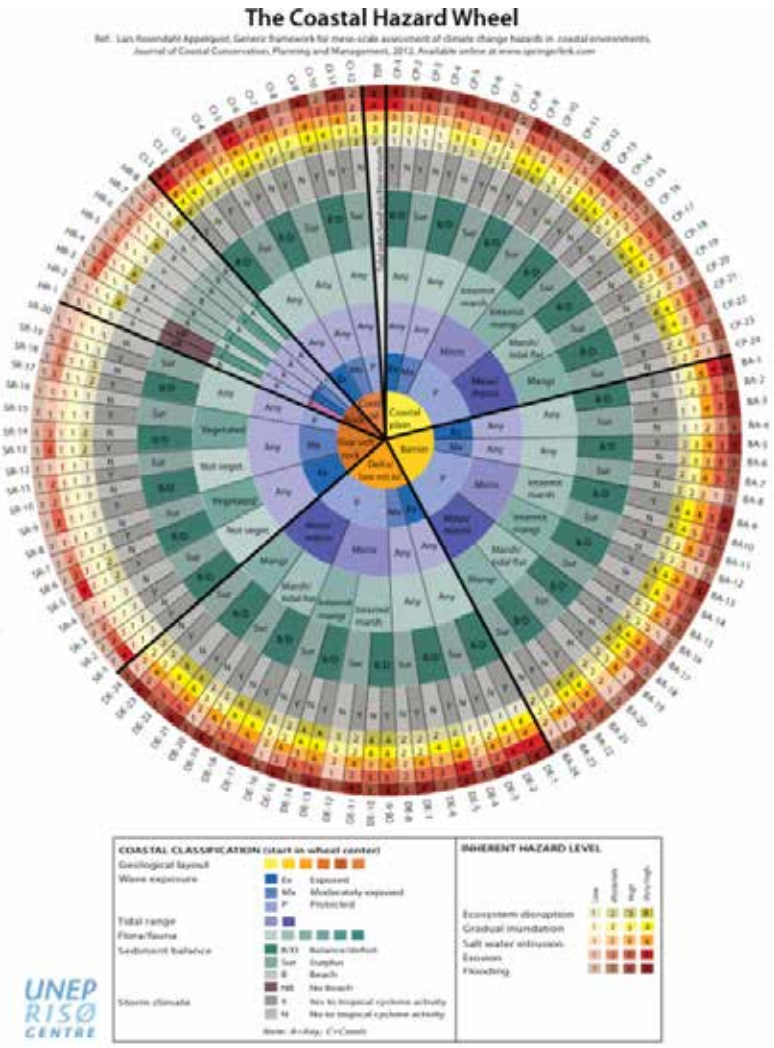


Figure 2. Coastal classification Wheel (abstracted from Rosendahl Appelquist & Halsnæs, 2015.

Sediment balance	Balance	Erosion = High (3)
Storm (tropical) climate	No	Flooding= High (3)

D. Athinaiki Riviera

D.1. Kavouri and Anavyssos beaches

Geological layout	Coastal plain	CP-6 (2-3-2-3-3)
Wave exposure	Moderate	Ecosystem disruption = Moderate (2)
Tidal range	Micro-tidal	Gradual inudation = High (3)
Flora/fauna	Any	Salt water intrusion = Moderate (2)
Sediment balance	Balance	Erosion = High (3)
Storm (tropical) climate	No	Flooding= High (3)

D.2. Vouliagmeni and Varkiza beaches

Geological layout	Coastal plain	CP-2 (1-2-2-3-3)
Wave exposure	High	Ecosystem disruption = Small (1)
Tidal range	Micro-tidal	Gradual inudation = Moderate (2)
Flora/fauna	Any	Salt water intrusion = Moderate (2)
Sediment balance	Balance	Erosion = High (3)
Storm (tropical) climate	No	Flooding= High (3)

Discussion and Conclusions

According to the results on biodiversity threat, the threat is low (category 1) for groups B and C, and moderate (category 2) for groups A and D1. In the micro-tidal environment of Greece, the gradual inundation is moderate (category 2) for group C (dune beaches) and D2 (pocket beaches not exposed to high waves), high (category 3) for group B (deltaic coast) and D2 (pocket beaches exposed to high waves), and very high (category 4) for group A (coastal barrier in front of a lagoon). Regarding saltwater intrusion, it was assessed as moderate (category 3) for groups B, C, and D, and high for group A. The risk of erosion is high (category 3) in groups A, C, and D, and very high (category 4) in group B. Finally, the risk of coastal (marine) flooding is high (category 3) in groups B, C, and D, and very high (category 4) in group A. Therefore, the main factors controlling the variability of exposure to coastal hazards appear to be primarily related to the geological layout and exposure to wave activity, followed by sediment balance and the type of flora and fauna.

Introduction

Rock weathering constitute a major factor controlling the hydrochemical evolution of river basins (Wang et al., 2022; Zhou et al., 2021; M. Zhu et al., 2021). Carbonate weathering is typically the main source of ions, followed by silicate weathering (Wang et al., 2020; Zhou et al., 2021). Land use and land cover changes in the river basin can have a direct influence on the hydrological realm and water quality (Lima et al., 2014; Raj and Azeez, 2010; Wang et al., 2022). Deforestation and agricultural expansion can lead to changes in the water balance, water availability, and water quality (Lima et al., 2014; Wang et al., 2022). Conversely, afforestation can increase the buffering capacity and pH of streams (Burgess-Conforti et al., 2022).

River basins are dynamic systems shaped by diverse factors, including geology, land use, and human activities, all of which can significantly influence the hydrochemical properties of both surface water and groundwater. In karst regions, characterized by soluble rock formations such as limestone and dolomite, the interaction between surface water and groundwater is particularly intricate. This complexity arises from the unique hydrological pathways and chemical processes inherent to these environments, where water movement and composition are heavily influenced by the dissolution of the surrounding rock (Xiao et al., 2021). Kazakis et al. (2018) point out that a holistic approach combining hydrodynamic analysis, vulnerability assessment, and integrated management strategies is essential for the sustainable exploration, protection, and management of Greece's karst aquifers, ensuring their long-term viability as critical water resources.

Karst aquifers are renowned for their heterogeneity and rapid flow dynamics, which contribute to significant variations in water quality and chemical composition. Research indicates that the dominant hydrochemical type of karst groundwater typically features bicarbonate and sulfate ions, reflecting the dissolution of carbonate minerals and the impact of surrounding geological formations (Yu et al., 2023; H. Zhu et al., 2021). The hydrochemical facies of karst groundwater are influenced by factors such as recharge mechanisms, land use practices, and pollution sources. These complexities underscore the need for comprehensive hydrochemical analyses to better understand the interactions within these aquifer systems (Kshetrimayum, 2015). Karst aquifers are highly vulnerable to contamination due to their unique hydrological characteristics, such as well-developed conduit systems, which allow rapid pollutant transport with minimal natural filtration (Kazakis et al., 2015).

In summary, hydrochemical investigations in river basins and karst groundwater systems are important for evaluating water quality, understanding hydrological processes, and managing water resources effectively. The integration of hydrochemical analyses of main and trace elements provides a comprehensive framework for unraveling the complexities of these aquatic systems (Pacheco Castro et al., 2018).

Study area

The study area is located in northwest Peloponnese in western Greece. The NW Peloponnese region has been the focus of numerous geological and tectonic studies, shedding light on the area's rock formations and their evolution (Doutsos & Poulimenos, 1992; Poulimenos et al., 1993; Flotte et al., 2005; Ghisetti & Vezzani, 2005; Trikolas, 2008; Backert et al., 2010; Ford et al., 2016). Geologically, the rocks in this region are classified as part of the External Hellenides (Koukouvelas, 2019, and references therein), specifically including formations from the Pindos and Tripolis Units.

From a paleogeographic perspective, the sequences of the Pindos and Tripolis Units were deposited along the eastern passive margin of the Apulian microplate. This margin was bounded to the east by the Pindos Ocean. The External Hellenides were formed during the Tertiary period as a result of the closure of the Pindos Ocean and the subsequent continental collision between the Apulian and Pelagonian microplates during the Alpine orogeny. A significant portion of the broader study area is now covered by post-Alpine Neogene and Quaternary formations, including modern alluvial deposits linked to the opening of the Corinth Rift.

The Pindos Unit occupies the largest part of the study area and comprises Mesozoic deep-sea carbonate and siliceous sedimentary rocks with a total thickness of approximately 1200 meters. These rocks are overlain by a clastic flysch sequence of Paleocene–Oligocene age (Degnan & Robertson, 1998). Structurally, the Pindos Unit is composed of distinct formations arranged from lower to higher levels. At the base lies the Triassic Clastic Formation, characterized by alternating sandstones, clays, and argillaceous layers interbedded with tuffs, granites, and gabbros, reaching a total thickness of about 100 meters. Above this, the Drymos Limestone Formation consists of hemipelagic limestones interbedded with cherts and clays, with a maximum thickness of 300 meters. This is followed by the Radiolarite Formation, a sequence of glassy cherts, clayey horizons, and pink limestones dated to the Jurassic–Lower Cretaceous, with a maximum thickness of 350 meters.

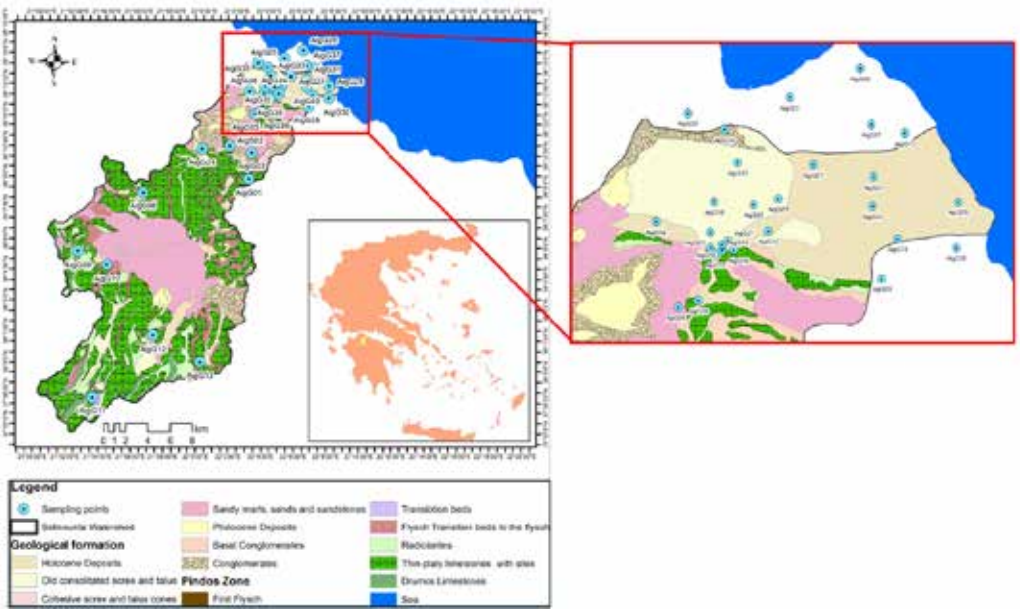

Figure 1: Geological map of the study area (modified by IGME geological maps)

The sequence continues with the Clastic Horizon, also known as the First Flysch, consisting of alternating sandstones and clays from the Lower Cretaceous, approximately 50 meters thick. Above this horizon lie the Upper Cretaceous Thin-Plated Limestones, containing cherts and reaching a thickness of 400 meters. Finally, the unit transitions into flysch deposits, including Transitional Flysch Layers and the Pindos Flysch Formation, composed of alternating sandstones, clays, and argillaceous layers of Paleocene–Oligocene age.

The Tripolis Unit, which underlies the Pindos Unit, has limited surface exposure within the broader study area. Its stratigraphy begins with a volcanic-sedimentary sequence of variable thickness, up to 400 meters, of Middle Triassic age, referred to as the “Tyros Beds.” Overlying this sequence is a thick carbonate succession, ranging from 3000 to 3500 meters, dating from the Triassic to the Eocene. This carbonate sequence is followed by a flysch sequence of Oligocene–Miocene age, which can be up to 1800 meters thick (Fleury, 1980; Jacobshagen, 1986). The Tripolis Unit includes dolomites and dolomitized limestones of Middle Triassic–Lower Jurassic age, neritic limestones with occasional dolomitic intercalations from the Upper Jurassic–Upper Cretaceous, and massive limestones rich in foraminifera of Paleocene–Middle Eocene age. These formations are capped by the flysch deposits of Oligocene–Lower Miocene age.

Hydrogeology

The flow of groundwater in porous media is influenced by the presence of faults (Knipe, 1997), which create boundaries with convergent and divergent flows, forming zones of drainage and recharge, respectively. Additionally, the depth of groundwater is a critical parameter for its protection. Greater depth offers a higher degree of protection from surface-originating pollutants, as contaminants must travel a longer distance to reach the saturated zone.

In the study area, groundwater level measurements were conducted to determine the direction of groundwater flow. Results indicate that groundwater flows in a southwest-northeast direction, from the mountainous region toward the coastal area. The highest hydraulic heads (64.87 m) are observed in the karstic aquifer, while the lowest are found in the coastal granular aquifer. Notably, no negative hydraulic heads were recorded in the study area.

Methodology

In this study, 40 water samples were collected from distinct sites, which included 7 springs, 2 surface water and 31 boreholes. From each sampling site, three separate water samples were collected and stored in thoroughly cleaned polyethylene bottles that had been acid-washed and rinsed. The first sample, with a volume of 1 liter, was designated for the analysis of anions, including (NO_3^-, NO_2^-, SO_4^{2-}, Cl^-, and F^-) and cations (Ca^{2+}, K^+, Mg^{2+}, and Na^+). The second sample, measuring 0.1 liters, was filtered using a Whatman 0.45 μm cellulose membrane and treated with 0.5 mL of ultrapure HNO_3 to analyze trace elements concentrations. Chemical calculations, such as the determination of saturation indices, were performed using PHREEQC version 3.0 (Appelo and Postma, 2004). The accuracy of the major element analyses was checked by using charge mass balance, and analyses were considered as acceptable when charge mass balance was less than 5%.

Results and Discussions

In Table 1 are presented the descriptive statistical parameters of the physicochemical characteristics, major elements, and trace elements for the 40 samples collected in the study area. Additionally, hydrochemical diagrams such as Piper and Durov were constructed for all samples collected during the investigation.

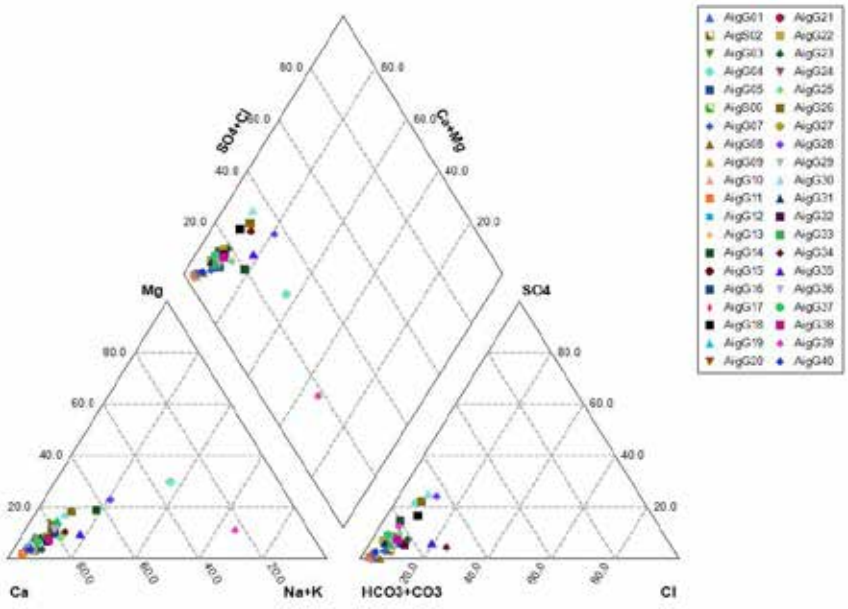

Figure 2. Piper diagram of samples in the study area

Piper diagram facilitates the identification of geochemical processes within a group of groundwater samples. The data from Selinountas river basin are shown in Figure 2. The results of ion exchange are particularly evident; when cation exchange occurs, the data points are projected parallel to the outer side of the diamond-shaped diagram. In contrast, when other reactions occur, the points deviate from the outer side. The dissolution of calcium carbonate is reflected in the movement of data points toward the calcium (Ca^{2+}) and bicarbonate (HCO_3^-) corners. The reduction of sulfate (SO_4^{2-}) shifts the points parallel to the anion axis, while the precipitation of calcium carbonate ($CaCO_3$) directs the points toward the sodium (Na^+), sulfate (SO_4^{2-}), and chloride (Cl^-) corners. The hydrochemical type Ca-HCO_3 represents the majority of the samples, and their chemical composition indicates rapid and shallow interactions with the geological formations of the area. Most waters in this category, primarily natural springs, exhibit low temperatures (Tw <20°C), although several boreholes show higher temperatures (Tw >20°C). Ca^{2+} concentrations range from 34.0 mg/L to 152.0 mg/L, with an average of 84.3 mg/L. Chloride (Cl^-) concentrations vary between 3.5 mg/L and 54.0 mg/L, with an average of 14.5 mg/L, which is typical for the study area.

The Mg^{2+}/Ca^{2+} ratio provides insights into the origin of water, the dissolution of subsurface minerals, and the geochemical processes that have occurred. In the study area, this ratio ranges from 0.017 to 0.86, with an average value of 0.14. All samples are associated with limestone and dolomitic aquifers. Specifically, the borehole samples AigG15 and AigG16 exhibit Mg^{2+}/Ca^{2+} values of 0.17 and 0.12, respectively. In regions dominated by limestone or dolomitic rocks, the Ca^{2+}/Cl^- ratio is typically high, as limestone contributes significant amounts of calcium to the water. Typical values may range from 0.5 to 10 or more, depending on the chloride concentration. In the study area, the samples show Ca^{2+}/Cl^- ratios ranging from 3.31 to 37.64, indicating calcium dominance resulting from the dissolution of carbonate rocks.

Table 1. Statistical parameters of chemical composition.

	Min	Max	Average	Std. Division
pH	7,37	8,05	7,76	0,16

U (μg/L)	0,03	0,85	0,22	0,14

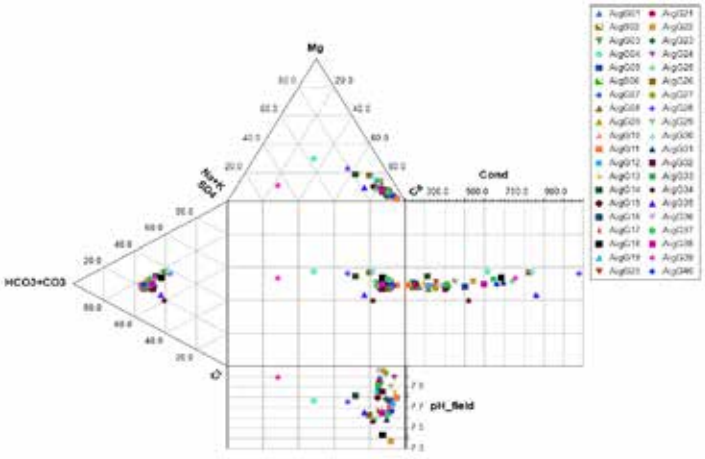

Figure 3. Durov diagram of samples in the study area.

The lithium (Li) concentrations of samples range from 0.5 to 43.5 μg/L, with an average value of 4.7 μg/L. The highest concentrations were recorded in boreholes AigG04 (43.5 μg/L), AigG28 (30.7 μg/L), and AigG39 (13.9 μg/L), while the remaining samples showed values between 0.5 μg/L and 5.9 μg/L. Boreholes Coca Cola AigG15 and AigG16 reported lithium concentrations of 3.8 μg/L and 4.1 μg/L, respectively. Chromium (Cr) concentrations range from 0.0 μg/L to 3.5 μg/L, which are below the drinking water limit (25.0 μg/L). Arsenic (As) concentrations were below the drinking water limit in all groundwater samples from the study area. Strontium (Sr) is found in natural waters at concentrations that depend on the geology of the area, with typical values reaching up to 2000 μg/L. In the analyzed samples, strontium concentrations range from 113.8 μg/L to 2261.5 μg/L, with the highest value recorded in sample AigG04. The average concentration is 434.0 μg/L. Generally, higher strontium concentrations are observed in waters that flow through limestone or dolomitic rocks, as well as in areas with geology rich in celestite ($SrSO_4$) or strontianite ($SrCO_3$) (Banner, 1995).

Iron (Fe) can be released to groundwater under specific conditions from minerals such as amphiboles, pyroxenes, ferromagnesian micas, iron sulfides, sandstones with oxides, carbonates, and clay minerals. The concentrations of Fe range from 9.6 μg/L to 720.5 μg/L, while the highest concentration occurs in sample AigG26 which was the only sample with concentration above drinking limit. Manganese (Mn) typically occurs alongside iron, enriching groundwater in acidic environments. Its sources include soils, sediments, and metamorphic rocks rich in micas and amphiboles. The drinking water limit for manganese is 50 μg/L, and samples from boreholes AigG26 and AigG29 exceed this limit.

Conclusion

In conclusion, the hydrochemical analysis of 40 water samples from the study area has provided significant insights into the quality and characteristics of the region's groundwater resources. The Ca-HCO□ hydrochemical type dominates in the water samples. The hydrochemical pattern of the samples suggests quick and shallow interactions with the region's geological formations. The parameters with concentration above the drinking limit are two (Fe and Mn), however the excess is limited only to two samples (AigG26 and AigG29).

Such concentrations might pose potential risks to human health. These results underscore the critical role of hydrogeological variability which shapes groundwater hydrochemical regime in river basins.

Assessment of natural and anthropogenic contamination of the sediments in the Sacca di Goro lagoon (Po river delta, northern Italy)

Rapti D.[1,2]

(1) University of Ferrara, Department of Chemical, Pharmaceutical and Agricultural Sciences, cpr@unife.it (2) New Energies And environment, spinoff company of Ferrara University, Ferrara, Italy

Abstract

The definition of heavy metal content in lagoon sediments plays a critical role in distinguishing between natural contamination (geohazard) and anthropogenic impact, and is essential for assessing the risk posed by these pollutants in the aquatic environment.

In particular, the Sacca di Goro lagoon, located in the Po River delta (Northern Italy), represents a significant area of interest due to its natural and economic value. Spanning an area of approximately 20 km², with an average depth of 1.5 meters and salinity levels of 29‰, the lagoon is not only crucial for its biodiversity but also plays a pivotal role in regional aquaculture, particularly for mussels and clams (Figure 1).

In this unique lagoon system, understanding the quality of the sea-bottom sediments is fundamental not only for the health and growth of cultivated species but also in addressing potential bioaccumulation problems of heavy metals that may impact both wildlife and human health. By evaluating the qualitative status of the sediments, we can develop effective strategies for sustainable environmental management and safeguard productive aquaculture activities while minimizing risks to the ecosystem.

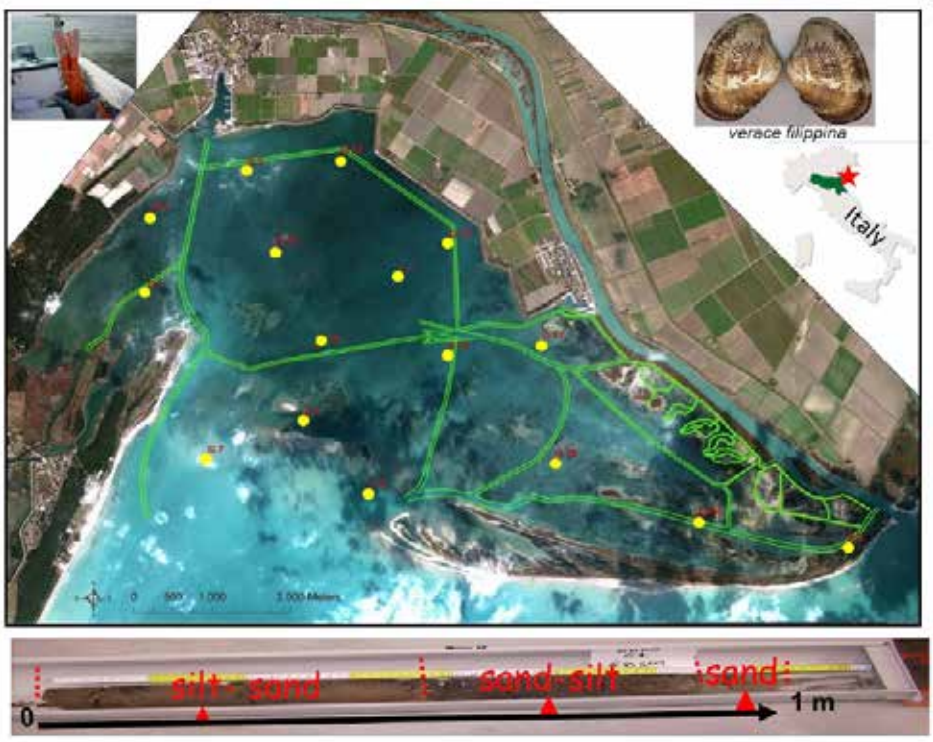

Figure 1: Location of the Sacca di Goro lagoon. The yellow circles represent the sampling points. Below, an example of a continuous core drilling. The green lines represent the sub-lagoon channels.

In the present study, fifteen continuous core drilling surveys were conducted, with depths ranging from 100 to 200 cm, distributed evenly across the lagoon area. A total of 70 sediment samples were collected and analyzed for grain size composition, organic matter content, and concentrations of various elements such as SiO_2, TiO_2, Al_2O_3, Fe_2O3, MgO, MnO, CaO, Na_2O, K_2O, P_2O_5, Ba, Ce, Co, Cr, La, Nb, Ni, Pb, Rb, Sr, Th, V, Y, Zn, Cu, Ga, Nd, S, and Sr. Furthermore, in selected samples, sediment toxicity was evaluated using the bacterial bioluminescence toxicity assay, which provides insight into the potential biological impact of the sediments.

The comprehensive dataset obtained from these analyses enabled us to achieve several important goals: i) defining the overall environmental quality of the sediments, ii) identifying areas with the highest contamination risks, iii) establishing a relationship between grain size distribution and chemical concentrations (Figure 2), and iv) emphasizing the local occurrence of natural pollution phenomena linked to metals such as chromium (> 50 ppm) and nickel (> 30 ppm), as well as human-induced contamination from lead (> 30 ppm) and copper (> 60 ppm).. Additionally, the toxicity results from the bioluminescence assay further clarified the potential harmful effects of these sediments on marine life.

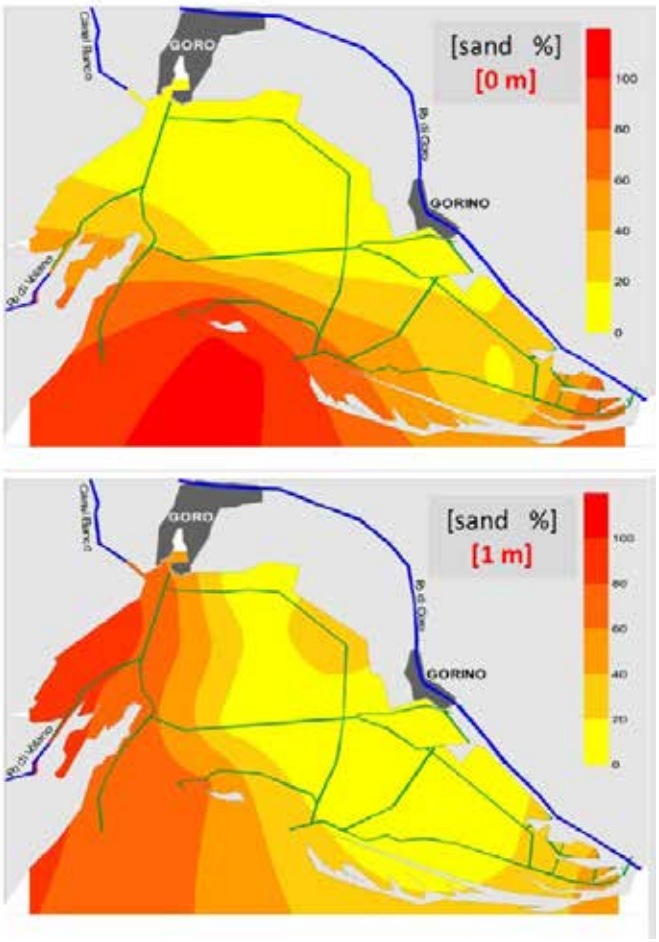

Figure 2: Example of the spatial distribution of sand content in the sediments at depths of 0 cm (lagoon bottom) and 100 cm.

This study provides valuable information for the formulation of effective management policies that can mitigate the risks posed by both natural and anthropogenic pollution, while ensuring the sustainable development of the aquaculture industry and the protection of the broader ecosystem in the Po River delta.

EXTENDED ABSTRACT 267

The role of hydrogeology in the sustainable exploration of shallow geothermal resources

Rapti D.[1,2]

(1) University of Ferrara, Department of Chemical, Pharmaceutical and Agricultural Sciences, Italy cpr@unife.it (2) New Energies And environment, spinoff company of Ferrara University, Ferrara, Italy

Abstract

Climate change, the diffusion of micropollutants in the atmosphere, as well as European energy and environmental policies, are driving the research and use of renewable and eco-sustainable energy resources to support the energy transition process.

The optimization of a geothermal exchange system requires a holistic approach that takes into account both the energy needs of the building and the hydrogeological, chemical, and thermophysical characteristics of the subsoil, as well as the presence of natural and legislative constraints.

In this context, a new dynamic closed-loop heat? exchanger designed for the exploitation of shallow geothermal resources has been installed at a test site in the alluvial Po plain (northern Italy). By means of *in situ* and laboratory tests, we collected data on:

a) sedimentary sequences and grain size, obtained through continuous core drilling and laboratory tests;

b) hydrogeological conditions and the local conceptual hydrogeological model up to a depth of 80 meters, assessed via pumping tests, measurement, and analysis of hydrodynamic data;

c) hydrochemical characteristics of the aquifer systems, determined through chemical and isotopic analyses (oxygen, deuterium, strontium);

d) thermo-physical monitoring, conducted via the implementation of a Distributed Thermal Response Test and laboratory measurements of thermal conductivity. Additionally, a monitoring system based on Distributed Fibre-Optic Temperature-Sensing (DTS) has been installed to better define underground temperature profiles under both natural and thermal solicitation conditions (Fig. 1).

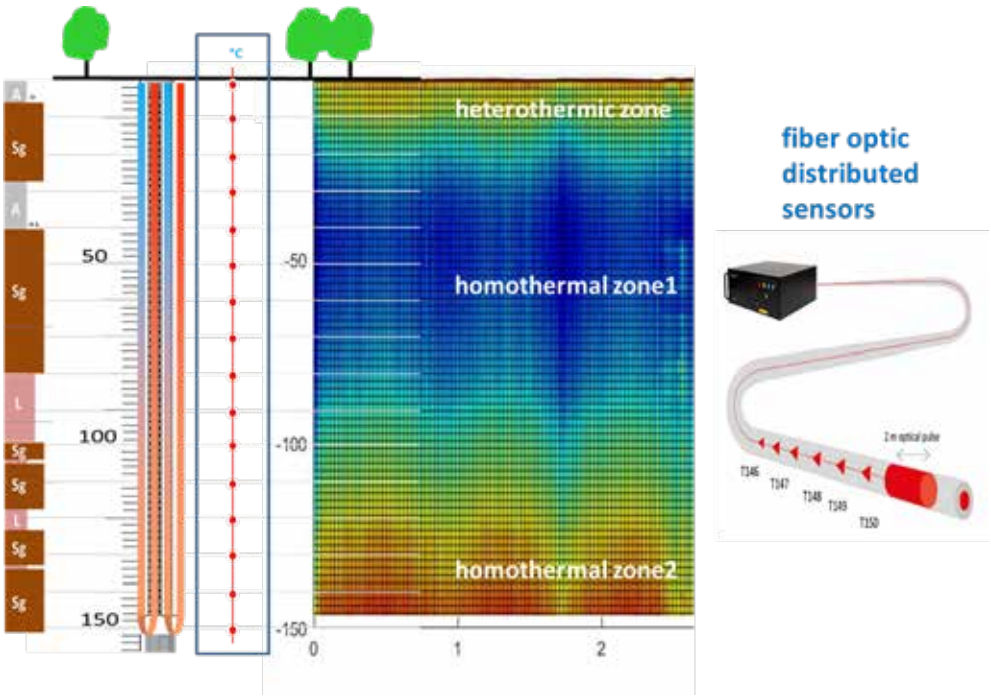

Figure 1. Results of the Distributed Fibre-Optic Temperature-Sensing (depth in meters; A: clay; Sg: sandy; L: silt).

By employing a comprehensive and holistic methodology, the integrated analysis of various data sets facilitated a rigorous characterization of the hydrodynamic and thermo-physical properties of the local aquifers. This characterization was further enhanced through the utilization of advanced numerical simulation models. Additionally,

the study assessed the subsoil's responses to the thermal stresses that could potentially be induced by a low-enthalpy geothermal plant with an approximate capacity of 350 kW. Finally, this analysis enabled us to assess the energy and environmental sustainability of these innovative dynamic closed-loop heat exchangers.

EXTENDED ABSTRACT 268

Liquefaction susceptibility in delta environments: the case of the Po delta area (northern Italy)

Rapti D.[1] Papathanassiou G.[2], Valkaniotis S.[2], Taftsoglou M.[3], Caputo R.[3]

(1) University of Ferrara, Department of Chemical, Pharmaceutical and Agricultural Sciences, Ferrara, Italy cpr@unife.it.

(2) Aristotle University of Thessaloniki, School of Geology, Thessaloniki, Greece

(3) University of Ferrara, Department of Physics and Earth Sciences, Ferrara, Italy.

Abstract

We know that, during a seismic event, liquefaction phenomena are not randomly distributed over an active or recent floodplain but are strongly dependent on the depositional evolution of the area like grain size of the sediments, depositional age shallow layering, and depth of the groundwater level. Recent unconsolidated sediments (Holocene age), deposited by fluvial or wave action, such as those found in paleo-channels and point bars in coastal areas, generally exhibit a higher frequency of liquefaction compared to sediments deposited under different conditions within the same floodplain and/or coastal zone.

Based on these considerations, Youd and Perkins (1978) proposed the division of geological units into four classes of liquefaction susceptibility: low, moderate, high, and very high. They also emphasized that water-saturated geological formations, such as river channels, floodplains, deltaic regions, and dunes, are generally characterized by a high to very high susceptibility to liquefaction.

The reliability of a liquefaction susceptibility map is heavily influenced by the investigation scale, as well as the density and accuracy of the geological, geomorphological, and hydrogeological data.

In this paper, an area of about 560 km², situated in the eastern sector of the Po River plain (northern Italy) within the Po River delta, including part of the modern delta, has been considered and analyzed in detail to examine the likelihood of geological units to liquefaction. To achieve this, a large variety of data has been considered. Lithological, chronological (14C data), geomorphological, hydrological, hydrogeological data, satellite imagery, modern and historical topographic maps, as well as historical and archaeological evidence, were integrated with data from continuous core drilling and penetrometer tests (Figure 1).

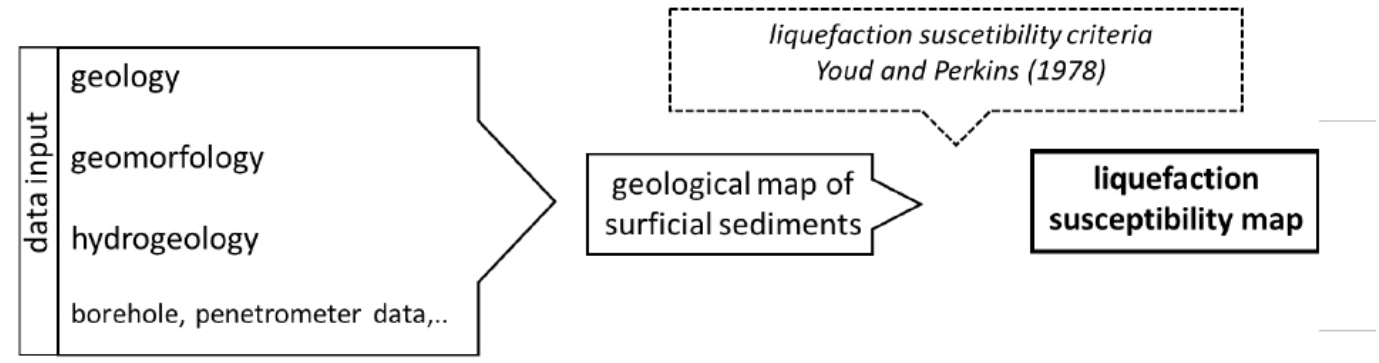

Figure 1. Flowchart showing the phases of the method applied in this study.

This integrated data analysis allowed us to define the liquefaction susceptibility map. Specifically, four classes were identified, corresponding to the following susceptibility levels:

a) *very high*, in the portion of the territory occupied by the floodplain of the main Po channel, which accounts for 4% of the overall area;

b*) high*, corresponding to 26% of the area, found in geological formations such as floodplains, channels, crevasse splays, abandoned channels, and coastal dunes;

c) *moderate*, covering approximately 20% of the territory, mainly characterized by beach barrier formations;

d) *non-susceptible features*, representing 50% of the territory, including marshes of interdistributary areas and brackish marshes and lagoons of the front delta plain, since they are fully infilled by clays, silty clays, and silts.

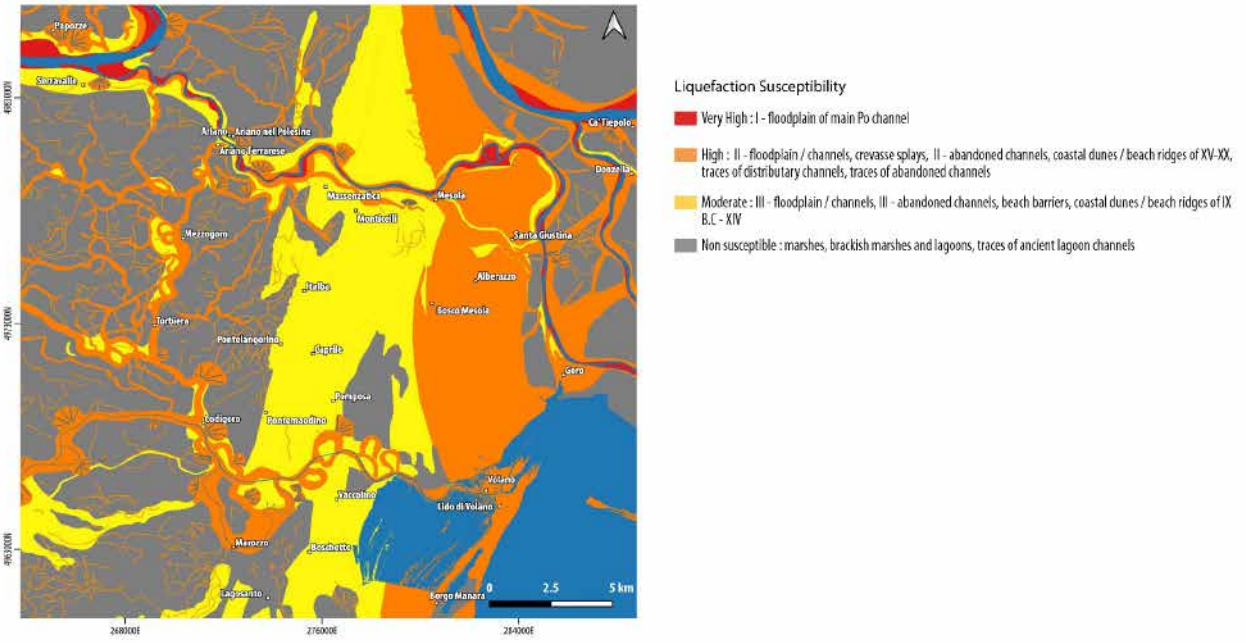

Figure 2. Liquefaction Susceptibility map of Po delta plain, based on the proposed refined classification of Youd and Perkins criteria (1978).

The obtained data could be used by public authorities to implement strategies and governance measures aimed at the sustainable management of the territory, considering the significant natural (a large portion of the area is included in the Natura 2000 protected areas network), environmental, cultural, and economic value of the Po Delta area.

EXTENDED ABSTRACT 269

Investigation of legislation and tools for coastline demarcation: the coastline along the Kalamas delta in Thesprotia as a case study

Rapti Georgia[1], Tzoraki Ourania[2]

1 University of the Aegean, Mytilene, Greece, grapti@hotmail.com, 2 University of the AegeanMytilene, Greece

Introduction / Background

The purpose of this study is first to investigate the Greek legislation regarding the delimitation of the coastline and second compare the delimitation tools used internationally. In addition, the question arises whether the automatic coastline extraction tool SAET is feasible to be used for the delimitation of coastlines by a simple user.The region of Thesprotia was chosen as a case study, and specifically, a part of the coastline along the Kalamas River delta.
For the Greek state, in 21.06.1837 was the first time that the definition of the coastline was established and it was defined its common use (Skandali G. D.,2010). Since then, many laws have used for the definition, protection and the exploitation of the coastline and the shoreline. The table below attempts to summarize the differences between the basic laws regarding the definition and mapping of the coastline.

Table 1. Differences of the basic Greek laws regarding the determination and mapping of the coastline

Low	Coast-beach width	Determination of the coast	Mapping -drawing of the coastline	Scale	Comments
L.2344/1940	20m	Testimonies of witnesses and without appropriate tools	Topographic and elevation chart and relevant report	Not specified

(F.E.K. – National Printing House,1940, F.E.K. – National Printing House,2001, F.E.K. – Joint Ministerial Decision 1089532/P.E./8205P.E./2005, 2005, National Printing House,2024)

With the help of the bibliographic review and the PRISMA Statement 2020 protocol,documents were extracted from the international bibliography Scopus, based on keywords.regarding the tools used for the delimitation of coastlines. A total number of 328studieswere selected, mainly published articles and conference proceedings, between the years 2000-2024 with the year 2022 presenting the largest number of studies. India appeared the country with the biggest involvement in studies and research on coastline detection and demarcation tools and also hadthe largest network of cooperation with other countries, followed by China and Italy.In almost half of the

studies, the coastline was demarcated due to integrated beach management because erosion and deposition had been observed. A large percentage concerned integrated management and monitoring. Other reasons were the detection of the coast, themonitoring of changes due to anthropogenic factors, or due to storms or for reasons of governance, or changes in the coastline due to tsunamis and due to changes in land use.Regarding the size, type and land use near the coasts, in numerous studiesthey were not mention but the next highest percentage involves small sandy beaches with multiple uses and close to urban areas.Most of the studies used a combination of data sources, followed by those that used Landsat, Sentinel and generally satellite images. In some of the studies the date source was not stated, while in others were used synthetic aperture radar, UAV/UAS or images from videos, cameras and mobile phones. Some chose SPOT, LIDAR, bathymetry. Among the less used are Global Navigation Satellite system (GNSS), Pléiades, QuickBird.

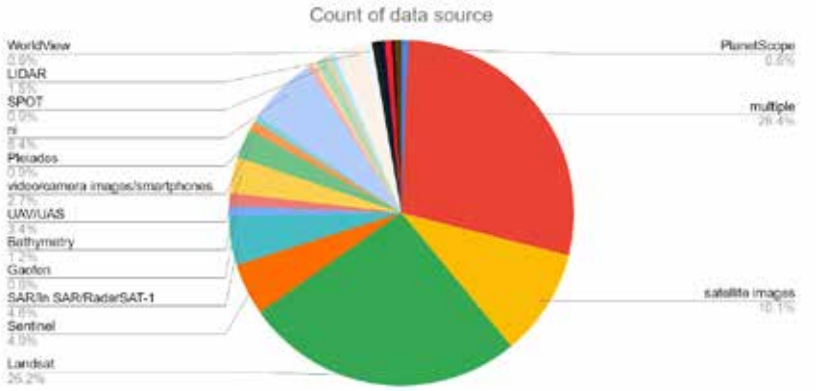

Figure 1. Data source used

Regarding the tools for coastline delineation in most studies, more than one tool was used, with the Digital Shoreline Analysis System (DSAS) and GIS being chosen quite often.In the table below we observe that the dominant tool for coastline delineation is the Digital Shoreline Analysis System (DSAS), while GIS is generally mentioned as a tool, some of the studies seems to have used some kind of model or an algorithm. Others used ENVI software, SAET, ERDAS and Convolutional Neural Networks, Google Earth Engine (GEE). Numerus studies used more than one coastal delineation tool, while SELI, AMBUR, SHOREX. CoastSat, CoastSnap, CLAHE, MATLAB, Pix4dMapper, Beachmeter, AgisoftPhotoscan, CET, ODSAS, Cliff DelineaTool, ArcMapCASSIE are also presented (Figure 2.)

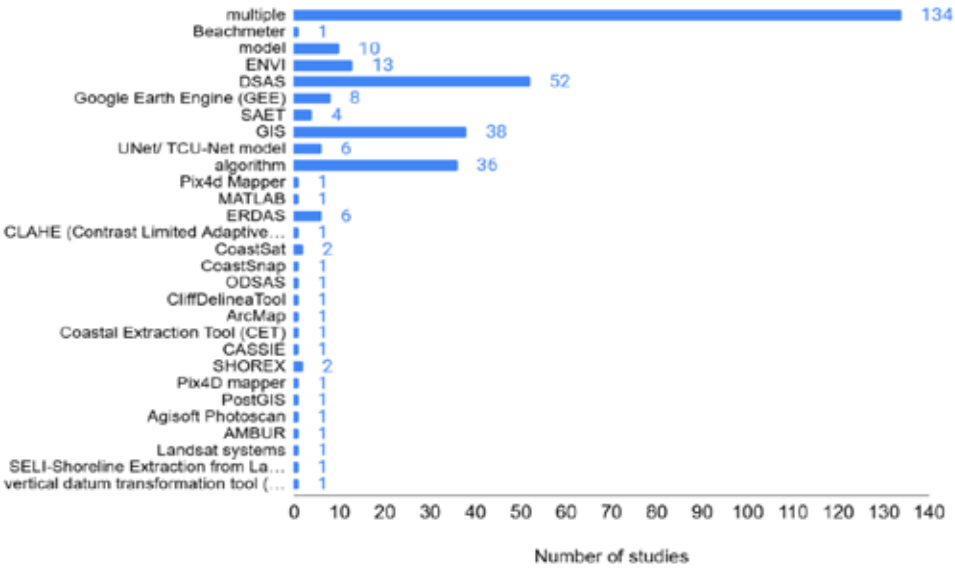

Figure 2. Shoreline extraction tools

In most studies, not just one coastal delineation method was chosen, but multiple, followed bythe segmentation and classification method.

Study area and storm events

The Kalamas River Delta is located on the coast of the Ionian Sea, in the region of Thesprotia (Epirus, northwestern Greece) and is one of the most important wetlands of western Greece. It has an area of approximately 85 km², and its shape corresponds to an “arc-shaped” delta and consists of two different mouths: one anthropogenic, active today, and the other located less than 10 km south (old estuary), which is now inactive and sheltered behind sandy beaches. In general, the front consists of sandy beaches and large sandy “tongues”. The construction of the dam in 1962 upstream of the delta as well as several works aimed at draining the land to facilitate cultivation and the construction of a river channel in 1951, have significantly changed the appearance of the delta. It should also be noted that the Kalamas River delta developed in the straits of Corfu, so it is protected from the strong currents that prevail in the Ionian Sea. (Chabrol et al., 2022, Epirus Water Resources Authority - EL05, (n.d.))

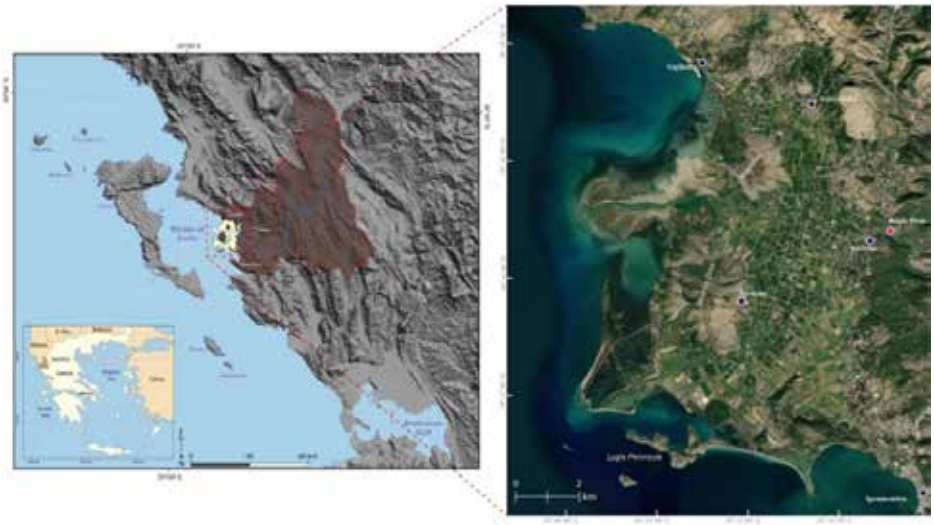

Figure 3. Study area (Chabrol et al., 2022)

Figure 4. Damage caused by the storm on 11/12/2021, (photos by author)

Figure 5. Damage caused by the storm on 06/01/2024 (photos by author)

Three storm events were selected because of the reported problems (erosion and flooding) in the area. The first one occurred 10-12 December 2021, the second one 6-7 January 2024 and the third 5-6 October 2024 (Cassandra storm). (meteo.gr, https://meteo.gr/article_view.cfm, https://www.cnn.gr/ellada/story/442473/kakokairia-cassandra-plimmyrisan-spitia-kai-katastimata-stin-ipeiro-xoris-reyma-stous-filiates.). In all three storm events strong southerly winds and a fairly high percentage of precipitation were the main characteristics. (https://www.in.gr/2024/01/06/greece/synagermos-gia-tin-kakokairia-ekspres-neo-ektakto-deltio-deite-xartes/, https://www.cnn.gr/ellada/story/442056/allazei-o-kairos-apo-paraskevi-me-tin-kakokairia-cassandra-na-xtypa-kerkyra-kai-ipeiro, meteo.gr)

Methodology

The Shoreline Analysis and Extraction Tool (SAET) software was developed within the framework of the European project ECFAS (European Coastal Flood Awareness System), with the aim of providing a solution to enhance the resilience of coasts to climate change and reduce the exposure of the population and infrastructure to risk.It was developed by the Geo-Environmental Cartography and Remote Sensing group of the University of Valencia (UniversitatPolitècnica de València, Spain) and is the work of Jesús Palomar Vázquez, Jaime Almonacid Caballer, Josep E. and is the intellectual property of the university SAET is a software developed in Python and focuses on the automatic extraction of coastlines from optical satellite images (Sentinel-2, Landsat-8 and Landsat-9). The main algorithm is based on the subpixel coastline detection approach, allowing the acquisition of the coastline before and after the storm, enabling comparison and the identification of the impact of storm erosion on beaches.(Palomar-Vázquez et al., 2023).

The first step for coastline delineation is the collection of satellite images, based on their coverage and acquisition date in relation to the storm. In our case, the study area is covered by a single Landsat scene and a Sentinel-2 tile. We then searched for the closest satellite images before and after the storm peak date (11/12/2021) by running SAET in “search only” mode and selected the images with the highest spatial resolution between (Landsat and Sentinel-2), so two Sentinel-2 images before and after the storm (12 November and 17 December) were selected, according to the criteria of the lowest possible cloud cover (up to 10%), the closest storm peak date (11 December). These two images were used as input to run SAET again, butthis time, in the “acquire” mode, and then in the “process” modeusing the AWEInsh water index for the segmentation method.Thus, two Sentinel-2 images were processed, resulting in the extractedcoastline.(Figure 6)The same procedure was followed for the following storms, for the one on January 6, 2024, Landsat images were selected, on 12/28/2023 and on 01/29/2004 (Figure 7) Finally, in the case of the Kassandra storm that hit the area on October 4,2024, 2 Landsat images were used on 09/01/2024 and 10/27/2024.(Figure 8)

Figure 6. Satellite-Derived Shorelines before and after the storm 11/12/2021 The coastline in green is the shoreline before the storm and the coastline in red is the shoreline after the storm.

Figure 7. Satellite-Derived Shorelines before and after the storm 06/01/2024 The coastline in green is the shoreline before the storm and the coastline in red is the shoreline after the storm.

Figure 8. Satellite-Derived Shorelines before and after the storm 04/10/2024 The coastline in green is the shoreline before the storm and the coastline in red is the shoreline after the storm.

Results

The analysis of the extracted coastlines for all three cases was done through the QGIS program, on a coastline length of approximately 2 kilometers, for each one separately. A single section of the coastline was selected in order to reduce the number of points to be compared of the coastlines obtained from SAET in order to make their analysis easier.These were then divided into 10 sections each.In the first storm in 2021, maximum erosion was observed at nine meters in some points but also deposition in some others with a maximum of eleven meters. It should be noted that erosion occurred on the largest part of the coastline. (Figure 9) In the second storm in January 2024(Figure 10), the greatest erosion observed was 15 meters, while the deposition reached 20 meters. In this case, the coastline, according to the analysis, showed total deposition after the storm.Finally, in the storm of October 2024 (Figure 11), the greatest erosion reached 15 meters, while the maximum deposition was 24 meters. In general, the storm left the coastline with erosion in most of its part.In some sections, the same phenomenon is observed in all 3 cases, which also agree with the damages that had been reported. The first two cases seem to have more similarities, while in the case concerning the storm Kassandra, the analysis also shows sections in which, while they showed deposition in the previous storms, after “Kassandra” they were eroded and vice versa.

Figure 9. Analysis of SDS before and after the storm in December2021 Dark blue indicates maximum erosion and yellow indicates maximum deposition.

Figure 10. Analysis of SDS before and after the storm in January 2024. Dark blue indicates maximum erosion and yellow indicates maximum deposition.

Figure 11 Analysis of SDS before and after the storm in October 2024. Dark blue indicates maximum erosion and yellow indicates maximum deposition.

Uncertainties

In the original SAET file, the area of interest is divided into 3 smaller beaches with a different code each, so the largest one was selected, with the code 2127.The beach areas were taken from the European zone dataset provided by the Earth Observation Service. Copernicus. Also, when applying the software in the “download” mode in order

toreceive satellite images from Sentinel, the error “Access token” occurred and it was not possible to overcome it by the specific user, while a request was made tobecome “online” again.In addition, it was not possible to produce SDS close to the dates of the events andin the three cases the time period before and after exceeds one month, while ideallyit should have been one day before and one day after the storm, we believe that this alsoaffected the results.It shouldbe noted that the cases selected for examination did not involve majorstorms.

Conclusions

Comparing the results, we observe that in all three cases, in most sections, the same phenomenon is observed, erosion or deposition, which is in agreement with the damages caused. The first two cases seem to have more similarities, while in the case of the storm Kassandra, the analysis also shows sections in which, while they presented deposition in the previous storms, after ̈Kassandra ̈they were eroded and vice versa.

The delineation of a coastline is now achieved:in a short time, almost automatically which reduces the error rate from the userand at low cost, since much of the data is freely available with a fairly high resolutionFor a given section of coastline after a coastal storm, SAET facilitates the selection of the closest satellite images in time to the analyzed events, ensures a sufficient level of coverage for the analysis of the coastline change, and automatically ‘downloads’ the images from the official satellite repositories, processes them and exports them to the location of the coastline. SAET: performs a tool for studying the impact and recovery of beach morphology in a coastal storm, but also in the case of anthropogenic interventions and long-term SDS, thus contributing to the effort to address and mitigate the effects of coastal and not only storms and to finding the most appropriate measures for their timely response.

Introduction

Ophiolites are fragments of oceanic lithosphere that have been tectonically emplaced along the continental margins in accretionary prisms during orogenic processes providing important insights regarding the petrogenetic activity within the oceanic lithospheric mantle beneath spreading centers in mid-ocean ridge (MOR) and suprasubduction zone (SSZ) settings (Dilek and Furnes, 2011, Ahmed, 2013, Dai *et al.*, 2013).These tectonic settings include oceanic spreading centres, hot spots, backarc and forearc basins (supra-subduction zone environments) as well as arcs and other extensional magmatic settings including those in association with plumes. Furthermore, they provide information about the magmatic, metamorphic and geotectonic processes that occurred in the oceanic crust and the upper mantle (Arai *et al.*, 2006, Uysal *et al.*, 2007). The mantle-derived ophiolites provide significant information for paleotectonic evolution of the oceanic lithosphere, partial melting processes, melt-rock interaction and melt fractionation of the uppermost mantle (Singh *et al.*, 2016). Specifically, the abyssal peridotites represent mantle residues produced by partial melting beneath MOR settings, whereas the highly depleted SSZ peridotites experience intense partial melting above a subduction zone.

The aim of the present study is to provide new petrographic and geochemical data of mafic rocks from the Edessa ophiolite complex, in order to shed light on their petrogenesis.

Geological setting

The ophiolitic complex of Edessa, comprises a series of oceanic crust and mantle fragments linking the Veria-Naousa ophiolite (Rogkala *et al.*, 2017) in the south with the Guevgeuli ophiolite (Giannakopoulou *et al.*, 2018) in the northeast (Figure 1). It represents remnants of oceanic lithosphere that was thrust out of one or more ocean basins during Upper Jurassic to Lower Cretaceous time (Michailidis, 1990).

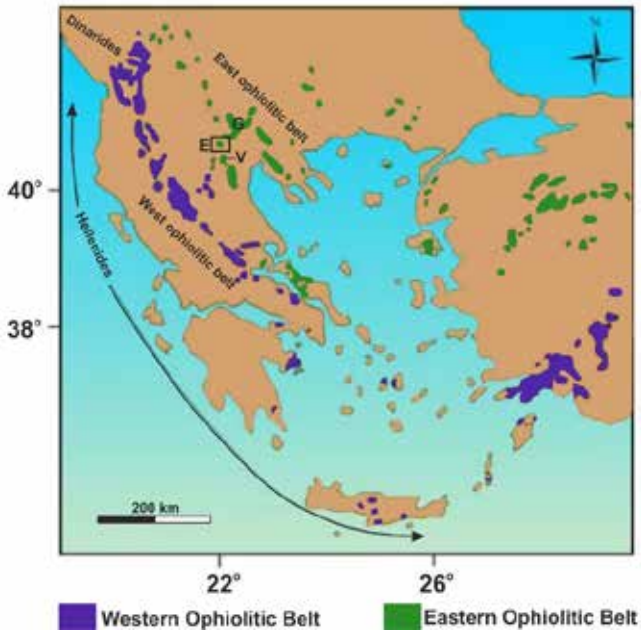

Figure 1. Distribution of ophiolites in the southernmost part of the Balkan Peninsula and Turkey (Rogkala *et al.*, 2019). Key to lettering: E = Edessa (also marked by the open square), G: Guevgeuli, V: Veria-Naousa.

The ophiolitic complex has been significantly affected by tectonically related emplacement mechanisms and it consists of several tectonic units (Pe-Piper and Piper, 2002, Saccani *et al.*, 2008). It includes lherzolites, serpentinised harzburgites

with high degree of serpentinisation, gabbros, diorites, diabasic sheeted dykes and pillow basalts. The serpentinised harzburgite is the dominant rock type amongst the ultramafics and encloses chromitites (Rogkala *et al.*, 2019). A sparse network of gabbroic and dioritic dykes crosscuts the serpentinised harzburgite. Massive diabase and basalt are thrust over serpentinised harzburgite and pass upwards into basaltic pillow-lava flows (Figure 2). A sparse network of rodingite dykes within the highly serpentinised harzburgites has also been identified. The ophiolitic rocks are unconformably overlain by Middle-Upper Cretaceous to Paleocene transgressive sediments (conglomeritic limestone, flysch).Other, non-ophiolitic volcanic rocks crop out to the eastern part of the ophiolite occurrence and they belong to the Almopias subzone (Vougioukalakis, 2002).

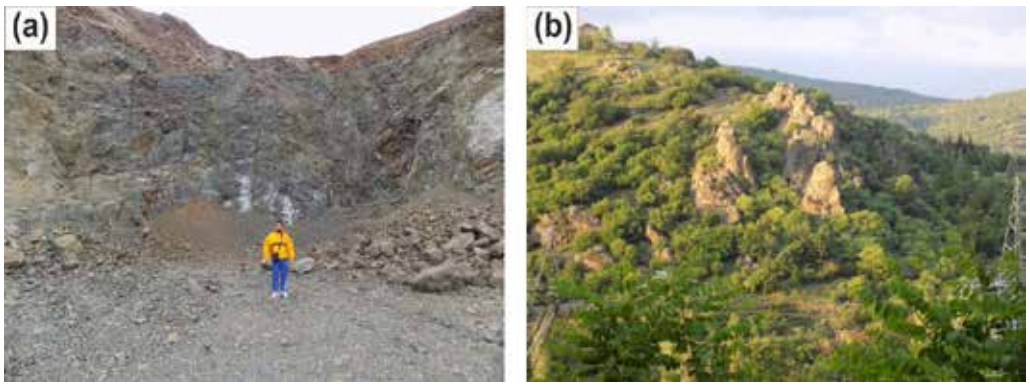

Figure 2. Mafic rocks from Edessa ophiolites: (a) Diabase, (b) Basalt.

Analytical methods

The textural characteristics of the samples were studied in polished-thin sections in a polarising microscope (Leitz Ortholux II POL-BK Ltd., Midland, ON, Canada) at the Department of Geology and scanning electron microscope (SEM) at the Laboratory of Electron Microscopy and Microanalysis, University of Patras. Whole-rock chemical analysis for major and trace elements was performed at Bureau Veritas Mineral Laboratories at Vancouver (Canada). Major element analysis was carried out using an XRF spectrometer and a sequential spectrometer (ICP-ES). Trace elements and rare earth elements were determined in totally digested samples by inductively coupled plasma-mass spectrometry (ICP-MS) in the same laboratory. Detection limits for major and trace elements range from 0.01 wt.% to 0.04 wt.% and from 0.01 ppm to 10 ppm, respectively. The analytical precision calculated by replicate analyses is better than 3% for most major elements and better than 5% for trace elements.

Results

Petrographic features

The Edessa mafic rocks comprise gabbroic (gabbros and less frequent diorites) and volcanics rocks (diabases and basalts). Diorites are moderately altered and they are fine to medium-grained rocks (Figure 3a). Their texture is granular but locally becomes porphyritic with subhedral to euhedral plagioclase phenocrysts. Sporadic, euhedral hornblende grains are enclosed within larger plagioclase crystals forming poikilitic textures. Gabbros are mainly comprised of clinopyroxene and plagioclase (Figure 3b). Ilmenite, magnetite, titanite and zircon are present in small amounts, less than 5% of the mode. Primary textures have been obliterated by alteration.

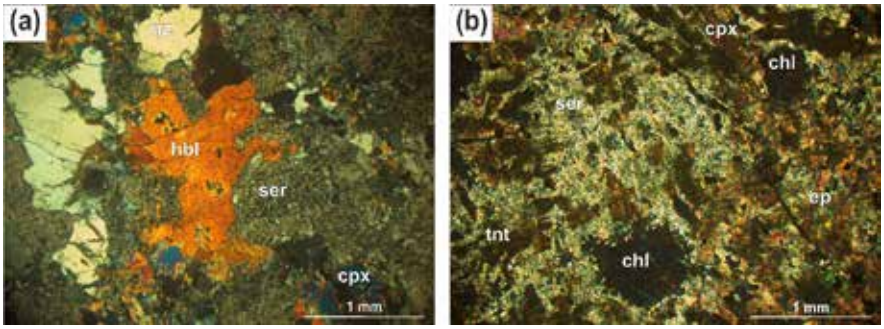

Figure 3. Photomicrographs of:(a) hornblende (hbl) crystal with irregular shape surrounded by sericitised (ser) plagioclase, quartz (qz) and clinopyroxene (cpx) in diorite, (b) subophitc texture in altered gabbro showing seriticised plagioclase (ser), clinopyroxene (cpx), chlorite (chl), epidote (ep) and titanite (tnt).

Diabase samples exhibit porphyritic, ophitic and subophitic textures. The mineral assemblage is similar to that of gabbros including clinopyroxene and subhedral plagioclase. In some cases the plagioclase is partially to completely altered to sericite (Figure 4a). Basalts display interwoven, porphyritic and microlitic textures (Figure 4b). Their primary assemblage includes plagioclase, clinopyroxene, magnetite, ilmenite and accessory zircon. They have suffered by a low-grade, oceanic alteration episode and by the development of quartz, epidote, chlorite, calcite and titanite, occurring in the groundmass and within joints or amygdules.

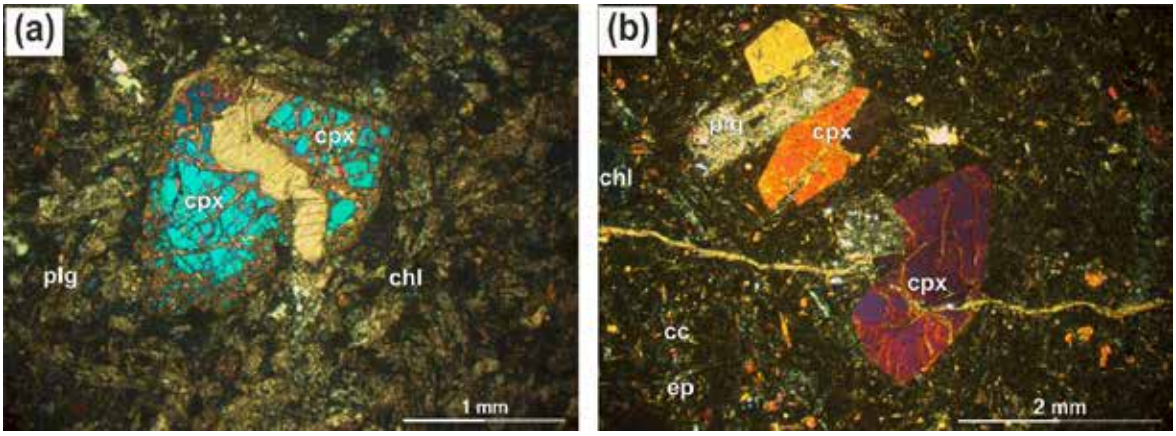

Figure 4. Photomicrographs of: (a) clinopyroxene (cpx) porphyroclast cross cutting by calcite (cc) and surrounding by plagioclase (plg), sericite (ser) and chlorite (chl) in diabase, (b) porphyritic texture in basalt showing clinopyroxene (cpx), plagioclase (plg), chlorite (chl), epidote (ep) and calcite veinlet.

Geochemical features

All the investigated mafic rock samples were moderately affected by alteration, resulting in the mobility of the large ion lithophile (LIL) elements (such as Na, K, Ca, Rb, Ba, Sr, Pb) and thus their measured values may not be able to define these rocks (Shervais, 1982). Therefore, we use only high field strength (HFS) elements (Ti, Nb, Y, Zr, Hf, Ta, REE) and transition elements (such as Y, V, Ni, Cu) for interpretation, as these elements are considered immobile during alteration and can effectively be used to describe the primary chemical features of rocks. Immobile-element ratios such as Zr/Ti and Nb/Y are commonly used to identify mafic, intermediate and acid rocks that they might have been variably altered (Winchester and Floyd, 1977, Pearce, 1996). In order to clarify the nature of the environment of mafic rocks, we have applied the Zr-Nb-Y diagram in the analyzed results. In this diagram, gabbro, basalt and diabase, except one sample (ED.110), are plotted in gabbro field, whereas the diorite clusters in the tonalite, a fact that supports the mafic character of the investigated samples (Figure 5).

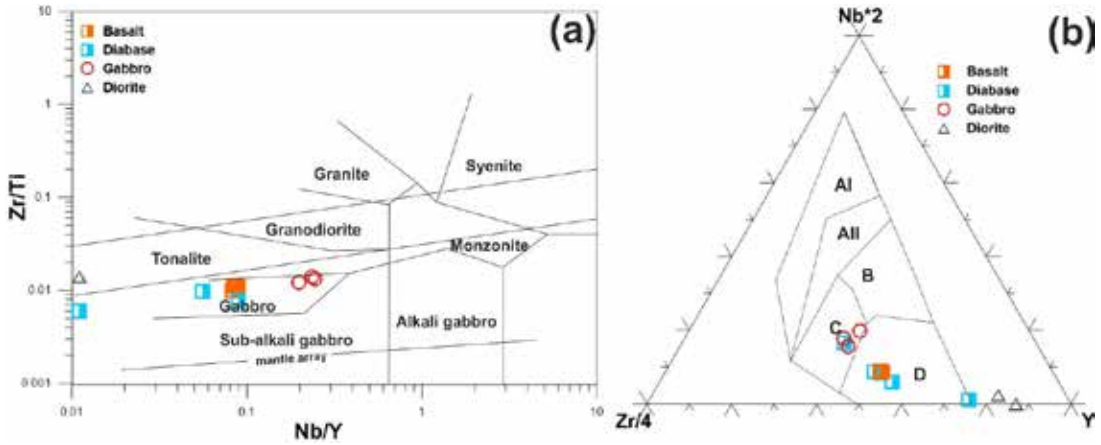

Figure 5. a. Binary classification diagram of Zr/Ti versus Nb/Y for the mafic rocks of Edessa ophiolites (Winchester and Floyd 1977; modified by Pearce 1996). b. Discrimination Nb-Zr-Y diagram (Meschede, 1986) (fields: AI = within-plate alkali basalts, AII = within-plate alkali basalts and within-plate tholeiites, B = E-type MORB, C = within-plate tholeiites and volcanic basalts, D = N-type and volcanic-arc basalts).

Basalts show remarkably high Ti and REE concentrations than the other mafic rock samples. The chondrite normalised REE patterns for diorite, gabbro, diabase and basalt are plotted individually and they show four distinct REE patterns (Figure 6). Though all studied samples show almost flat HREE pattern, gabbro shows highly fractionated LREE patterns relative to the HREE, with positive Eu anomalies, which implies plagioclase accumulation. These patterns are similar to E-MORB type represented from many ophiolitic complexes. Diabases present two subgroups. The first is enriched in LREE and depleted in HREE, similar to OIB-like lavas. The second is depleted in LREE and enriched in HREE, similar to the SSZ type. Basalt exhibits almost flat REE pattern without any LREE enrichment relative to HREE, which is similar to N-MORB type. Diorite shows totally depleted LREE pattern (SSZ type) with negative Eu anomaly, which implies removal of plagioclase.

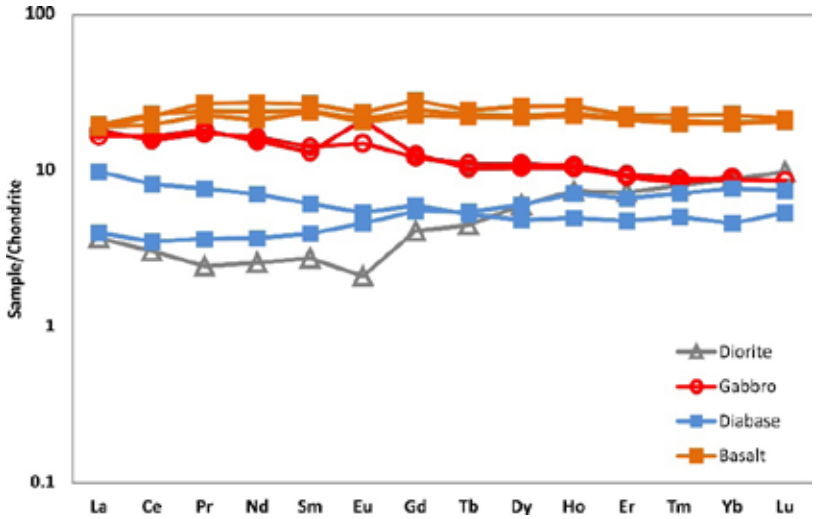

Figure 6. Chondrite-normalised REE patterns of the mafic rocks from the Edessa ophiolite. Normalising values are from McDonough and Sun (1995).

Conclusions

Based on these geological, petrographic and geochemical evidences, we suggest that mid ocean ridge (MOR) type mafic rocks (basalt and gabbro) from the Edessa ophiolite represent the section of older oceanic crust which was generated during the opening of the Axios Ocean. Conversely, diorite and partially diabase represent the younger oceanic crust which was formed at the forearc region by partial melting of the depleted mantle wedge modified by hydrous fluids released from the subducting oceanic slab.

Acknowledgements

We kindly thank Dr. A.K. Seferlis of the Laboratory of Electron Microscopy and Microanalysis, University of Patras for his assistance with the microanalyses and SEM micrographs. We kindly thank Dr. K. Hatzipanagiotou and Dr. B. Tsikoura for their assistance in the fieldwork, in the interpretation of the results and for their whole contribution of this study.

EXTENDED ABSTRACT 271

Shallow Depth P-wave Velocity Profiling Using Seismic Interferometry: The CORSSA Site

Roumelioti Z.[1], Katsaitis N.[1]
(1) Department of Geology, University of Patras, Patras, Greece, zroumelioti@upatras.gr

Abstract
We apply the method of seismic interferometry by deconvolution to analyze vertical accelerometer array data from the CORSSA site in Greece and determine P-wave velocities (VP) at shallow depths. We show that in the case of the CORSSA site, the method is able to overcome the challenges of resolving the much faster P-wave travel times and provide statistically robust mean velocity values for different depth ranges. Thus, we propose a V_P velocity model for the studied site to complement the previously proposed V_S models. We also compare the interferometry inferred V_P/V_S values with independent results and find them to be realistic and consistent with empirical relationships based on rich data sets from different parts of the world. Within the nearly 10 years that the studied dataset spans, we observe a significant temporal variation of V_P, mostly in the shallower depth ranges studied, which appears to be longer in duration than the seasonal variation previously reported for V_S at this site. However, the lack of temporal continuity in our dataset does not allow a detailed analysis of this variation.

Background and objectives
Changes in the ratio of P-wave to S-wave velocity, V_P/V_S, in soft sediments often reveal variations in fluid content, sediment compaction, material composition, and stress conditions. Monitoring these changes is critical for both geotechnical and geophysical applications. Historically, the method of seismic interferometry by deconvolution has been applied to horizontal recordings of vertical accelerometer array data sets to monitor temporal variations of V_S at shallow depths (e.g., Nakata and Snieder, 2011; Chandra et al., 2016; Gueguen, 2016; Roumelioti et al., 2020, Qin et al., 2022). The vertical component is usually not exploited in the specific method, primarily because the much faster travel times of P-waves are difficult to resolve.
The CORSSA vertical accelerometer array (e.g., Kassaras et al., 2016) was installed in the coastal area of the city of Aigio (northern Peloponnese, western Gulf of Corinth) a few years after the catastrophic 1995 M6.5 Aigio earthquake. The primary goal of this infrastructure was to collect strong motion records to be used in studies of site effects and soil response. To understand the changes in the seismic wavefield as it propagates from the bedrock to the ground surface, four stations were installed inside boreholes at different depths (14, 31, 57 and 178 m) and one station was installed on the surface inside a lightweight protective structure. The infrastructure operated in trigger mode for several years, although with several interruptions due to technical problems, and its data for the period 2022-2012 have been organized and published as a database (http://corssa.gr/; Kassaras et al., 2016).
The CORSSA dataset has been analyzed by seismic interferometry by deconvolution with respect to the horizontal recordings and associated Vs (Roumelioti et al., 2018), revealing a seasonal variation of V_S in shallow layers that decreases with depth and becomes undetectable below ~30m. In this work, we extend the analysis to the vertical components of the earthquake records in the CORSSA database, with the aim of determining the V_P profile for the CORSSA site and investigating the V_P values with respect to previously published V_S in terms of their ratio, V_P/V_S, and its change with depth.

Methods and Data
Seismic interferometry by deconvolution on an array of sensors comprises the division of the spectral representation of one trace at one receiver by that of another. Assuming that the distance between a specific earthquake source and the array is many times larger than the array inter-station distances, the spectral division is expected to remove any source-specific imprints and common path propagation effects, yielding the transfer function of the medium between the two involved stations, which resembles a pulse signal. This transfer function is the inverse Fourier transform of:

$$D_{j-i}(\omega) = \frac{A_j(\omega)A_i^*(\omega)}{|A_i(\omega)|^2+\varepsilon} \quad (1)$$

where $A_j(\omega)$ and $A_i(\omega)$ represent the Fourier transforms of the recordings at the *j*-th and *i*-th (reference) receivers, respectively, and ε the water-level parameter, introduced to stabilize the deconvolution at very low denominator values (Clayton and Wiggins, 1976). By measuring the travel times of the resulting pulses and knowing the exact distances between stations in the array, it is possible to compute wave velocities in the between the two stations propagating medium.
For this study, the seismic interferometry by deconvolution was applied to the vertical components of recordings from four CORSSA borehole stations, using the surface station as a reference. In total, we analyzed records of 709 earthquakes at each

station. Some characteristics of the dataset, such as the distribution of magnitudes (local magnitude, M_L) in magnitude bins, the distribution of magnitude with epicentral distance, and the distribution of peak ground acceleration (PGA) with distance, are shown graphically in Figure 1.

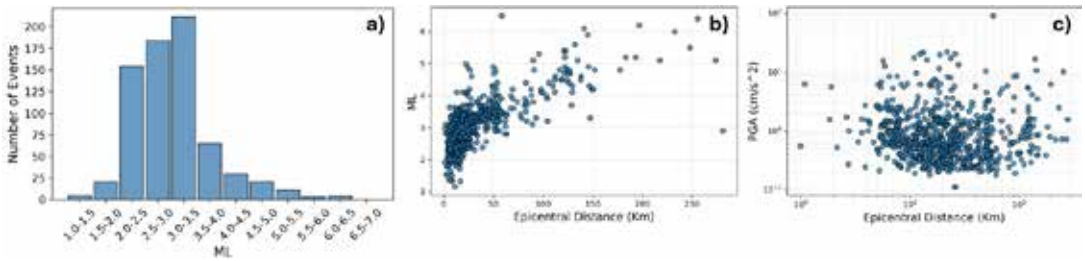

Figure 1. Brief description of the processed dataset: a) Distribution of earthquake records in the dataset in magnitude (M_L) bins, b) M_L occurrences and c) PGA (east-west component of the surface CORSSA station) with respect to the epicentral distance of the earthquakes from the CORSSA site.

We set ε=10% and resampled the inverse Fourier transform of $D_{i-i}(\omega)\,D_{i-i}(\omega)$ with a step 100 times smaller than the original. In this way, we artificially densified the pulse-like transfer functions to improve the accuracy of the picking of the travel time of the pulse (e.g., Roumelioti et al., 2020; Qin et al., 2023). Figure 2 shows a sample output from the application of the described method to the vertical recordings of a M_L3.5 earthquake at 14 km distance. The subplots show the results of the interferometry at different depth intervals and include an upward propagating pulse. We use the top of this pulse as a characteristic point to follow its propagation and measure its travel times from one sensor depth to the other. At the 14m subplot in Figure 2, two pulses appear, one on the negative side of the time axis and one on its positive side. This means that there is significant wave energy that has been reflected at the surface and propagated downward, but it does not affect our results, which are based solely on time measurements on the negative side. In recordings richer in low frequencies, or as V_P increases, the two pulses may move closer together and become inseparable, making it impossible to measure V_P.

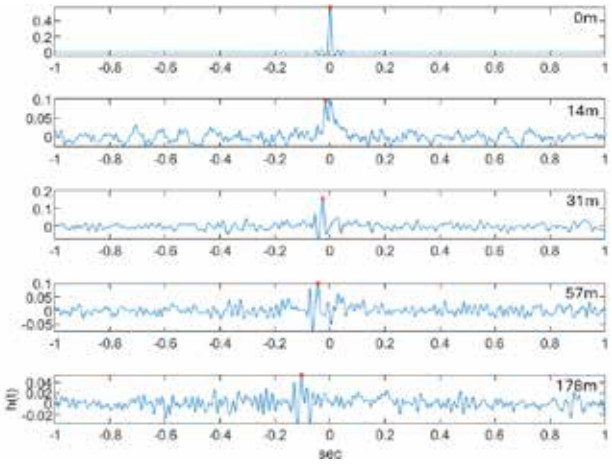

Figure 2. Example output of the interferometry by deconvolution on the vertical components of a record (29/12/2011, 15:19UTM, M_L3.5, R14km) at the CORSSA site. Each subplot shows the deconvolution of a waveform at the depth marked on the top right with respect to the waveform at the surface. A propagating pulse appears on the negative side of the x-axis and its top is marked (red dot) as a characteristic point to measure time differences (i.e., travel times).

V_P from seismic interferometry by deconvolution

We have applied seismic interferometry by deconvolution to resolve P-wave velocities in the depth intervals 0-14 m, 0-31 m, 0-57 m, 0-178 m, 14-31 m, 31-57 m, and 57-178 m. As noted above, there are inherent difficulties in applying the method to the much faster P-waves. The first is the sampling rate commonly used for ground acceleration monitoring, which is low for resolving very small changes in the propagation time of the impulse response of soft soils. In our case (sampling rate of 200 s/s), we limit this restriction to some extent by resampling the interferometric result at a higher rate, allowing a more accurate measurement of the travel times. The second major difficulty is the very high velocities of the P-waves, even in soft sediments, which in combination with the often small distances between the stations result

in extremely short travel times that cannot be resolved. A third difficulty is that the wavelengths of interest change as we attempt to define velocities at different depth intervals, and not all recordings have the necessary frequency content to provide an unambiguous time reading. As a result, the efficiency of the method at a particular location and depth interval may not always be known a priori, but only through trial and error. Furthermore, even if the method is successful but V_P increases with time, it may fail above a certain level of increase.

For all of the above reasons, in our application at the CORSSA site although we had many stable results, we also had numerous "outliers", which we define in the following. To isolate and work with the most populated concentrations of resulting V_P values, we applied a two-step interquartile range (IQR) outlier removal. First, we removed V_P values that were outside 3 times the IQR (Q3-Q1) of the overall distribution. These "extreme" outliers were also manually checked and were found to be related to poor quality waveforms or to the events with the richest low-frequency signal, resulting in broad pulses with an almost flat top (i.e., the area where we usually expect a sharp peak to be used for travel time measurement). In the second step, we performed a standard removal of values outside 1.5 times the IQR. The procedure is shown graphically in Figure 3 for the example case of the 0-14m depth interval. The IQR, i.e., the area where 75% of the computed values are concentrated, is shown in purple and the lighter color marks the 1.5×IQR area. Everything that falls within these two areas is included in the subsequent analysis, and values outside these areas are considered outliers. Figure 3 also marks the mean of the finally considered values ± 1 standard deviation (s.d.).

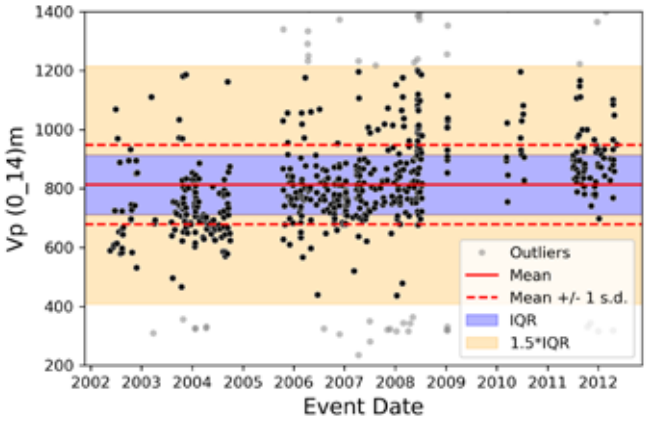

Figure 3. Graphical description of the outlier removal procedure for the example case of V_P estimates for the depth interval 0-14m. Gray points, lying beyond 1.5 times the interquartile range (IQR) (orange shaded area), are considered as outliers and are not being used in the estimate of the mean V_P value.

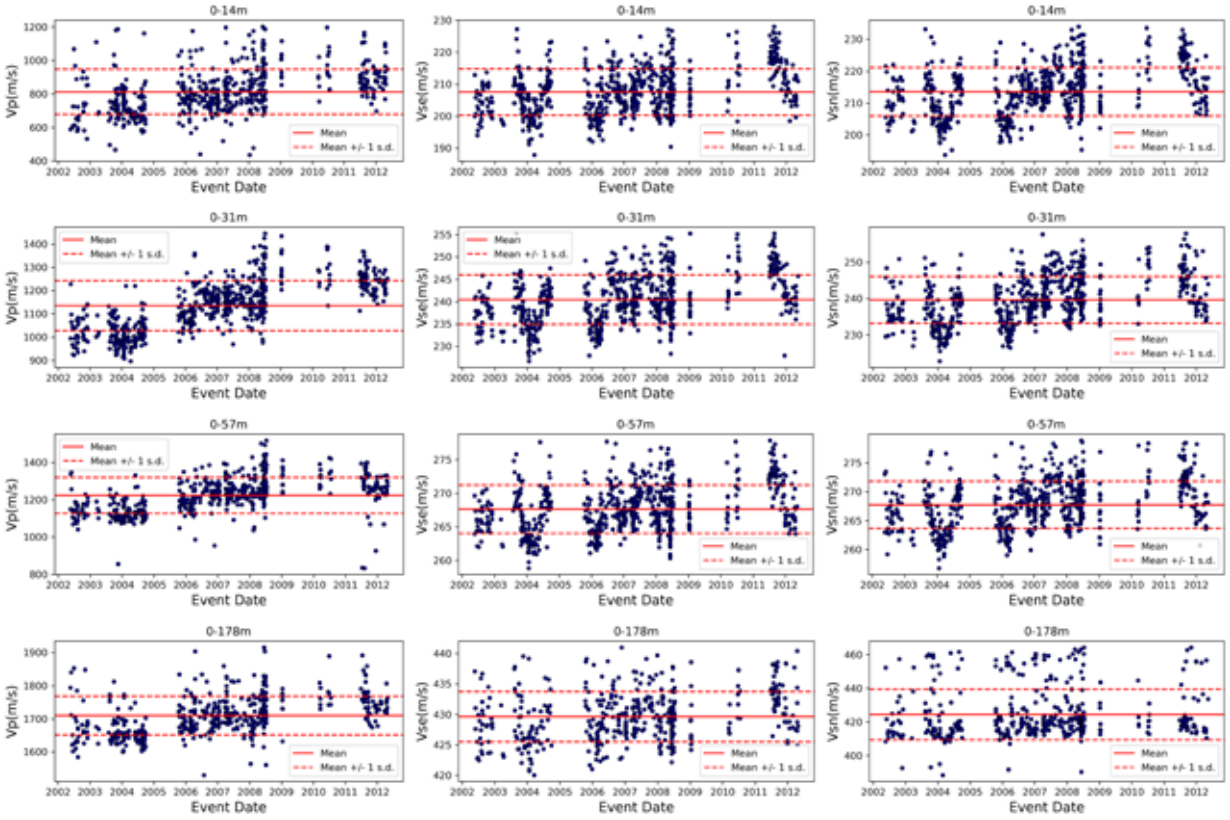
The results of the interferometry by deconvolution for all depth intervals examined are summarized in Table 1. More specifically, Table 1 lists percentage of final data points and outliers with respect to the initial dataset of 709 earthquake records for each depth interval, the mean V_P ± 1 s.d. and the corresponding information for the two horizontal components (from Roumelioti et al., 2018), east-west (V_{Se}) and north-south (V_{Sn}), for comparison. The agreement of the results of the two V_S is remarkable, as well as the amount of data finally considered for V_P despite the difficulties mentioned above. The depth interval with the largest number of outliers, for both V_P and V_S computations is the 0-178m interval. This is a rather unsurprising result considering the very weak character of most of the waveforms in the dataset (Kassaras et al., 2016) (Figure 1c). An interesting finding was the high mean V_P in the 14-31m depth interval, quite higher than the underlying examined "layer", most likely indicating an increased presence of groundwater.

Table 1. Mean V_P and V_P/V_S values inferred from interferometry for the CORRSA site and percentages of determined values and outliers with respect to the starting dataset. Depth intervals are defined by the downhole sensors' installation depths. V_S values for the two horizontal components of Roumelioti et al. (2018) are included for comparison.

Depth Interval (m)	Data/Outliers (%) for V_P	V_P (± 1s.d.) (m/sec)	Data/Outliers (%) for V_{Se}	V_{Se} (± 1s.d.) (m/sec)	Data/Outliers (%) for V_{Sn}	V_{Sn} (± 1s.d.) (m/sec)	V_P/V_{Se}	V_P/V_{Sn}
0-14	76/24	813 (135)	97/3	208 (7)	97/3	214 (8)	3.9	3.8
0-31	93/7	1135 (107)	99/1	240 (6)	98/2	240 (6)	4.7	4.7
0-57	77/23	1224 (96)	96/4	268 (4)	94/6	268 (4)	4.6	4.6
0-178	67/33	1710 (59)	63/37	430 (4)	61/39	424 (15)	4.0	4.0
14-31	76/24	1754 (233)	93/7	277 (7)	86/14	271 (11)	6.3	6.5
31-57	81/19	1382 (46)	91/9	308 (3)	93/7	314 (4)	4.5	4.4
57-178	87/13	2140 (32)	71/29	602 (5)	60/40	583 (11)	3.6	3.7

Figures 4 and 5 show the results graphically, Figure 4 for interferometry results with respect to the surface station and Figure 5 for pairs where both stations were in boreholes. Each row of the subplots corresponds to a different depth interval (i.e., station pair in the interferometry), while the columns from left to right include: the V_P values derived in this study, the V_{Se} and V_{Sn} values computed by Roumelioti et al. (2018) using the same method. In all subplots, the mean velocity ± 1 s.d. (i.e., the values included in Table 1) is also marked. Although our dataset is not continuous in time, it is clear that there is a temporal variation in both V_P and V_S values that increases in amplitude with depth. Although the left column in Figure 4 may suggest some seasonal variation, it is certainly not as clear as for V_S, and the temporal discontinuity of the dataset examined, as well as the variability of V_P make any identification even more difficult. It is possible that the temporal variation of V_P is longer in period than an expected seasonal one. This can be seen very clearly in the upper left subplot of Figure 4, where V_P values in 2003-2004 are mostly clustered around 700m/s, whereas in 2006-2008 they are around 800m/s. Reasons for such slower changes could be, for example, multi-year changes in groundwater, or sudden compaction of sediments after shaking caused even by relatively distant strong earthquakes.



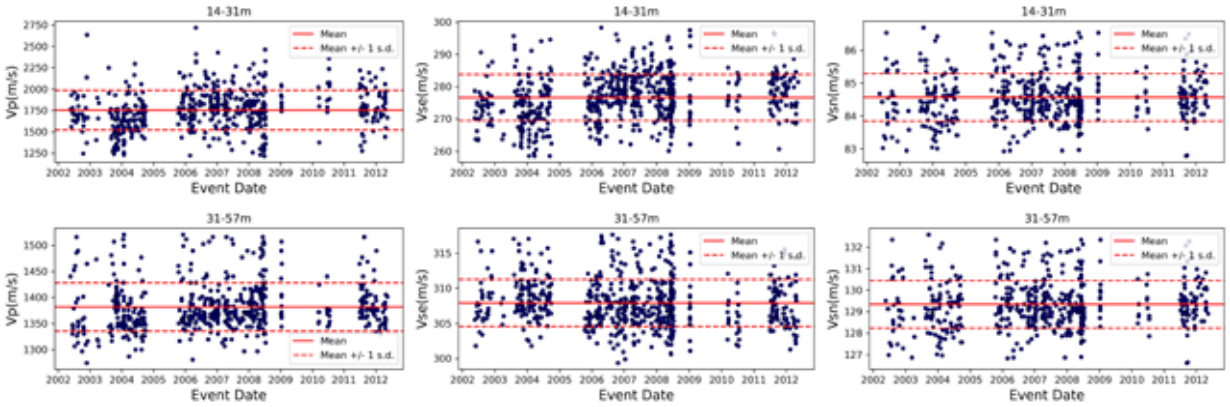


Figure 4. Velocity variation with time for depth intervals noted at the top of each subplot (0-14m, 0-31m, 0-57m, 0-178m from top to bottom. The left column contains the V_P values, the middle the V_S in the east-west component (V_{Se}) and the right column the V_S in the north-south component (V_{Sn}). V_S values are taken from Roumelioti et al. (2018).

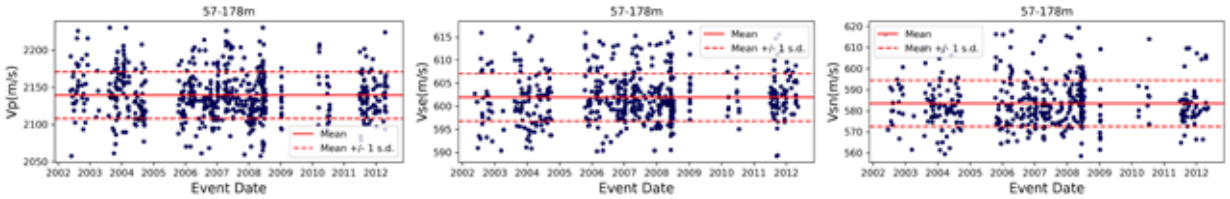

Figure 5. As in Figure 5, but for the intermediate depth intervals (from top to bottom) of 14-31m, 31-57m, and 57-178m.

V_P profile at the CORSSA site

The mean VP values derived for the depth intervals 0-14m, 14-31m, 31-57m and 57-178m are plotted in Figure 6 in the form of a velocity profile, along with previously proposed VS profiles (CORSSA, 2002; Roumelioti et al., 2018). Although the applied method provides well-constrained mean VP values directly at the site and from actual ground motio data, a shortcoming is that the interferometric "layer" thicknesses in Figure 6 have no physical or geological meaning and are defined by the depths of the sensors in the accelerometer array.

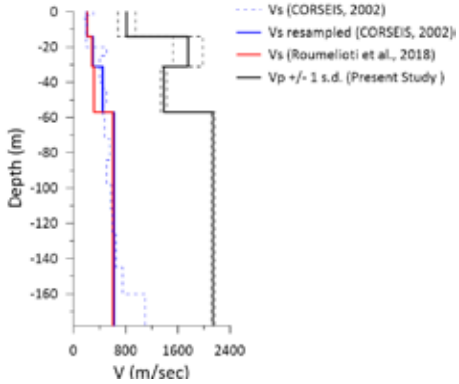

Figure 6. Seismic wave velocity profiles at CORSSA. The V_P profile is a result of this study and "layers" thicknesses are enforced by the depths of the borehole array sensors. The V_S profiles are from Roumelioti et al. (2018) and include the information from the European project "CORSEIS" (2002) as originally provided and resampled at the depth intervals of the CORSSA array.

V_P/V_S ratio

The last two columns in Table 1 show the V_P/V_S using the mean velocity values for each depth interval examined. The results using the mean V_S values in the two horizontal components show insignificant differences. V_P/V_S has values <4 in the shallowest (0-14m) and deepest (57-178m) depth ranges and well >4 in the 14-31m and 31-57m intervals. Figure 6 shows how these values compare to previously published V_P-V_S relations. We chose to compare the CORSSA values to the empirical relation of Brocher (2005), who has incorporated many northern California profiles that are more representative of younger tectonic terranes such as the one examined in this study. We also compare our values with two relations proposed in a more recent study by Nagashima and Kawase (2021), which is based on a very large number of KiK-net and K-NET station sites in Japan. Nagashima and Kawase (2021) found an abrupt increase in V_P around 4m depth and attributed it to the transition from unsaturated to saturated soil formations. As a result, they proposed two different V_P-V_S relationships. The CORSSA values for the three deepest ranges investigated compare well with the Brocher (2005) relation and the saturated soil version of Nagashima and Kawase (2021). The 0-14m appears to be more compatible with the unsaturated version of the Nagashima and Kawase (2021) relationship, suggesting that the top 14m at CORSSA is mostly unsaturated. This is also supported by the absolute value of the mean V_P for this layer, ~ 800m/s, which is much lower than the speed of P-waves in water (1200 to >1400 m/s, also depending on the salinity).

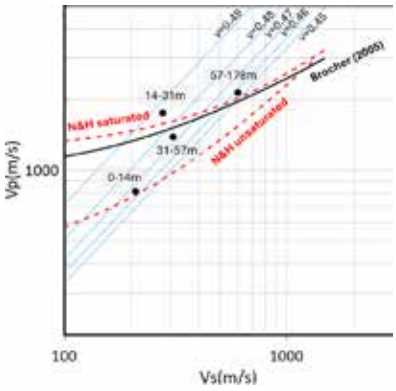

Figure 6. Mean V_P versus mean V_S for the examined depth intervals at the CORSSA site. Blue straight lines mark the V_P, V_S relation for Poisson's ratios (v) of 0.45-0.49. Previously published pertinent relations are also shown for comparison; black curve for Brocher (2005) and red dashed curves for Nagashima and Kawase (2021; N&H) for saturated and unsaturated soils.

Conclusions/Discussion

We applied the method of seismic interferometry by deconvolution to the vertical components of a dataset of 709 earthquake records at the CORSSA borehole array. We examined the four borehole stations of the array (at depths of 14, 31, 57 and 178m) with respect to the surface station, as well as station pairs at 14-31m, 31-57m, and 57-178m, and computed V_P velocities for the corresponding depth intervals. Due to the high velocities of the P-waves, the short distances examined and the weak character of most of the waveforms in the dataset, the results included several unrealistically high or low V_P values, many of which were removed as outliers using a two-step interquartile outlier removal approach. The outliers for the V_P computation were in the range of 7-33% of the initial number of data points, which is considered rather small considering the previously mentioned difficulties in measuring V_P. Based on the final data points, we computed the mean $V_P \pm 1$ s.d. for each depth interval examined and we provided a V_P velocity model for the site of the CORSSA infrastructure. We used our V_P values and the V_S values of Roumelioti et al. (2018) to compute V_P/V_S ratios for the different depth intervals examined, but also to demonstrate that continuous monitoring of this quantity is feasible with the applied method.

Research Highlights

- Effect of different lithological types on the chemical composition of the soil.
- Application of multivariate analysis and G.I.S. techniques to determine controlling factors on soil geochemistry.

Abstract

Geochemical mapping is commonly applied by geoscientists to document the spatial distribution of elemental concentration levels in materials occurring at the Earth's surface, such as soil. Here, we present the applied methodology for establishing the soil geochemical mapping in the unique island of Lesvos that exhibits a complex geological structure with different rocks occurring on island surface. A total of 74 surface (0-20 cm depth) soil samples were collected from 66 locations on a 5 km x 5 km grid extending across the whole island. Preliminary results in terms of distribution of major and trace element concentrations and interpretations based on geology and mineralization will be presented.

Introduction / Background and Objectives

Geochemical mapping is a technique rooted in mineral exploration but has now found worldwide application in environmental studies. Geochemical mapping has a crucial role, nowadays, not only for mineral exploration, but also for studies about environment and human health (Kirkwood et al., 2016). Officially, International Geochemical Mapping Project was accepted by UNESCO/IUGS just in 1988 and technical – regional committees, which include scientists and organizations from all over the world, coordinated the project with aim to resolve scientific and technical issues. For example, many surveys have a huge number of samples that have been analyzed for different groups of elements by a variety of analytical methods, with uncertain quality control (Darnley, 1990). Another problem is the sampling density and the map scale that should be followed, but these depend on the objectives of each project (Demetriades et al., 2022). By definition the geochemical maps are based on the concentrations of chemical elements from samples of surface media such as soil, water or stream sediments (e.g. Salminen et al., 1998).

In this project, Lesvos Island is the study area and soil samples were collected in order to produce geochemical maps of elements across the whole island. The samples were collected during July 2024 and the aim was to contribute new knowledge in terms of the geochemical characterization of the island. The density of soil sampling followed a 5 km x 5 km grid in order to produce a comprehensive geochemical mapping of the island's soils.

The diverse geological formations that occur on the island, the various types of mineralizations found in the northeastern Aegean, but also the limited research on the geochemistry of the island's soils, motivated us to carry out this research. The main objective is the accomplishment of the soil geochemical mapping in terms of major and trace elements with the aim to determine the effect of local geology on soil geochemistry. On the island of Lesvos, geological mapping has been carried out previously (Hecht, 1972; Katsikatsos et al., 1986; Thomaidou, 2009), but extensive geochemical mapping of soils on the island has not been carried out.

Description of the study area

Lesbos is the third largest island in Greece, covering an area of 1,630 km² and is located in the northeastern part of the Aegean Sea, very close to the Anatolian coast. Regarding the geomorphology of Lesbos, two large, enclosed bays dominate the southern part of the island: Kalloni Bay and Geras Bay, which are clearly related to the tectonic evolution of the broader northern Aegean area and especially to the neotectonic activity. Two large mountain masses, Mount Lepetymnos (968 m) at the northern part and Mount Olympus (967 m) at the southern part of Lesbos, between the two bays, stand out on the overall mountainous island of Lesbos. In general, the topography of Lesbos is varied, showing abrupt changes and is quite pronounced in other areas as well, such as the Amali Peninsula (527 m) and especially in the western part, where Mount Ordymnos (589 m) dominates, creating a very impressive landscape with steep transitions toward the island's western coast (Thomaidou, 2009).

Lesbos Island, located in the northeastern Aegean Sea, is known for its unique geological features, diverse

rock formations, and significant tectonic activity. The island's geology offers a fascinating glimpse into the Earth's geological processes, particularly with respect to its volcanic history, the presence of numerous mineral deposits, and its tectonic setting along the boundary of the Eurasian and African plates (Apostolopoulos et al., 2009).

Lesbos has a rich volcanic history. Volcanic activity is responsible for much of the island's landscape, with lava flows, volcanic ash deposits, and geothermal activity still visible in several locations. The island's most famous volcanic area is near Molyvos, where extensive basaltic lava flows have been found. Sigri, on the western part of the island, is another significant volcanic site, with large volcanic deposits and fossilized lava formations (Georgiadis, 2001).

Obviously, the geological structure and composition of Lesvos played a key role in the geomorphology of the island. The western and northern parts are mostly covered by volcanic rocks and there are the important volcanic centers of the island. This is one more element that contributes to the morphology, with the existence of large calderas (e.g. the caldera of Vatoussa), but also the presence of important dykes (e.g. the dome of Ypsilos) that characteristically elevate the morphology of the island, creating large differences in altitude with rounded mountain ranges without vegetation (Papadopoulos et al., 1991).

On the contrary, the south-east part of Lesvos, i.e. the areas of Mount Olympus, the village of Agiasos up to the town of Plomari, as well as the area around the Gulf of Gera and the peninsula of Amalis, have a mountainous landscape but smoothed by erosion and with significant vegetation cover (Papadopoulos et al., 1991).

However, it is mainly neotectonic activity that has played a decisive role in shaping the morphology of Lesbos, as it is responsible for the large depressions of height and the strong transitions that occur (Apostolopoulos et al., 2009), as Turkey's microplate moves to the SW and pushes the Aegean area, forcing it to make an expansion in the same direction. The wider tectonic field in the NE Aegean region is dominated by the action of large clockwise horizontal displacement faults, on which the region is mainly moving and which, together with normal-moving fault surfaces, form the lacy-looking Asia Minor coastline (Georgiadis, 2001).

At Western Lesbos volcanic rocks dominate, mainly basalts and andesites, along with pyroclastic deposits (tuffs and tephra). Central and Eastern Lesbos are characterized by the occurrence of predominantly sedimentary rocks, including limestone, marl, conglomerates and sandstones. Also, at specific regions, north and at the center of the island, metamorphic rocks are observed, such as schists and gneisses. In the western region of the island, Sigri, fossil-rich sedimentary rocks are observed (Papanikolaou, 2005) and of course geothermal deposits, such as silica, appeared in some regions of the island linked to geothermal springs (Georgiadis, 2001).

The rest of Lesvos, i.e. the northern, western and central parts of the island around the Gulf of Kalloni, is occupied by Neogene volcanic formations (Figure 2) and other mineral deposits covering the pre-alpine and alpine rocks universally. Exceptions are the small outcrops of alpine and pre-alpine rocks in the north-western edge of Lesvos in the areas of Sigri and Gavathas and some isolated micro-outcrops of the same rocks in the area of Eressos. These small occurrences are exposed beneath the surrounding Neogene volcanic formations in the form of island (Thomaidou, 2009).

Lesbos Island's mineral deposits are mostly associated with its volcanic history and hydrothermal activity. Although the island is not renowned for large-scale mining operations, there are localized mineral occurrences worth noting. For example, silica was deposited through hydrothermal processes during and after volcanic activity in the Miocene epoch and was found in hydrothermal veins and as silicified material in the Petrified Forest. The fossilized trees in the Petrified Forest are a result of extensive silicification, making silica the most visually striking mineral deposit on the island. Sulfide minerals, such as Chalcopyrite (CuFeS□) and Galena (PbS) are scattered and often localized to hydrothermal zones near volcanic centers. Clay Minerals, such as Kaolinite and Montmorillonite formed through the hydrothermal alteration of volcanic rocks and found in areas with extensive weathering and hydrothermal influence. Also, there have been occasional reports of minor occurrences of Gold (Au) associated with hydrothermal quartz veins, though in trace amounts, and Copper (Cu) linked to chalcopyrite in volcanic and hydrothermal systems.

The island's land use is characterized by extensive olive cultivation, significant forested areas, agricultural zones, and protected natural habitats (Figure 1). The most esteemed olives are harvested between Plomari and Agiasos from November to December. Lesbos features diverse forested regions, including pine and oak forests, as well as Mediterranean maquis vegetation. The island's varied habitats support a rich array of plant species, contributing to its impressive biodiversity. Beyond olive groves, Lesbos maintains areas dedicated to vineyards, pastures, and other agricultural activities. Livestock farming, particularly sheep and goats, is also prevalent, supporting the production of traditional cheeses.

Also, recognizing its ecological significance, several areas of Lesbos are designated under the Natura 2000 network, aiming to preserve valuable and endangered species and habitats. Notable protected regions include:

- Kalloni Bay: A vital wetland area supporting diverse bird species.

- Gera Bay – Mount Olympus: An area encompassing significant ecological elements.
- Western Lesbian Peninsula: A region with unique ecological features.

These protected areas underscore Lesbos's commitment to conserving its unique natural environment.

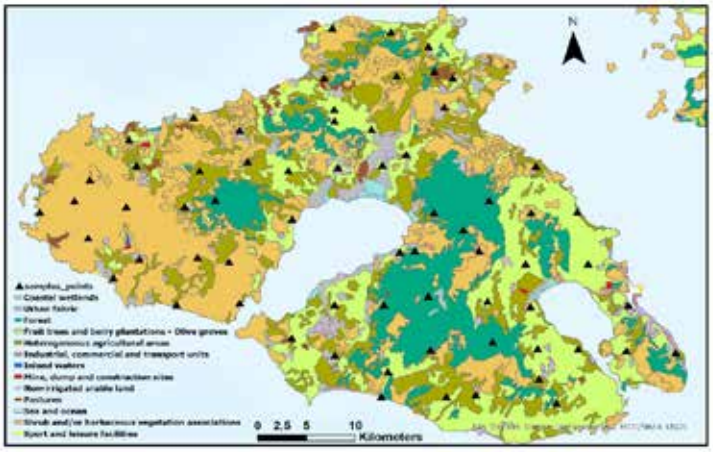

Figure 1: Land use map of the study area in Lesvos Island, showing sampling points on the Corine Land Cover (CLC) map (Heymann et al., 1994).

Sampling and Analysis

A total number of 74 soil samples (0 – 20 cm depth), from 66 locations, were collected from all over the island (Figure 2). The sampling procedure was common for the collection of 66 soil samples, as well as for the 8 randomly selected duplicate samples. All soil samples were collected at distance at least 200 m from main roads and away from tree roots, recent crops and rubble. To collect the soil sample, it was necessary to create a square with a side of 20 cm and digging to a depth of 10-20 cm (Demetriades et al., 2022). Approximately 1.5 - 2 kg of sample was collected, and the duplicate samples were spaced 3 m apart from each other (Demetriades et al., 2022). After daily collection of soil samples, the bags of these samples were left open in order to release the soil moisture. Upon return to the laboratory, they were placed in a drying oven at 40°C for 48 hours to remove the volatile components of the soil.

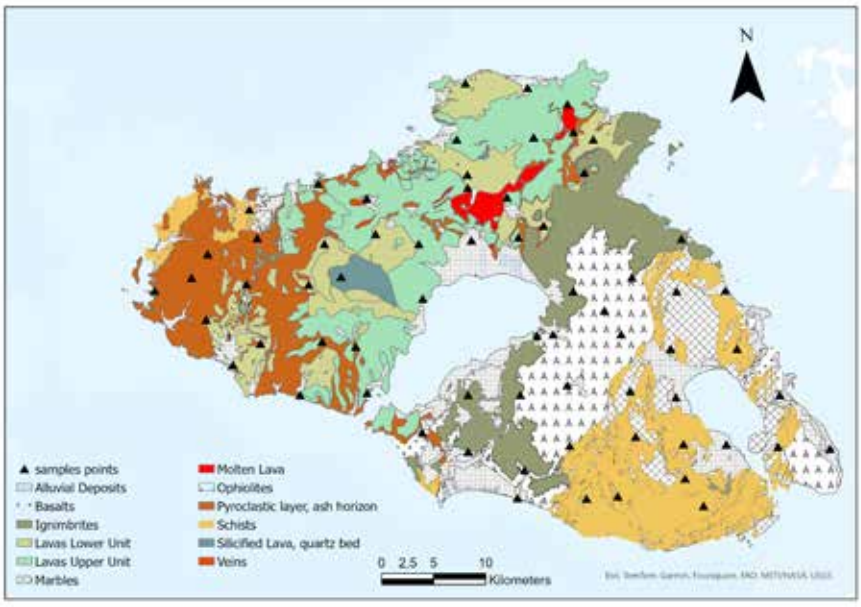

Figure 2: Geology (Hecht, 1972) and sampling points of the soil samples in Lesvos Island.

Sample preparation included disaggregation, during which each soil sample was disaggregated in a porcelain mortar

and sieved through a 2 mm sieve. Between the samples, the mortar and sieve were thoroughly cleaned with air and acetone. A portion of the 2mm fraction of the soil samples was mechanically pulverized in an automatic agate mortar to obtain a particle size of <0.063 mm. Initially, the soil samples were homogenized and divided in four quarters. Two of the diagonal quarters of the soil sample were selected to be pulverized. This step is repeated (3 times in total) to obtain approximately 100 ml of soil sample of less than 200 μm in size. Between the samples, the mortar was also cleaned with 30 ml of cristobalite to avoid cross contamination. The mortar and the tools used (spoon, beakers, brushes) were thoroughly cleaned with air and acetone (where necessary) after the end of the powdering of each sample.

The analysis will be carried out with aqua regia for soils and the samples will be analyzed by ICP-MS for trace elements (e.g. As, Cd, Zn, Pb, Cu, Cr, Ni) and by ICP-OES for major elements (e.g. K, Na, Ca, Fe, Al, Mg).

Results and Discussion

The analytical data will be processed in terms of quality control and the elemental concentrations will be compared with the island's geology.

Abstract

This paper examines the integration of drama and science as an innovative approach to teaching scientific concepts, focusing on the educational theatrical production *Pluto is Lost!*, created and performed by students at the 3rd Junior High School of Glyfada, Athens, Greece. The initiative aimed to introduce students to the Solar System and environmental science—subjects often overlooked in the Greek compulsory school curriculum—while fostering creativity, teamwork, and critical thinking. The project was implemented within the framework of the "Learning Science Through Theatre" program, which promotes interdisciplinary learning by merging science education with artistic expression.

Through a project-based learning model, students engaged in five phases: defining goals, designing, executing tasks, presenting results, and evaluating outcomes. They humanized astronomical and environmental concepts by creating a storyline where celestial bodies and Earth's ecosystems were personified, and the dynamics of the Solar System and environmental sustainability were explored through imaginative narratives. The embodied learning process enabled students to express scientific ideas through gestures, movements, and emotional engagement, enhancing comprehension and retention.

The production also addressed contemporary challenges, such as climate change, environmental conservation, and societal issues, connecting science to real-world contexts. Dissemination efforts included performances in collaboration with local institutions and recognition through multiple awards, including the "Learning Science Through Theatre" award for best theatrical and musical performance, the EPI2 award from the Athens Science Festival, and presentations at COSPAR 2022 (Athens, Greece) with the latter receiving a full grant.

The study concludes that combining science and theatre effectively engages students, promotes scientific literacy, and encourages creative exploration of complex topics. This initiative highlights the potential of arts-based methods in science education, offering a replicable model for fostering interdisciplinary learning and inspiring passion for STEAM fields.

EXTENDED ABSTRACT 274

Rheological behaviour along the Hellenic Subduction Zone and the Adria-Eurasia continental collision

Russo D.[1,2], Caputo R.[1,2]

(1) Department of Physiscs and Earth Sciences, University of Ferrara, Ferrara, Italy, davide.russo@unife.it (2) Centro Interuniversitario per La Sismotettonica Tridimensionale, CRUST-UR Ferrara, Italy

Based on the approach and workflow of the recently proposed 3D thermo-rheological model of the broader Aegean Region (Maggini et al., 2023), the present work focuses on the rheological properties corresponding to both the slab interface of the Hellenic Subduction Zone (HSZ) and the basal thrust of the Adriatic-Eurasian Continental Collision Zone (CCZ). For the purpose of this note, the geometry of the interfaces (Figure 1) was mainly reconstructed on the basis of the results of Bocchini et al. (2018), especially for the HSZ sector, and Halpaap et al. (2018) for the continental collision zone. For the Montenegro sector of the CCZ, the results of Schmitz et al. (2020) were also considered.

The aforementioned 3D model is based on a simplified approach: two main rheological behaviours have been assumed to occur at depth within the study area, namely the brittle and the ductile, described by the constitutive equations for frictional sliding (e.g. Sibson, 1977; Scholz, 1988; Ranalli, 1995) and power-law creep (e.g. Brace and Kohlstedt, 1980; Sibson, 1983; Ranalli, 1995) deformational mechanisms, respectively.

The calculations required to reproduce the thermo-rheological features of the considered area have been performed through purposely written MATLAB scripts (Maggini, 2020; Maggini and Caputo, 2020a; 2020b; 2021). The first output obtained is a number of 1D rheological profiles or “strength envelopes” (e.g. Sibson, 1977; Goetze and Evans, 1979; Brace and Kohlstedt, 1980; Scholz, 1988), which reconstruct the vertical rheological behaviour and the geothermal gradient of the investigated rock volumes in correspondence of the nodes of a regular horizontal grid (115 x 115 pixels). Among the input parameters, a considerable influence was attributed to the heat flow; derived merging and smoothing, applying a Gaussian filter in order to remove outliers, local-scale (e.g. Fytikas and Kolios, 1979; Taktikos, 2001) and regional scale (e.g. Hurter and Haenel, 2002; Cloetingh et al., 2010) measurements. The adopted strain rate was based on weighted and averaged available maps mainly derived from GPS measurements (e.g. Kahle et al., 1998; Hollenstein et al., 2008; Floyd et al., 2010; Kreemer et al., 2014; Chousianitis et al., 2015; England et al., 2016). Considering the results of Byerlee (1968) a standard value (0.6) was attributed to the internal friction coefficient; however, in correspondence of major the seismogenic sources (from GreDaSS 2.0; Caputo and Pavlides, 2013) this value was reduced to 0.5. This choice was motivated by the presence of well-defined shear zones in these crustal volumes, characterized by wearing processes that cause a significant reduction in the friction coefficient values (e.g. Viti et al., 2018; Collettini et al., 2019). For the frictional sliding equation, the Skempton coefficient (e.g. Skempton, 1954; Wang, 2000) was taken equal to 0.4, basically assuming, as a first approximation, a hydrostatic fluid pressure (e.g. Ranalli and Murphy, 1987; Ranalli, 1995). Both the upper and lower plates were modelled considering four vertical litho-mechanical layers (i.e. sedimentary cover, upper crust, lower crust and upper mantle), each one associated to a representative lithology and the related thermo-rheological parameters given by the considered constitutive equations (see Maggini, 2020 for a more detailed description and references).

The thickness of the considered layers was reconstructed from the depth of the top of the crystalline basement, the Moho discontinuity and the Lithosphere-Asthenosphere Boundary (LAB). The first two were strongly influenced by the work of Makris et al. (2013), while the LAB from the work of Sodoudi et al. (2006).

The selected pixel size for the 3D model is 10 x 10 km with vertical steps each 100 m. All the input parameters, have been accordingly averaged using standard GIS tools. In order to provide the 3D cover for the Aegean Region, the 1D logs were then interpolated to reconstruct a pseudo 3D model.

Following the general results of Maggini et al. (2023), and for the purpose of the present note, we examined a 500 m thick volume on each side of the modelled plate boundary (Figure 1), in both the continental-continental and oceanic-continental lithosphere domains, north and south of the Cephalonia Transform Fault Zone, respectively. In particular, we analysed the rheological behaviour of the lowermost part of the upper plate (i.e. Eurasian or Aegean) and the uppermost part of the lower plate (i.e. African or Nubian in the oceanic subduction zone and Adriatic block in the continental collision zone). Although in principle four different combinations, or “rheological contrasts”, of brittle *versus* ductile and upper *versus* lower plate could occur, the results emphasise the predominance of three conditions, each one uniformly and regularly covering wide sectors of the investigated interface zones (Figure 2).

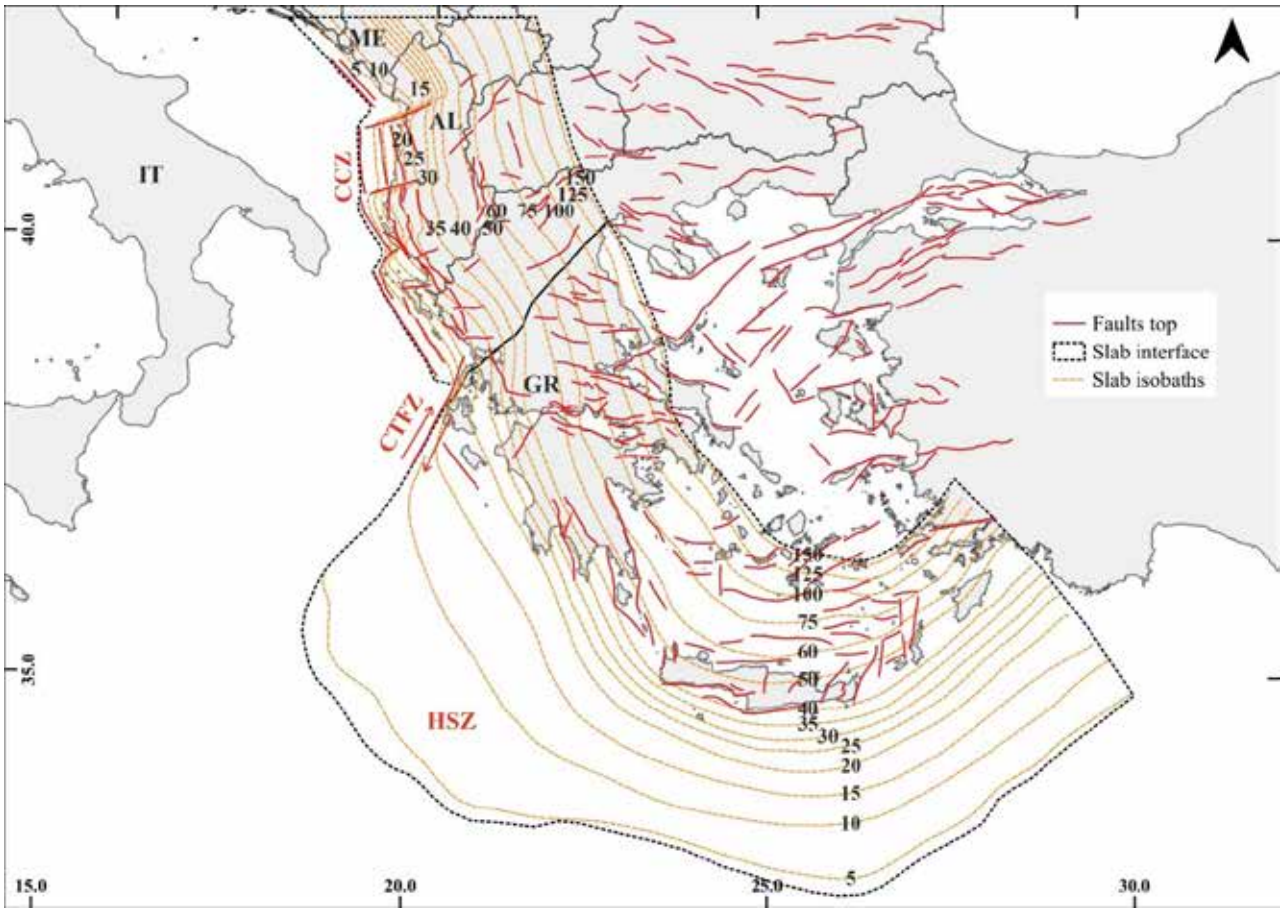

Figure 1. Modelled geometries of the Hellenic Subduction Zone (HSZ) and the Adria-Eurasia Continental Collision Zone (CCZ) based on Bocchini et al. (2018) and Halpaap et al. (2018). Black dotted polygons represent the projection of the slab interface; black solid line is the separation between continental collision and oceanic subduction domains. CTFZ = Cephalonia Transform Fault Zone. Slab isobaths expressed in km (orange dashed). Red solid represents the seismogenic sources top lines from GreDaSS 3.0 (Caputo et al., 2025; submitted to this congress).

Based on these results, five different 'rheological zones' were reconstructed in the continental collision area and in the vicinity of the basal thrust. The first emphasises a predominant brittle behaviour in both the Adria microplate and the European plate (Figure 2, blue) and extends down to a depth of ca. 25 km, except in the Montenegro sector where its limit is shallower at ca. 15 km. The second modelled zone, developing down to a depth of ca. 30 km (25 km in Montenegro), exhibits brittle behaviour in the upper plate and ductile behaviour in the lower one (Figure 2, green). The same brittle-on-ductile conditions have been recognised between 40 and 75 km-depth, but geometrically separated by an interposed sector, between 30 and 40 km, characterised by a ductile-on-ductile behaviour (Figure 2, magenta). Finally, at depths greater than 75 km, the conditions in the investigated area show again a ductile-on-ductile setting.

As concerns the HSZ, only three major sectors have been recognised along the interface; the outermost and shallower one (Figure 2), roughly at the base of the sedimentary accretionary wedge, shows a predominant brittle behaviour both above and below the slab interface. This condition persists down to a depth of ca. 50 km, although this limit is not homogeneous, being at ca. 45 km in the western sector of the HSZ, at ca. 50 km in the central sector and at ca. 40 km on the eastern side (Figure 2). The second zone, modelled continuously to a depth of about 100 km, is characterised by a predominance of brittle behaviour at the base of the overlying plate facing a ductile behaviour at the top of the lower plate (Figure 2, green). Deeper than 100 km, the interpolate shear zone shows predominant ductile properties on both sides of the interface (Figure 2, magenta). Finally, in a small sector of the HSZ at a depth of 35 and 40 km in correspondence of Aetolo-Akarnania and northern Peloponnesus, the results of the rheological model show that the interface is characterised by predominantly ductile behaviour in the upper plate and brittle characteristics in the lower plate (Figure 2, yellow).

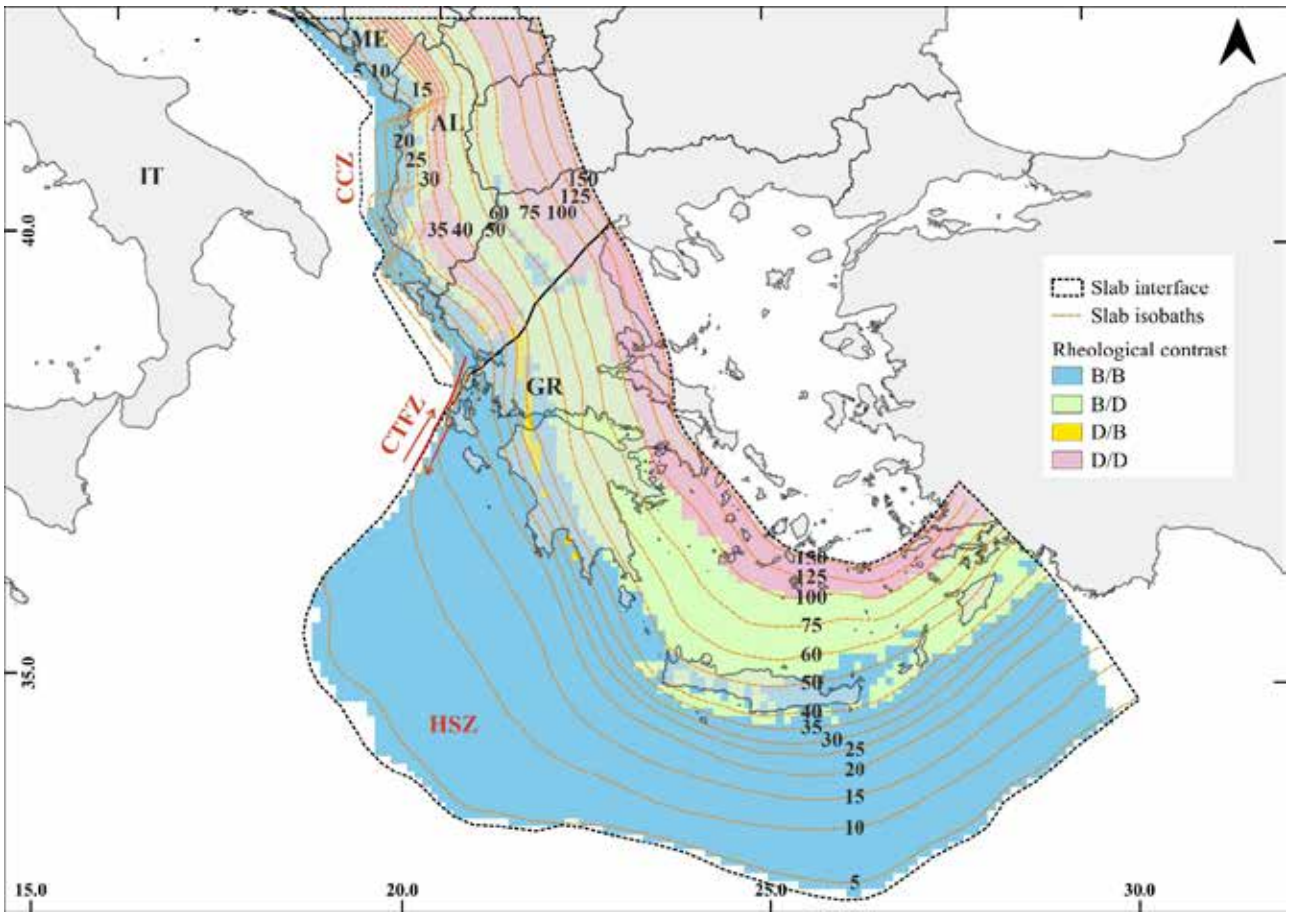

Figure 2. Same as Figure 1; coloured areas represent the recognised rheological behaviours (B/B = brittle/brittle; B/D = brittle/ductile; D/B = ductile/brittle; D/D = ductile/ductile) in correspondence of the slab interface (orange dashed).

Based on these results and considering both the overall geometry of the interplate surface and the associated seismicity (Bocchini et al. 2018), as a preliminary major conclusion the possible maximum down-dip extension of the seismogenic portion (i.e. the Wadati-Benioff zone) along the Hellenic subduction could be constrained at ca. 100 km-depth. Indeed, at greater depths, where at least 1 km-thick rock volume embedding the interplate shear zone has been modelled to behave ductilely, seismogenesis is not expected to occur. Accordingly, deeper recorded seismicity should likely occur within the subducting slab and not along the plate interface. These latter considerations are supported by literature; in Meier et al. (2004), for example, the relocated interplate seismicity plotted on the reconstructed profile across the Aegean generally does not exceed 60 km-depth, with only a few events between 80 km and 100 km. Halpaap et al. (2018), who tomographically imaged the Hellenic Wadati-Benioff zone, identified earthquake clusters characterised by inter-slab seismicity between 40 km and 60 km, while in Bocchini et al. (2018), the interface seismicity is imaged at depths systematically shallower than 100 km.
As a final comment, it should be noted that geometrical models of the interface surface slightly differing from the selected one used in the performed exercise would not likely impact on the overall obtained results especially in terms of the distribution of the contrast in terms of rheological contrast between upper and lower plate.

Introduction

The late 2024 earthquake activity below the Caldera of Santorini and the early 2025 seismic crisis between Santorini and Amorgos, in particular below Anydros Ridge, renewed the interest on the tectonic / volcanic / magmatic structure and the active geodynamic processes that control the evolution of the area. Here below we re-evaluate existing data along with new marine geological-geophysical data obtained in February 2025 with the aim to contribute to the understanding of the processes that led to the recent earthquake activity and their relationship with the long-term deformation of Santorini-Amorgos Zone.

The Santorini-Amorgos Zone is a complex morphological feature (Fig. 1) composed of seven NE-SW trending, spindle-shaped or elongated basins: Anydros, Anafi, Amorgos South, Amorgos North, Kinairos, Astypalea North and Astypalea South Basins. Two uplifted, shallow ridges, Anydros and Astypalea, separate the aforementioned basins. Two more, smaller ridges, Akrotiri and Anafi, occur south and southwest of Santorini (Tsampouraki-Kraounaki et al. (2021). Akrotiri Ridge marks the SW-ward prolongation of the southern part of Thera where the metamorphic alpine basement outcrops. Anafi Ridge extends WSW of Anafi Island.

Mascle & Martin (1990) proposed NE-SW strike-slip faulting in the area and Papadopoulos & Pavlides (1992) characterized Amorgos Fault as oblique-normal with significant right-lateral component. Piper & Perissoratis (2003) and Piper et al (2007) have suggested that the NE-SW faulting, the narrow basement ridges and the basin inversions in the area are evidence of strike-slip regime. Sakellariou et al. (2010) proposed that both Thera and Kolumbo volcanic centers occur within the NE-SW-trending Anydros graben, which constitutes a negative flower structure related to a 40 km long, possibly dextral, strike-slip zone, the Kameni-Kolumbo strike-slip, which can be extended SW-wards to the Christiana volcanic island. Sakellariou & Tsampouraki-Kraounaki (2019) and Tsampouraki-Kraounaki et al. (2021) suggest that the NE-SW-trending Santorini-Amorgos Shear Zone undergoes dextral transtensional deformation accommodated by NE-SW strike-slip to oblique faults and E-W normal step-over faults (Fig. 2). This is compatible with the microseismicity data observed by Bohnhoff et al. (2006), the results of Papadimitriou et al. (2015) on the seismic activity in the caldera of Santorini and the dextral transtensional movement of 4.5 mm yr-1 between Amorgos and Astypalea islands observed by Briole et al. (2021). Nomikou et al. (2016, 2018), Hooft et al. (2017) and others propose normal NE-SW trending faulting as the main deformation mechanism that forms the geomorphological features of the area with secondary, steep faults probably indicating strike-slip component. Finally, Tzanis et al (2020) studied the kinematic regime of the Santorini area by using gravity, magnetotelluric and DGPS data and suggested that Santorini-Amorgos area is characterized by NW-SE dextral strike slip faults and NE-SW normal to sinistral faults.

Data

Swath bathymetry, airgun seismic profiles, deep-towed side scan and chirp subbottom profiles and sediment cores have been collected during various cruises of HCMR's research vessel AEGAEO in the broader area around Santorini, between Santorini, Anafi, Astypalea, Amorgos, Kinairos and Kos (Fig. 1). New swath bathymetry data and high resolution sparker subbottom profiles were collected during the recent cruise of R/V AEGAEO (12-17 Febr. 2025) in the area around Anydros Island (Fig. 3) and between Santorini and Kolumbo.

Results & Discussion

Seismic profiles studied and interpreted by Tsampouraki-Krounaki et al. (2021) show that the northwestern steep flank of Akrotiri Ridge is controlled by the NE-SW striking, NW-dipping Akrotiri Fault (AF) (Fig. 2). The possible prolongation of AF to the NE coincides with the southeastern wall of Santorini Caldera as well as with the boundary between the alpine basement (that outcrops in Athinios and Profitis Ilias Mt.) to the South and the volcanic formations to the North. The Profile 1 of Fig. 6 shows a schematic NW-SE cross section across the Caldera with the NW-dipping inferred prolongation of AF. The recent earthquake activity in the Caldera occurred at shallow depths below the Nea and Palaia Kameni Islands and Fira, along the NE-SW striking "Kameni Line". "Kameni Line" strikes parallel to the prolongation of AF. It is proposed here that the "Kameni Line" represents the linear distribution of earthquake epicenters that, at depth, occur on the NW-dipping, steep Akrotiri Fault. If so, Akrotiri Fault may be considered as the southern boundary of the volcanic activity that has shaped Santorini throughout Quaternary.

Geodetic data obtained during the seismic activity showed fast movement of the northern part of Santorini toward

NE (unpublished data of EPPO Seismic Hazard Committee, M. Foumelis courtesy). That motion occurred roughly in the first half of February 2025, it affected mainly the northern part of Thera and the island of Therasia while the southeastern part of Thera remained almost unaffected. In other words, the NE-ward movement affected mostly the volcanic part of Santorini on the hanging-wall of Akrotiri Fault, while the foot-wall of the fault (the basement) remained more or less stable.

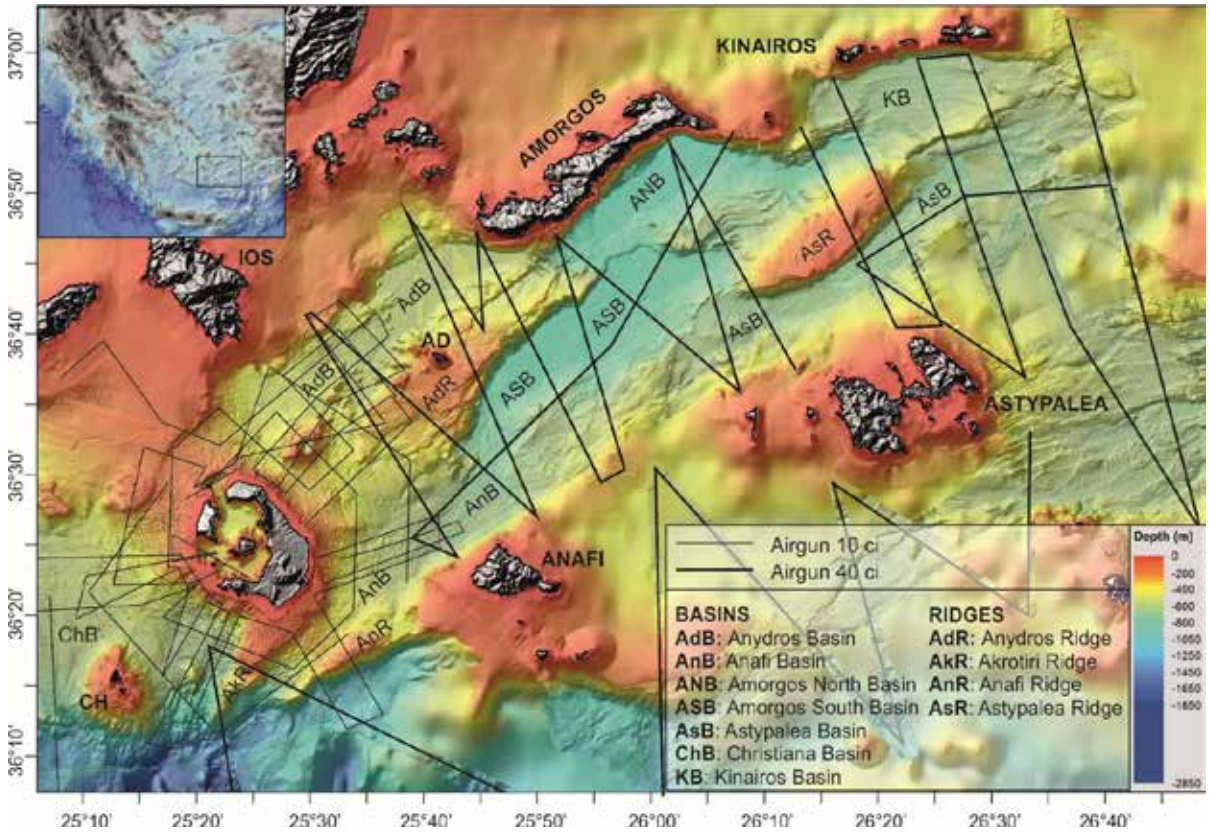

Figure 1. Shaded relief map of the Santorini-Amorgos Zone modified after Tsampouraki-Kraounaki et al (2021).

Anydros Ridge is a shallow, positive, SW-NE trending morphological feature that has been uplifted between the 400 m deep Anydros Basin to the NW from the 700 m Amorgos South Basin to the SE (Fig. 2, 3). It displays a rather complicate shape controlled by SW-NE and E-W striking faults. Morphological and seismic/subbottom profiling data indicate a mean, gentle, NW-ward tilting of Anydros Ridge seafloor by 0.5°-1.5° (Fig. 4, 5). Astypalea Ridge along with Amorgos and the Kinairos-Levitha Islands display similar, NW- / N-ward tilting, with steep, high SW- / S-ward facing slopes and gently sloping northwestern / northern flanks (Fig. 2, 3). Several faults crosscut the top of Anydros Ridge, they have led to local subsidence and the creation of small depressions filled with sedimentary deposits with up to 80 msecs thickness on top of the alpine basement of the ridge (Fig. 4, 5). Two geometrical unconformities U1 and U2 within the seismic stratigraphy of the sedimented depressions display gentle NW-ward dip direction, following the tilting of the ridge.

Geodetic data obtained during the seismic activity showed significant NW-ward tilting of Anydros Island (unpublished data of EPPO Seismic Hazard Committee, M. Foumelis courtesy) roughly in the first half of February 2025. The sense of the tilting of Anydros Island coincides with the tilting of the entire Anydros Ridge as described above.

The mostly linear and steep SE slope of the ridge has developed along the SE-dipping Anydros Ridge South Fault Zone (AdRSFZ). The NW limit of the ridge is rather irregular and less well defined and is largely controlled by multiple segments of the NW-dipping Anydros Ridge North Fault Zone (AdRNFZ) (Fig. 2, 3).

The sparker subbottom profile of Fig. 4 provides a high-resolution imaging of the shallow sub-seafloor structure across Anydros Ridge and at short distance southwest of Anydros Island. Three NW-dipping fault splays of AdRNFZ offset the seafloor (Fig. 4B). The northern one displays minimum cumulative offset of 50 msecs, extends further to the NE and outcrops on Anydros island (Fig. 3). On site measurements of the geometric and kinematic data on Anydros (unpublished data of EPPO Seismic Hazard Committee, D. Galanakis courtesy) show a steep, NW-dipping oblique normal fault with significant dextral horizontal component.

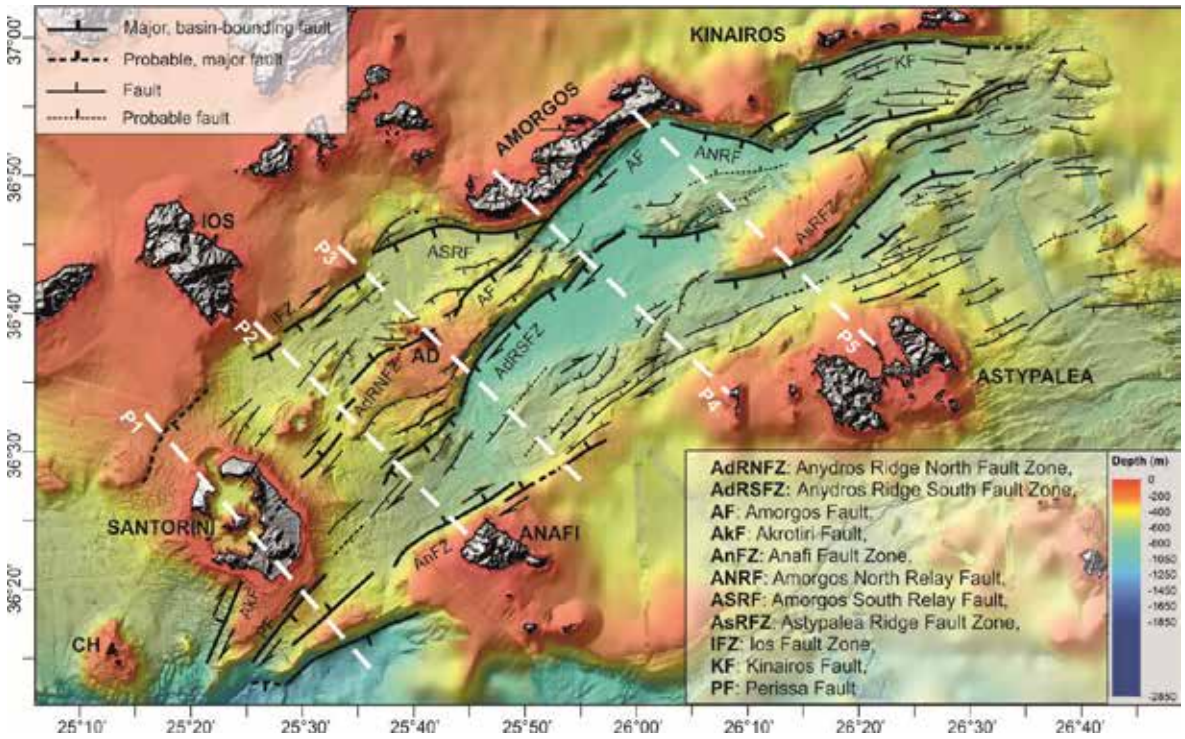

Figure 2. Shaded relief map and fault network of the Santorini-Amorgos Zone modified after Tsampouraki-Kraounaki et al (2021). White dashed lines P1 – P5 indicate the location of the geological profiles shown on Figure 6.

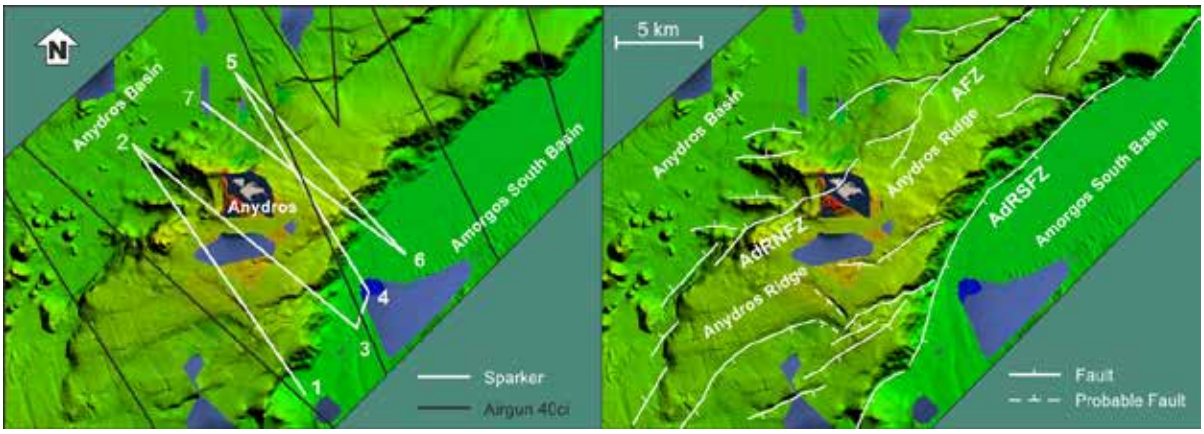

Figure 3. Shaded relief map, airgun and sparker profiles (left map) and fault network (right map) of Anydros Ridge.

The trace of the NW-dipping AdRNFZ terminates at a short distance north-northeast of Anydros Island. Further to the NE the structure of Anydros Ridge is controlled by the SE dipping Amorgos Fault Zone (AFZ). The sparker subbottom profile of Fig. 5 provides a high-resolution imaging of the shallow sub-seafloor structure across Anydros Ridge and at a few kilometers distance northeast of Anydros Island. Fig. 5B and C shows the SE-dipping fault splays of AFZ that offset the seafloor and unconformity U2 by up to 50 msecs or less.

The northeastern termination of the NW-dipping AdRNFZ and the southwestern termination of the SE-dipping AFZ are only a couple of kilometers apart (Fig. 3). The reversal of the tectonic polarity between them is not well understood.

Re-exploitation of the pre-2025 data along with the analysis of the new swath bathymetry and seismic profiling data provide insights into the geological and tectonic structure of the Santorini-Amorgos Zone. The five profiles shown on Fig. 6 aim to provide a schematic visualization of the here proposed structure of the upper crust at up to 10 km depth. Under the light of the new knowledge and information derived from the multiple datasets obtained during the recent seismic activity, they may be used as a first draft scheme that may certainly need corrections or improvements and can contribute to the understanding of the longterm processes that controlled the evolution of Santorini-Amorgos Zone and the processes that led to the 2025 seismic activity.

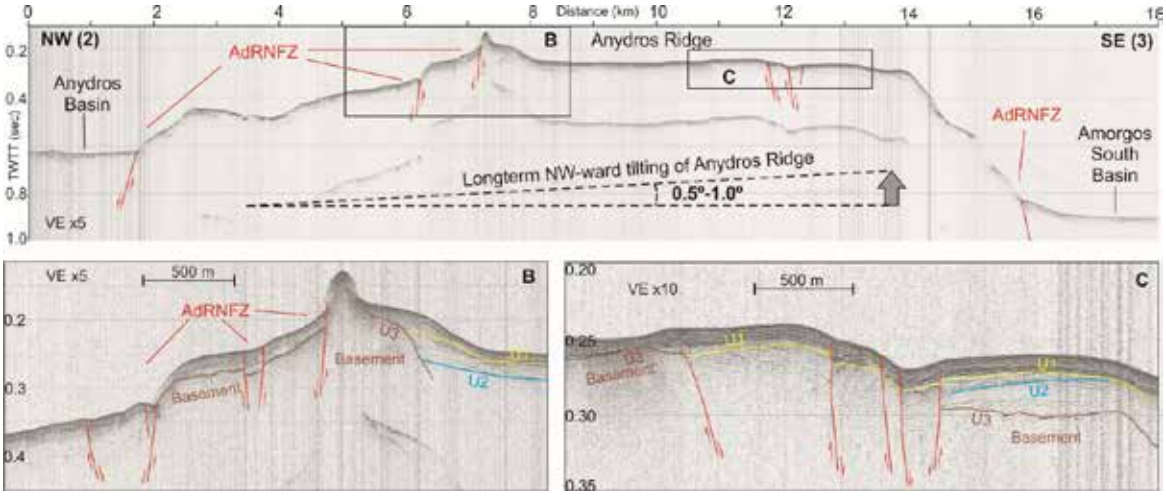

Figure 4. Sparker Subbottom Profile 2-3 across Anydros Ridge. See Figure 3 for location.

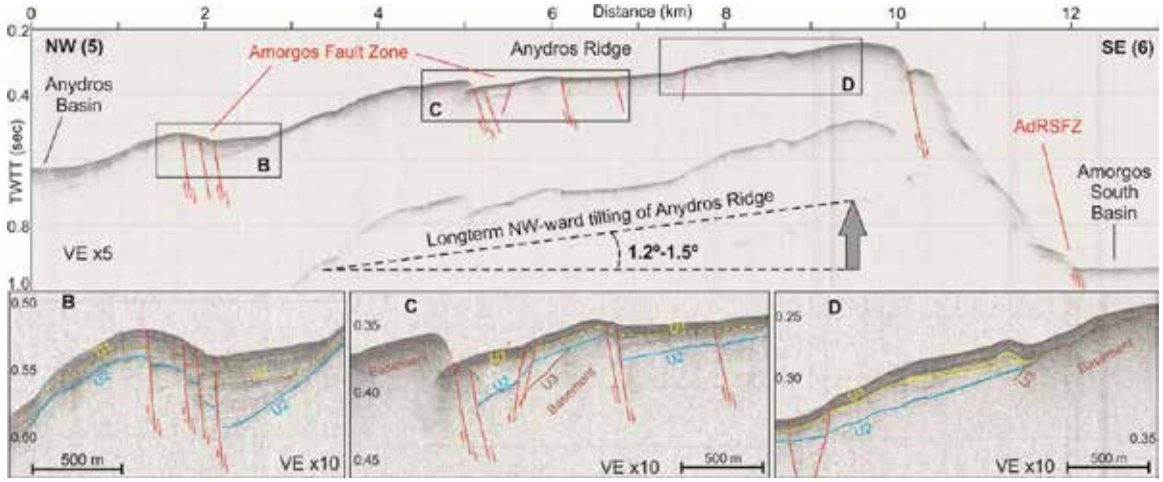

Figure 5. Sparker Subbottom Profile 5-6 across Anydros Ridge. See Figure 3 for location.

Profile 1 (Fig. 6), across Therasia, Caldera/Kameni, Thera, Anafi Basin and Anafi Ridge, proposes that magmatic and volcanic activity of Santorini is confined between Ios FZ and Akrotiri FZ. The latter marks the boundary between the alpine basement and the volcanic formations of Santorini. The late 2024 – early 2025 earthquake activity in the Caldera occurred at shallow depths below the Nea and Palaia Kameni Islands and Fira, along the NE-SW striking "Kameni Line". It is possible that the earthquakes were triggered by magma flow on the NW-dipping Akrotiri Fault.
Profile 2 (Fig. 6), across Anydros Basin, Anydros Ridge and Anafi Basin, proposes that magmatic and volcanic activity of the Kolumbo volcanic chain is confined below Anydros Basin, between Ios FZ and AdRNFZ.
Profile 3 (Fig. 6), across Anydros Basin, Anydros Ridge, Anydros Island, Amorgos South Basin and Anafi Basin, shows the transtensional Anydros and Amorgos South Basins separated by the uplifted Anydros Ridge. Anydros Basin displays symmetrical geometry while Amorgos South Basin exhibits enhanced subsidence along its NW margin. The eastern termination of Anafi Basin displays SE-ward asymmetry. Preliminary location of the earthquake hypocenters indicates that the 2025 seismic activity occurred predominantly below Anydros Ridge between AdRNFZ and AdRSFZ.
Profile 4 (Fig. 6), across Amorgos Island, Amorgos North Basin, Amorgos South Basin and Astypalea Basin, displays NW-ward asymmetry of the Amorgos North and South Basins and SE-ward asymmetry of the Astypalea Basin.
Profile 5 (Fig. 6), across Amorgos Island, Amorgos North Basin, Astypalea Ridge, Astpalea Basin and Astypalea Island, displays NW-ward asymmetry of the Amorgos North Basin and NW-ward tilting of Astypalea Ridge.
All major faults drawn on the above profiles are considered as oblique normal faults with significant component of dextral lateral slip. It is proposed here that lateral slip on some of the faults may exceed vertical slip.
The entire Santorini-Amorgos Zone is considered here as a transtensional feature or dextral oblique rift that has evolved during Quaternary.

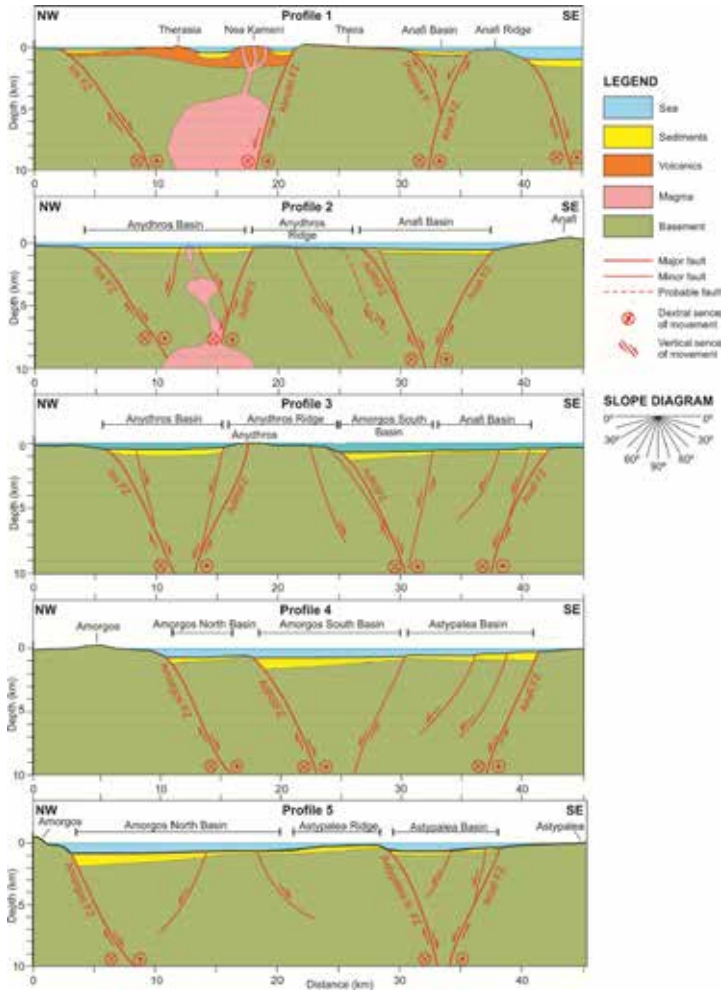

Figure 6. Schematic cross-sections across the Santorini-Amorgos Zone. The location of the five profiles is shown on the map of Figure 2. No vertical exaggeration. Abbreviations and names shown on the profiles are as in Fig. 1 & 2.

Conclusions

Re-exploitation of the pre-2025 data along with the analysis of the recently collected swath bathymetry and seismic profiles provide the following conclusions on the geological and tectonic structure of the Santorini-Amorgos Zone that can contribute to the understanding of the longterm processes controlling its evolution and the processes that led to the 2025 seismic activity:

- The “Kameni Line” represents the linear distribution of earthquake epicenters that, at depth, are probably associated with the NW-dipping, steep Akrotiri Fault.
- The geodetically observed NE-ward movement of Santorini that occurred in the first half of February 2025 affected the hanging-wall of Akrotiri Fault, while the foot-wall of the fault (the basement) remained more or less stable.
- The significant NW-ward tilting of Anydros Island observed on geodetic data during the seismic activity coincides with the long-term tilting of the entire Anydros Ridge observed on swath bathymetry and seismic profiling data.
- The NW-dipping Anydros Ridge North Fault Zone (AdRNFZ) controls the NW flank of Anydros Ridge and crosscuts the island of Anydros. Geometric and kinematic data of this fault measured on Anydros show a steep, NW-dipping oblique normal fault with significant dextral horizontal component.
- The trace of NW-dipping AdRNFZ is followed laterally towards northeast by the trace of the SE-dipping Amorgos Fault Zone (AFZ). The reversal of the tectonic polarity between these two fault zones is not well understood.
- Earthquake activity and ground deformation observed during the early 2025 seismic crisis are compatible with the long-term deformation of Santorini-Amorgos Zone.

Acknowledgements

This work uses swath bathymetry and seismic profiling data acquired during several cruises of R/V AEGAEO between 2001 and 2017 and funded partly by THERA (2006) and Eurofleets2 LGT-AMORGOS-56 international projects and partly by national (HCMR) funds. The February 2025 cruise of R/V ARGAEO was implemented within the “Athena vs. Egeladus” project funded by the Hellenic Foundation for Research & Innovation (HFRI). The authors are grateful to the colleagues and technicians who contributed to the acquisition of the data during all mentioned cruise. The crew and the captain of R/V AEGAEO are particularly acknowledged for their continuous support and smooth collaboration.

EXTENDED ABSTRACT 276

Airborne and marine survey of the 8th June 2023 earthquake-triggered coastal collapse at Mylos Gialtron, North Evia: Contribution to the understanding of coastal zone vulnerability

Sakellariou D., Morfis I., Vandarakis D., Livanos I., Kourliaftis I.
Institute of Oceanography, Hellenic Centre for Marine Research, 19013 Anavyssos, Greece, sakell@hcmr.gr

Introduction

An earthquake with magnitude Mw:4.9 occurred on June 8th 2023, 10 km southwest of Atalanti, at 9 km depth (https://bbnet.gein.noa.gr/HL/seismicity/mts , 2023-06-08, 12:33:53.52, Lat: 38.5635°, Long.:22.9209°) (Fig. 1A). The tremor was felt in North Evia and triggered a landslide on the coastal zone of Mylos Gialtron (Fig. 1B). A 20 m long by 10 m wide part of the sandy beach in front of Mylos collapsed into the sea and created local turbulence of the seawater.
One week after the earthquake, on June 15th 2023, the Inst. Of Oceanography of HCMR undertook airborne mapping and documentation of the coastal collapse at Mylos Gialtron with a drone. Two weeks after the earthquake, on June 22nd and 23rd, a marine survey was implemented using a multibeam echosounder on board the research vessel Alkyon of HCMR. The results of the airborne and marine surveys on the coastal slide at Mylos Gialtron are presented here below and provide insights into the vulnerability of the Greek shoreline to co-seismic and non-seismic coastal slides.

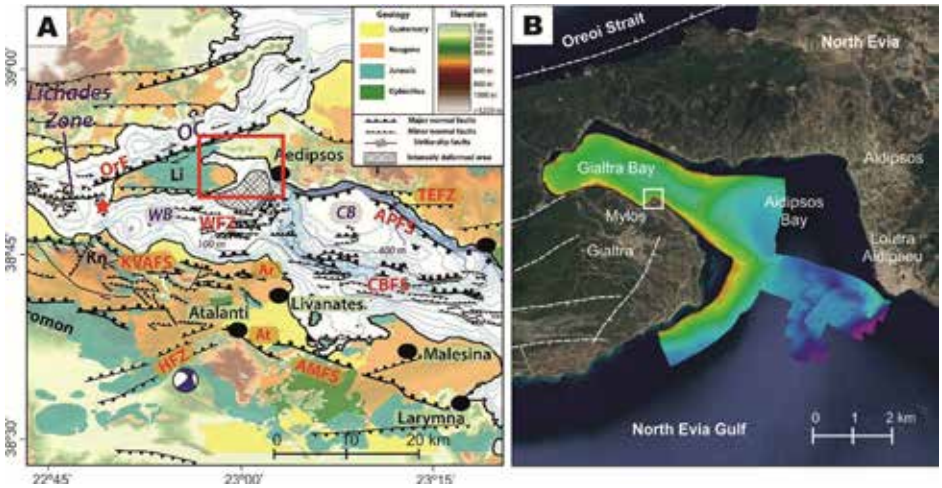

Figure 1. A: Geological and tectonic map of the broader North Evia Gulf (modified after Caroir et al., 2024). Red box: Fig. 1B. Blue-white beachball: Epicenter and moment tensor solution of the 8th June 2023 earthquake. B: Google Earth image with location of Mylos Gialtron (white box) and swath bathymetry coverage during the survey on board R/V Alkyon. White dashed lines: Faults after Galanakis et al. (1998) and Caroir et al. (2024).

Tectonic and Geographic Setting

Active neotectonics of the broader area of Eastern Central Greece, North Evia Gulf, North Evia and Oreoi Strait is dominated by E-W, SW-NE and NW-SE striking normal, oblique and dextral/sinistral strike-slip faults (Galanakis et al., 1998; Kranis, 2007; Sakellariou et al., 2007; Ganas et al., 2016; Caroir et al., 2024 and references therein). The two nodal planes observed by the moment tensor solution (https://bbnet.gein.noa.gr/HL/seismicity/mts) of the 8 June 2023 Mw 4.9 earthquake are compatible with the local tectonic pattern (Fig. 1A).
The sandy beach of Mylos (windmill) is located in North Evia, north of the village of Gialtra and west of Loutra Aidipsou, roughly 30 km north of the epicenter of the 8th June 2023 earthquake. It is a small, flat, triangular cape on the southern shoreline of Gialtra Bay that has been formed by the deposition of alluvial deposits due to the local coastal marine currents. The onshore area adjacent to Mylos is built mostly of carbonates and schists and displays rough relief.

Methods

In this study, a DJI Matrice 210 RTK Unmanned Aerial Vehicle (UAV) was used for the airborne mapping of the coastal

and shore morphology and the documentation of the shallow coastal collapse (Casella et al., 2020; Papakonstantinou et al., 2016). The UAV was equipped with a Zenmuse X5S sensor and RTK technology. Six (6) Ground Control Points (GCPs) were implemented to achieve geolocation accuracy of ±2 cm. The flight plan consisted in nine (9) N-S and eight (8) E-W oriented tracks (Fig. 2 A) (Trajkovski et al., 2020; Zhou et al., 2024). In total, 185 photos were taken from 120m Above Ground Level (AGL), the front and side overlap were at 80% and the Ground Sampling Distance (GSD) was at 2.69 cm/pixel. The achieved Root Mean Square Error (RMSE) of accuracy of the resulted Orthomosaic, Digital Surface Model (DSM) and Digital Terrain Model (DTM) was about 0.012 m (Fig. 2B). The Pix4d mapping software was used for the construction of the maps. The total area covered was 377 X 319 m and the coordinate system used was GCS_GGRS_1987. Based on the height of the drone flight the DSM and Orthomosaic resolution was fixed at 2.69cm/pixel. Noise and surface filters were implemented to eliminate potential errors during the processing. The Inverse Distance Weighting Method was used for the construction of the DSM (and DTM) raster.

A Teledyne/RESON SEABAT T50-R, 200 – 400 kHz multibeam echosounder hull-mounted on HCMR's Research vessel Alkyon was used for the acquisition of swath bathymetry data in the Aidipsos and Gialtra Bay. T50-R multibeam echosounder emits up to 1024 beams arranged in iso-distance or iso-angle mode at 165° across the vessel's track and offers maximum swath equal to up to 5 times the current water depth. A Sea Bird Electronics SeaCat 19 Profiler CTD (Conductivity – Temperature – Depth) was used for the sound velocity profile of the water column during the survey. The resulted swath bathymetry of 13.5 km^2 in Gialtra and Aidipsos Bays has been processed at 1 m spatial resolution.

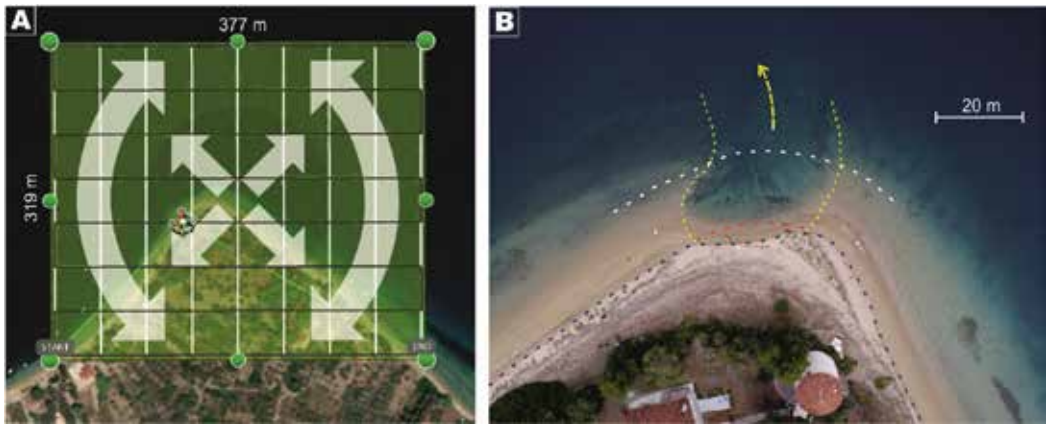

Figure 2. A: Flight plan of the drone over the area of Mylos Gialtron. B: Airphoto of the coastal collapse at the tip of Mylos Gialtron sandy beach taken from the drone on June 15, 2023. Blue dashed line: post-earthquake shoreline. Red dashed line: pre-earthquake shoreline. White dashed line: pre-earthquake 4 m depth contour (approximately).

Results

The swath bathymetry data showed that Gialtra Bay is a flat, 35-40 m shallow embayment with a large number of a few meters high mounds of probable biogenic origin (Fig. 3). The up to 50% steep littoral slope connects the southern, narrow coastal zone with the flat bottom of the Bay. The northern side displays gentler slope value. A 30 m shallow, NE-SW trending sediment ridge (Barrier in Fig. 3) separates the shallow seafloor of Gialtra Bay to the East from the deeper Aidipsos Bay. The latter is characterized by rather flat seafloor that deepens smoothly to 55 m depth towards the center. Aidipsos Bay is open to the South to the North Evia Gulf. A prominent, >5 m deep valley incises the 50 m shallow, flat seabed between Gialtra and Loutra Aidipsou and connects the 55 m deep seafloor of Aidipsos Bay with the 440 m deep Central Basin of the North Evia Gulf.

Three areas with slope failures have been identified on the seafloor (Fig. 3). An amphitheatric scar occurs east of Gialtra at depths between 20 and 30 m and marks a submarine landslide that took place not very long ago, possibly not earlier than 5-6 kyrs before present, when the area was already drowned by the last sea-level rise. Multiple evidence of recent coastal slides and mass transport deposits have been observed off the shoreline of Mylos Gialtron (Fig. 4 & 5) and will be described below. Finally, evidence of composite on- and offshore slope failure and rock falls have been found at the southwestern part of Gialtra Bay coastal zone (Fig. 6).

The Mylos Gialtron coastal collapse(s)

The airborne DTM and orthophotomosaic of Mylos Gialtron provide a precise documentation of the onshore coastal plain, the sandy beach and the shallow seafloor up to roughly 9 to 10 m depth (Fig. 4). The western slope is steeper than the eastern one and show evidence of slope failures at shallow depth. The scar created by the coastal collapse

of 8th June 2023 at the northern tip of the shoreline has been mapped in detail up to the depth of 4.5 m (Fig. 4 & 2B). The airphoto of Fig. 2B shows the coastal zone at the tip of Mylos Gialtron one week after the earthquake-triggered collapse of 8th June 2023. A 20 m long by up to 10 m wide part of the sandy beach and its offshore continuation are missing because they collapsed northwards and slid downslope leaving behind an amphitheatric scar. The dashed red line shows the shoreline prior to the collapse. The white dashed line shows the approximate location of the 4 m depth contour prior to the collapse. Note that the 4 m depth contour is less than 20 m away from the shoreline indicating a minimum mean coastal slope value of 25%. The two yellow dashed lines mark the edges and the yellow arrow shows the direction of the slide.

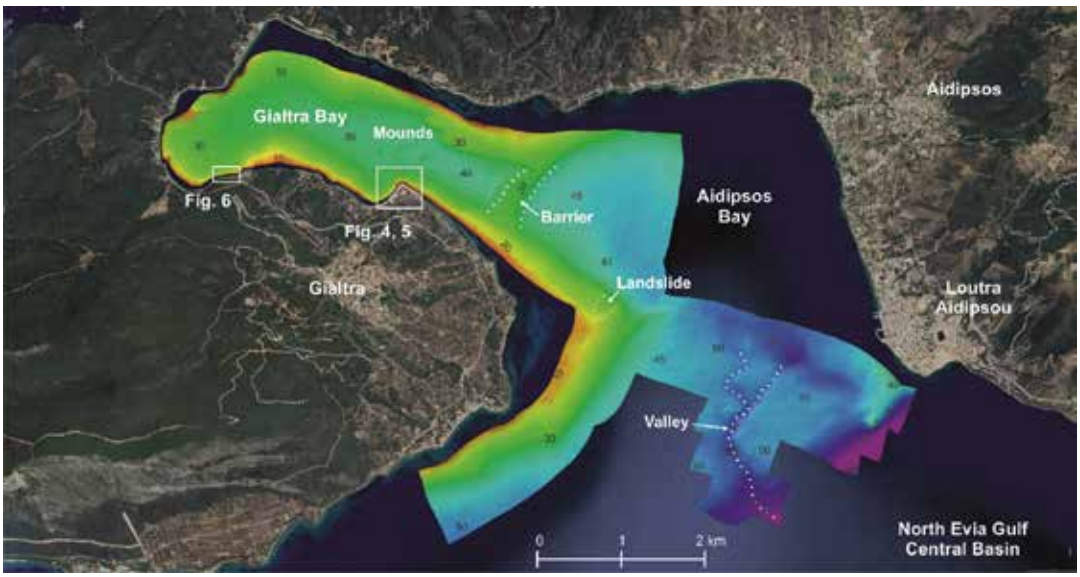

Figure 3. Swath bathymetry of the Aidipsos and Gialtra Bay acquired on board R/V Alkyon on June 22-23, 2023.

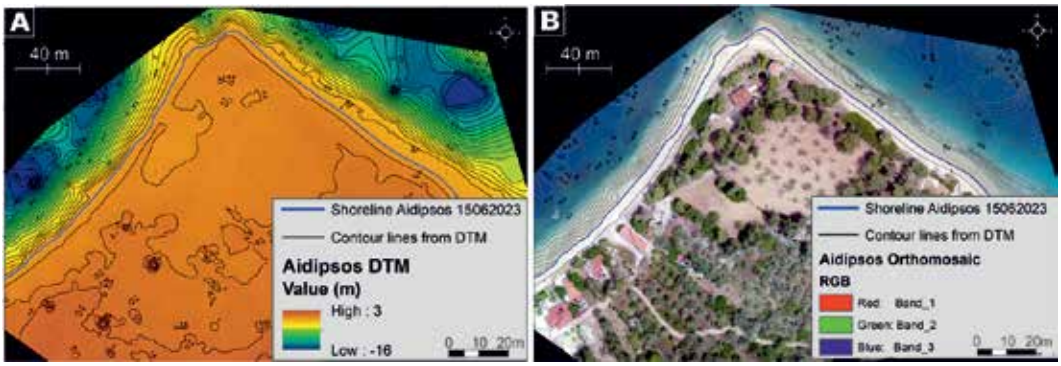

Figure 4. DTM (A) and Orthophotomosaic (B) derived from the airborne survey at Mylos Gialtron on June 15, 2023.

The swath bathymetry acquired with R/V Alkyon complemented the airborne mapping of the seafloor off Mylos Gialtron. Thanks to the crew of R/V Alkyon, the vessel navigated at very short distance from the shoreline during the marine survey in order to achieve sufficient complementarity, without gaps between the airborne and the marine coverage.

Multiple shallow slope failures are evident off the western shoreline of Mylos (Fig. 5A). The toe of the slope deposits reaches 30 m depth. No scar has been identified on the airborne and marine data indicating that these failures may have taken place at least some tens of years ago, sufficient time for the dynamic coastal zone environment to heal the failure scars.

The coastal scar at the northern tip of the sandy beach continues downslope toward north-northwest (Fig. 5B). A 15 m wide and 3-4 m deep gully incises the slope down to roughly 15-20 m depth and is followed by the depositional lobe. The lobe widens to reach a diameter of at least 50 to 60 m and extends up to the 30 m depth contour. Assuming a mean thickness of 2 m for the depositional lobe, the estimated volume of the slide is calculated to >7,000 m^3. Local witnesses reported extensive turbulence of the seawater in front of the sandy beach when the collapse took place. This indicates that the collapse and the slide evolved abruptly and at high velocity, however, no tsunami was reported.

At least one more, older, depositional lobe is evident on the seafloor. The white dashed line on the map of Fig. 5A outlines the morphological expression of an older lobe that is located further off the slide deposits of 8th June 2023. This older lobe extends off the 35 m depth contour, at roughly 150-200 m distance from the shoreline and has the shape of a wide, flat mound with its highest surface 2-3 m higher than the surrounding seafloor. The shape and orientation of this depositional lobe strongly indicates that it is the result of a coastal slide similar to but two times larger than the one of June 2023. Local witnesses reported to the survey team that a coastal collapse similar to the one of 8th June 2023 occurred at the time of the 9th July 1980, M:6.3 Almyros earthquake. It has not been possible to verify this information, however it is reasonable to assume that the older slide may have been triggered by an earthquake in the recent past.

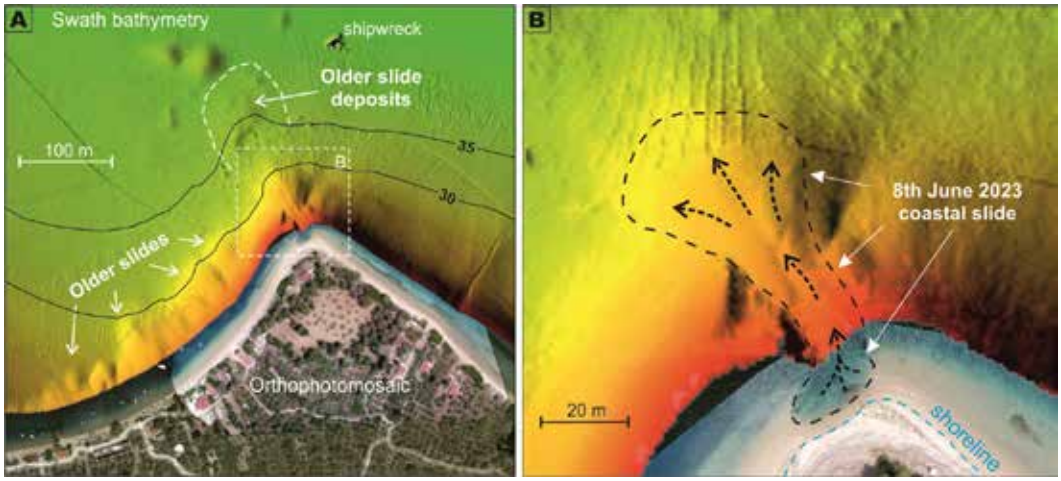

Figure 5. A: Orthophotomosaic and shaded bathymetry of the coastal and offshore Mylos Gialtron area. White arrows point to landslide deposits before the 8th of June 2023. Black thin lines are depth contours B: Detail of previous image showing the 8th June 2023 co-seismic coastal collapse and slide deposits off the sandy beach of Mylos Gialtron.

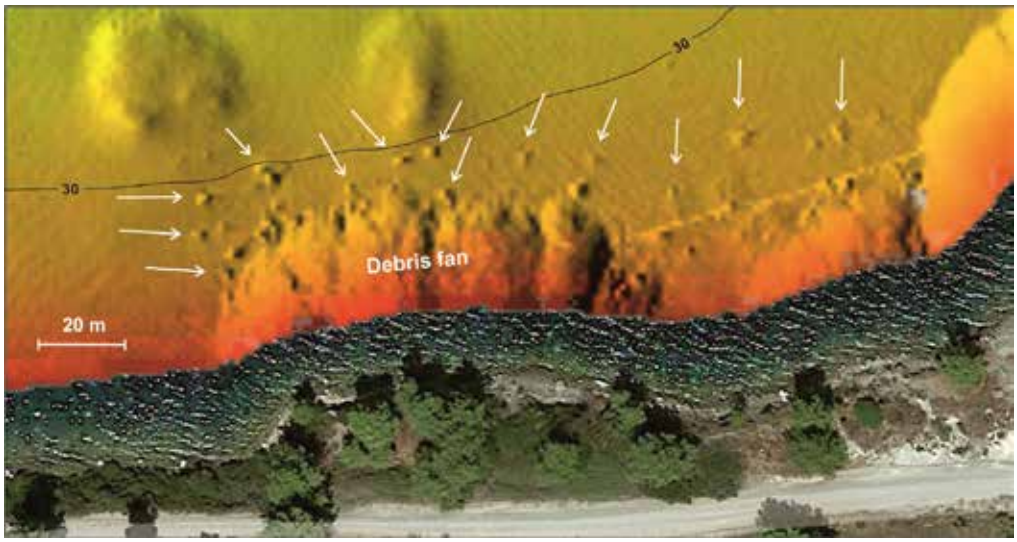

Figure 6. Shaded swath bathymetry off the southern shoreline of Gialtra Bay (see Fig. 3 for location) showing a submarine debris fan and multiple boulders (arrows) fallen from the nearby onshore rocky cliff. Thin black line: 30 m depth contour.

Evidence of coastal slope failure has been found on the seafloor at the southwestern margin of Gialtra Bay (Fig. 6). The shaded relief of the seafloor shows a 100 m wide submarine fan. The fan has evolved off and parallel to the convex-shaped shoreline and is incised by several small gullies. The foot of the debris fan is at 25-28 m depth and is surrounded by multiple, small positive features (pointed with arrows on Fig. 6). Based on their shape, dimensions and context they are interpreted as rock boulders with diameter up to roughly 2 meters. Both the debris fan and the boulders may have derived from a landslide on the nearby onshore, north-facing, mountain flank. The available data

provide no constraints on the possible age of the landslide that is responsible for the creation of the debris fan and the rock falls.

Discussion

The co-seismic coastal collapse and submarine landslide of 8th June 2023 is probably the first one in Greece that has been documented right after its occurrence with the use of airborne and marine survey techniques. The results presented above highlight two main critical factors that favor the development of slide events in the coastal zone once a proper triggering mechanism (e.g. earthquake) is activated (Fig. 7A & B).

The first factor is the presence of a coastal sedimentary prism built and thickened by fast accumulation of non-coherent sediments, e.g. the loose deposits that accumulate along the shoreline and build the sandy beaches and the dynamically changing, on- and offshore coastal zone. The second factor is the presence of a relatively steep slope on the seafloor at short distance off the shoreline. In the case of Mylos Gialtron the submarine slope starts at 10-15 m off the shoreline and displays dipping value >25% basinwards. Certainly, the initial, driving factor for the collapse is the magnitude of the seismic acceleration that will or will not destabilize the non-coherent coastal deposits.

The schematic drawing shown on Fig. 7 visualizes in a simplified way the main factors described above as well as the evolution of the coastal collapse to a submarine landslide. Fig. 7A shows the structure of the coastal zone before the event. The red, dashed line marks the sliding plane of the imminent slide. The area highlighted in yellow indicates the sedimentary material (evacuation zone) to be involved into the coastal collapse and slide. The red line in Fig. 7B marks the slide scar and the red half arrow points the pathway of the sliding mass. The yellow lobe on the deep seafloor visualizes the deposition lobe of the landslide.

The structural and morphological characteristics as presented above for Mylos Gialtron and visualized in Fig. 7 are fairly common along the Greek shoreline. Large or smaller segments of the coastal zone of the Ionian Islands, the Gulf of Corinth, the islands of the Hellenic Arc (Crete, Kasos, Karpathos, Rhodes), the eastern Peloponnese to the Argolikos Gulf and Myrtoon Sea, the coast of Evia to the Aegean Sea and the North Evia Gulf, the Sporadhes Islands are some of the areas along the Greek coastline that (a) display structural and morphological characteristics similar to the ones described above and (b) are characterized by frequent, high earthquake activity.

These areas need to be systematically surveyed with the aim to document precisely the structure and morphology of the coastal zone, estimate and understand their vulnerability to coastal landslides similar to or even larger than the recent one at Mylos Gialtron and design measures for the mitigation of their impact on the coastal societies.

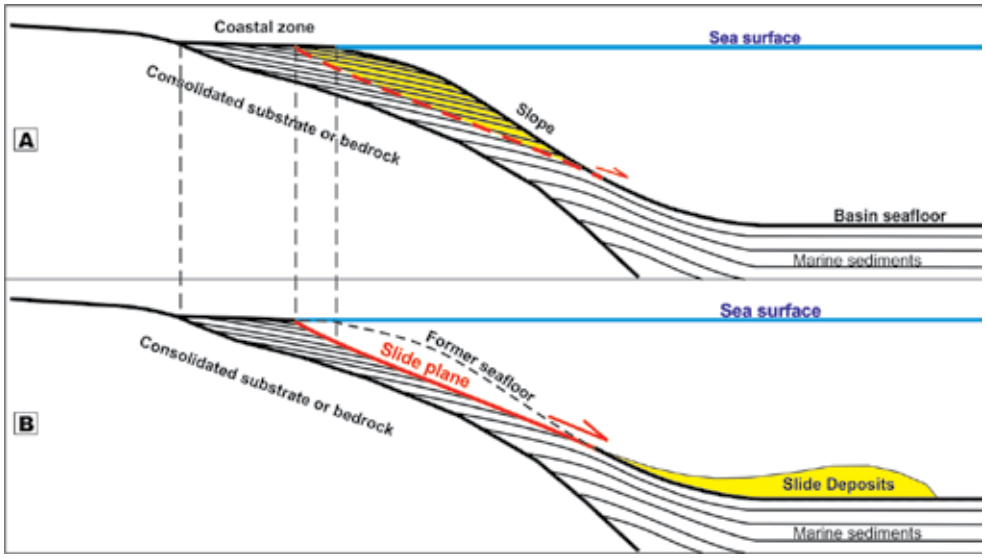

Figure 7. Schematic visualization of the coastal collapse and submarine landslide of 8th June 2023 at the sandy beach of Mylos Gialtron. See text for description.

Conclusions

The coastal collapse at Mylos Gialtron, southern shoreline of Gialtra Bay in North Evia was triggered by the Mw:4.9 magnitude earthquake of June 8th 2023, 10 km southwest of Atalanti. Airborne orthophotomosaic, digital terrain and surface models (DTM, DSM) of the coastal zone combined with swath bathymetry mapping of Gialtra and Aidipsos Bays provided detailed documentation of the coastal collapse and showed that it evolved as submarine landslide.

Gialtra Bay is characterized by flat, 35-40 m shallow seafloor with an up to 50% steep southern slope and gentler sloping northern margin. It is separated from the deeper Aidipsos Bay by a 30 m shallow, NE-SW trending sediment ridge. Aidipsos Bay displays rather flat, up to 55 m deep seafloor and is open to the South to the North Evia Gulf. A prominent, submarine valley incises the 50 m shallow, flat seabed between Gialtra and Loutra Aidipsou and connects Aidipsos Bay with the 440 m deep Central Basin of the North Evia Gulf.

A 20 m long by up to 10 m wide part of the sandy beach at Mylos Gialtron and its offshore continuation collapsed and slid downslope, toward the 35-40 m deep flat seafloor of Gialtra Bay, leaving behind an amphitheatric scar. The sliding mass created a 15 m wide by 3-4 m deep gully on the slope down to roughly 15-20 m depth. The gully is followed by the 50 to 60 m in diameter depositional lobe that extends up to the 30 m depth contour. Assuming a mean thickness of 2 m for the depositional lobe, the estimated total volume of the slide is calculated to >7,000 m^3.

One more, older, larger depositional lobe is found on the seafloor. It extends beyond the 35 m depth contour, at roughly 150-200 m distance from the shoreline and has the shape of a wide, 2-3 m high, flat mound. The shape and orientation of this depositional lobe strongly indicates that it is the result of a coastal slide similar to but two times larger than the one of June 2023. According to local witnesses, a coastal collapse at the same spot was triggered by the 9th July 1980, M:6.3 Almyros earthquake, 43 years before the recent coastal collapse. This collapse may be associated with the older slide.

Further evidence of extensive on/offshore landslide, debris flow and rock falls has been found at the southwestern margin of Gialtra Bay. According to the bathymetric and morphological data this slope failure is relatively recent, however no precise age constraints are available.

Certain, larger or smaller segments of Greece's coastal zone (e.g. Ionian Islands, Gulf of Corinth, Hellenic Arc islands, Eastern Peloponnese etc.) display structural and morphological characteristics similar to the ones of Mylos Gialtron coastal zone and are characterized by frequent, moderate to high earthquake activity. These areas need to be systematically surveyed with the aim to understand their vulnerability to coastal landslides similar to or even larger than the recent one at Mylos Gialtron and design measures for the mitigation of their impact on the coastal societies. Detailed geological mapping along the broader, on- /offshore coastal zones is of outmost importance for the understanding of their morphology and sedimentary structure and the assessment of coastal landslide vulnerability.

Acknowledgements

The implementation of this two-phase survey has been possible thanks to the internal funding by the Institute of Oceanography of the Hellenic Centre for Marine Research and the assistance of the Major of Istiaia-Aidipsos Municipality and the Master of Aidipsos Harbor. Our colleagues M. Moschides and N. Nicolis, captain and engineer of R/V Alkyon, are greatly acknowledged for their continuous support and assistance during the marine survey.

Abstract

Late summer of 2024 an unusual raise of the seismic activity was observed inside the Caldera of Santorini Volcanic Complex. This was the first time since the 2011-2012 unrest period that increased seismicity was recorded inside the Santorini Caldera. Together with the raise of the seismicity, daily GNSS data from a permanent station in Imerovigli (station SANT) as well as two other operating stations in Santorini, exhibited change on the kinematic behavior of the Island. The typical SE directional motion of the SANT station (with respect to ITRF2014) observed the last decade was altered to a strong ENE motion. Moreover, increased uplift started taking place in the SANT station with a rate of almost 80mm/yr, an order of amplitude higher than the typical of 2-3 mm/yr of the last years. This kinematic motion could be explained by volcanic activity inside the caldera, modeled as a typical Mogi point source.

However, at the end of January 2025, almost 6 months after the initiation of the activity inside the caldera, there was an abrupt migration of the seismicity NE of Santorini, in the marine area between Thira and Amorgos Islands. During a period of almost a month (February 2025) intense seismic activity was recorded in the marine area around the islet of Anydros, located ~25km NE of Thira. Several seismic events of M>3 were recorded almost every day, during that period, with the larger event to be of M5.3. This intense seismicity was accompanied by strong ground deformation on the broad area of South Aegean. As was expected, the most intense ground deformation was observed in Thira Island and in Anydros Islet. However, the type of motion in SANT cGNSS station was of completely different type compare to the previous period (while the seismicity was located inside the Caldera). The SANT station showed a strong North motional component and intense subsidence. It has to be noticed that the daily amplitude of the ground deformation reached values up to 10mm/day during the peak of the seismic crisis (10-15 of February). Moreover, GNSS data from the surrounding islands, as is Ios and Naxos to the North of Thira exhibited changes in their kinematic behavior, highlighting the intense activity that was taking place in the marine area of Anydros Islet.

The strong ground deformation decreased around the end of February 2025, almost a month after its initiation. Since then, it appears that the rate of ground deformation has significantly decreased in both horizontal and vertical component. The decrease of ground displacement coincided with the decrease in the seismicity, that has been expressed not only with smaller number of events per day, but also and of smaller amplitude, with the events of ~M3 to be less than the previous one month long period.

A major issue during this crisis was the identification of the seismic activity; it was of volcanic or tectonic character / origin? In the complex environment of South Aegean, where the Santorini Volcanic complex is located, there is not an easy or unique answer to such issues. Major tectonic zones, as is the Amorgos area (with a history of strong earthquakes), volcanic centers as is the Kameni Islet and the submarine Kolubo volcano, create an extremely complex geological environment that requires a multidisciplinary approach in order to comprehend it. To better understand, explain and monitor the ongoing processes in the broad area of south Aegean the geodetic and seismological academic and research community of Greece took action establishing a dense network of continuous GNSS stations, as well as seismological stations. In this common effort several institutes from abroad also collaborate and joint efforts with the Greek institutes. The main scope of this effort is to achieve a better spatial coverage of the area, with permanent operating stations, and be able not only to monitor the daily progress of the deformation and seismological crisis but also to foresee its evolution. As result of this joint effort, it was the establishment, and/or

re-start of more the 20 permanent GNSS stations in the broad area of South Aegean Sea. The new GNSS stations that were established in the island of Thira, Thirasia, Ios, Amorgos, Anafi, Sikinos, and in the islets of Anydros and Christiana, together with the existing stations in the surrounding islands that were operated by other private entities (Hellenic Cadastre HEPOS, Metrica SA, JGC SA, TreeCompany SA,), together with new sites that were established by other international institutes in collaboration with the Greek ones (ie, CNRS - École Normale Supérieure - PSL, France, INGV, Instituto Nazionale di Geofisica e Vulcanologia, Italy) and with the support of Earthquake Planning and Protection Organization of Greece (EPPO) will provide on a continuous base all the necessary data in order to monitor this vital area of Greece, will help to better protect the local community and will also provide valuable insight on the geological processes that are taking place in the complex environment of Santorini Volcano, the broad area of South Aegean, as well as along the Hellenic Volcanic Arc. The daily GNSS data from all the operating stations are processed on a near real-time basis, using advanced algorithms, from all the participating institutions providing solutions and information not only for scientific use but also for operational use on the framework of the civil protection actions.

Acknowledgements
The authors would like to acknowledge the organization efforts of Dr. S. Lalexos on behalf of Earthquake Planning and Protection Organization of Greece. Daily GNSS raw (RINEX) data were contributed by: (1) The “Institute for the Study and Monitoring of Santorini Volcano” IMOSAV providing data from several GNSS stations in Thira, Thirasia and Nea Kameni (https://ismosav.gr/en/home/); (2) The Hellenic Positioning System (HEPOS) provides data from five stations in the south Aegean free of charge by the Hellenic Cadastre (www.ktimatologio.gr); (3) METRICA S.A. provides GNSS data from several stations located in the broad area of South Aegean (https://gr-sbc.nrtk.eu); (4) JGC Geoinformation Systems S.A. offers data from one permanent station in Thira (https://www.jgc.gr/jgc-net/) (5) TreeCompany and its GNSS network URANUS provides data from one station in Thira (https://uranus.gr/). Also, the authors acknowledge the contribution of Dr. P. Briole (from CNRS France) in order to establish new GNSS stations in the South Aegean area, as well as the establishment of GNSS sites from INGV (Instituto Nazionale di Geofisica e Vulcanologia, Italy).

EXTENDED ABSTRACT 278

Ground Deformation in Nisyros Volcano (Greece) Determined by GPS and SAR Interferometric Techniques

Sakkas V.[1], Tzanis A.[1], Lagios E.[1]
(1) Geophysics Laboratory, Department of Geology and Geoenvironment, National and Kapodistrian University of Athens, Greece, vsakkas@geol.uoa.gr

Introduction

The southeastern part of the Hellenic Volcanic Arc (HVA), including Kos, Yali and Nisyros islands, is geodynamically very active (Figure 1). Intense seismic activity occurred on Nisyros Island during 1996-1998, accompanied with strong ground deformation and temperature increase of the fumaroles. Nisyros Island lies above a basement of Mesozoic limestone (Geotermica Italiana 1983; 1984). The exposed rocks are Quaternary volcanics. The evolution of Nisyros Volcano during the past 160,000 years, together with the succession of calc-alkaline lavas and pyroclastic rocks, has been studied in detail by various authors (ie Hardimann 1999; Tibaldi et al. 2008).
Major fault systems have been identified within the volcanic edifices of the Kos-Yali-Nisyros Volcanic Field (Figure 1) on the basis of structural and geological investigations (ie Papanikolaou and Nomikou 2001; Nomikou and Papanikolaou 2011). The caldera's rim and its accompanying cone-shaped local faults are entirely volcanic structures, which are a result of the collapsing of the caldera after the last Plinian eruptions.

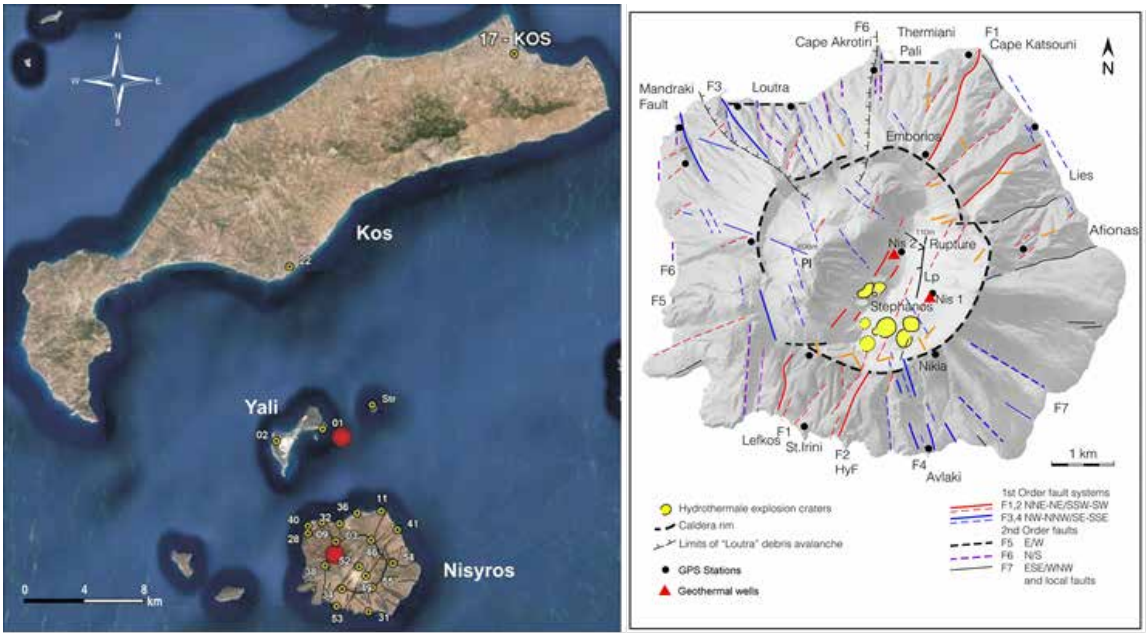

Figure 1. Left part: Distribution of stations of the GPS network of the Kos-Yali-Nisyros Volcanic Field. Solid red circles represent the two modelled Mogi point sources. Str stands for the station established on Strongyli Islet). Right part: Fault pattern of major faulting systems (F1 to F7), location of hydrothermal explosion craters and other significant features superimposed on a digital elevation model of Nisyros Island. Abbreviations of locations; PI: Prophitis Elias, Lp: Lakki Plain.

Earthquakes have been described throughout historical times as has been reported in detail since 1830 (Gorceix 1873a, b and c; Stiros and Vougioukalakis 1996). Their origin may be a result of regional tectonic processes, magma ascent, degassing phenomena of deep crustal magma and steam explosions within the hydrothermal system. The Mandraki Fault (Figure 1) that comprises a branch of the F3 fault system was reactivated in 1996 (Lagios et al. 2005) and caused damage to buildings and other structures within Mandraki (Ioannidis 1998). Tectonic processes expressed by the latest seismicity indicate tensional fracturing (Makris and Chonia 1999) which could reduce the lithostatic pressure and trigger explosive volcanic phenomena, such as those reported in 1871 and 1873 by Gorceix (1873a). The most recent seismic activity in the area was in 2017 with a strong earthquake (Mw6.2; Jul. 20, 2017) taking place NE of Kos Island (Ganas et al., 2019). Moreover, increased seismicity occurred during Jun-August 2021, in the marine area SW of Nisyros. Both these bursts of seismicity were of tectonic character and have not been

associated with volcanic activity.
Efforts for studying the ground deformation on Nisyros started after the outbreak of the seismic activity in 1996 and have involved GPS observations and SAR interferometric analysis (e.g. Lagios et al. 2005;). This study presents the ground deformation on Nisyros up to 2023 and addresses its evolution during the years 2002-2023 on the basis of combined GPS/GNSS and advanced SAR interferometric techniques.

GPS/GNSS Measurements

A geodetic GPS network (Figure1) was established in the broader area of Nisyros in June 1997 in order to study ground deformation. It initially consisted of 21 stations and included a local reference station (17-Kos) at the northeastern part of Kos Island (Lagios et al. 2005). Another station (benchmark) was installed on Strongyli Islet in 2013. Moreover, a continuous operating GNSS station was established in Mandraki in November 2016, as well two more continuous station were established in 2023 in Nikia and Yali. Campaign measurements were performed in periodic times, with the last measuring period to be December 2023. All campaigns were made in the static mode using tripods cantered above the permanently installed benchmark at a given station. Post-processing was performed using the Bernese GNSS Software, versions 5.2 (Dach et al. 2015), together with post-computed satellite orbits (available through the International GNSS Service) to improve the error estimation. Accuracies of 2 to 5mm and 4 to 8 mm were achieved for the horizontal and vertical components, respectively.
The GPS measurements during the active period (1997-1999) showed that the amplitude of the horizontal deformation ranged from 20 to 60 mm. The maximum horizontal displacement occurred between 1997 and 1998 during the peaking (1997) and subsequent high level (1998) of seismic activity. The period 1999-2002 Nisyros entered a different mode of deformation with a clear westward in-crease of the horizontal component in almost all its western part for the period 2001-2002. Vertical deformation in the sense of a general uplift of the whole island occurred over almost the entire active period of observation up to 2002, and in particular the majority of stations exhibited uplifts of 40 to 60 mm between 1997 and 1998. Greater values of uplift were measured at stations installed on the western uplifted side of the activated Mandraki Fault.
The GPS network on Nisyros after 2002 was remeasured in August 2012, which was a decade after its establishment. Through this decade (2002-2012), there was no significant seismic activity in the broader area, nor was there any other type of volcanic activity as would be detected via temperature increase in the fumaroles. It may thus be assumed that the ground deformation that occurred in the island was of an almost linear character without any strong fluctuations. After 2012, the network was re-measured more often, in total eight times up to 2023, deducing a more accurate velocity field of the area (Figure 2).

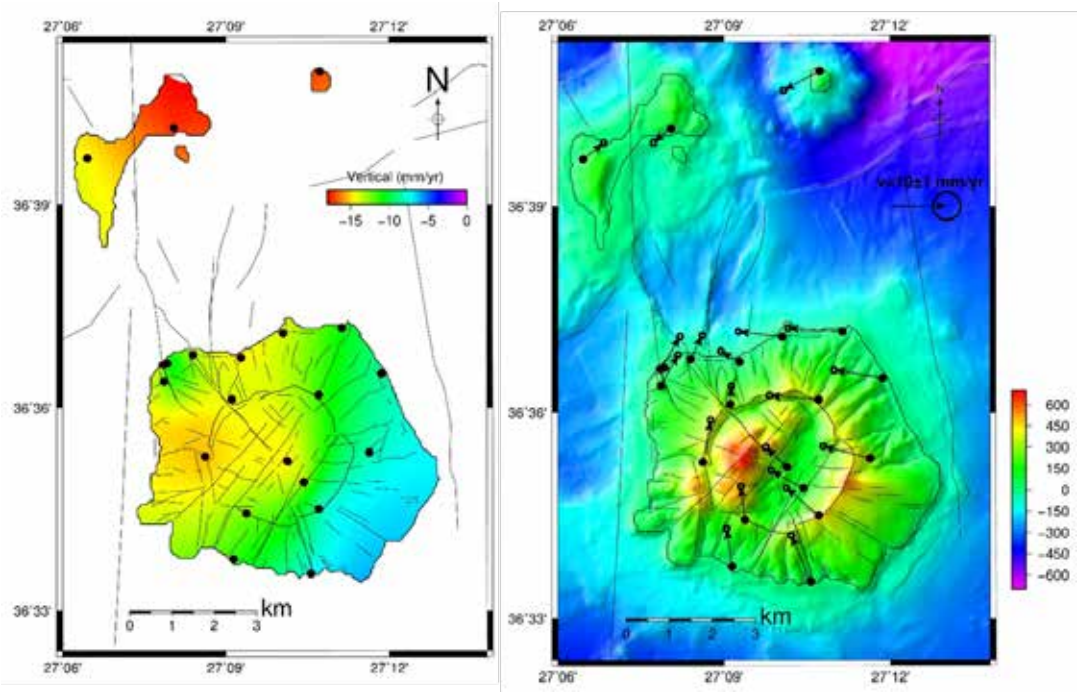

Figure 2. Vertical (left panel) and horizontal (right panel) deformation on Yali-Nisyros for the period 2002-2023 (relative to ITRF2014 reference frame, subtracting the regional motion of the area).

As can be seen on the velocity map for the period 2002-2023 (Figure 2), the most prominent aspect of ground deformation is the subsidence that took place in Nisyros and Yali during this ,ore than 20 years period. The subsidence reached values of more than 10mm/yr in the northern part of Nisyros, but with smaller values (~3-5 mm/yr.) in the southern and eastern parts. The horizontal velocity vectors of the stations located on the NE had motion to the SW, while the stations on the NW exhibited motion to the ENE. The amplitudes of the horizontal velocity vectors are slightly higher for the stations at the northeastern part (~9 mm/yr.) as compared to the northwestern part (~5 mm/yr.). The two GPS stations located in Lakki Plain also subsided. Generally, it should be noticed that the stations located outside the caldera's rim had exhibited stronger deformation as compared to those located inside the rim for both horizontal and vertical components. The nearly opposite direction of horizontal motion that is observed for the stations located at the eastern and western parts of Nisyros may be due to the strong subsidence which had taken place at its northern and central parts during this period, thus forcing the facing eastern and western flanks of the island to 'collapse' towards its centre which produced the observed westward and eastward horizontal motions, respectively.
Significant subsidence (~8 mm/yr.) had also occurred in Yali islet. The horizontal velocity components of the two stations, located on the extreme eastern and western parts, have similar amplitudes (~8 mm/yr.) and clearly point towards the central area of the islet. It is concluded that strong subsidence likely occurred in the region between Yali and Nisyros which caused the two edges of the islet to converge toward this area, consistent with the deformational pattern observed at those two stations.

SAR Interferometry

Conventional Synthetic Aperture Radar (SAR) Interferometry (InSAR) and GPS measurements are the most widely used techniques to measure the ground deformation in volcanoes. For the period 2003-2010 ASAR ENVISAT images were processed in ascending and descending orbital geometry using the SqueeSAR™ Technique. Based on this technique Line of Sight (LOS) velocity maps were produced (Figure 3).

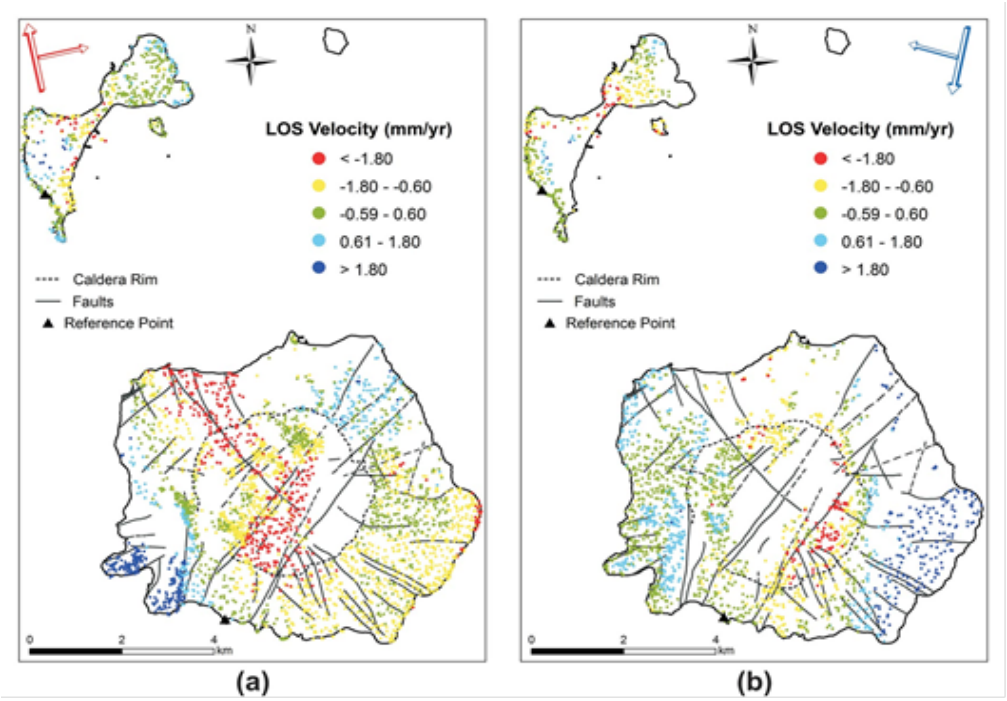

Figure 3. LOS Velocity Field deduced from the SqueeSARTM for Ascending (left panel), and Descending (right panel) orbital geometries, for the period 2003-2010. Red and blue arrows indicate the orbit and acquisition directions for the ascending and the descending data sets, respectively.

Greater negative LOS velocities (~2.5 mm/yr) are observed along the F3 faulting system and between F1 and F2 faulting zones inside the caldera in the ascending image. These values are not observed in the descending image. The western part of Nisyros and west of the caldera's rim show similar velocities for both images, ranging from relatively stable to slightly positive values (~1.5 mm/yr). The greatest LOS velocities (1.8 to 3.0 mm/yr) are observed in the ascending image near the two small peninsulas at the extreme southwestern part, bounded by F1 and F6 faulting systems. The southeastern part of Nisyros shows small negative LOS velocities (~-1.5 mm/yr) in the ascending

image and positive values (up to 2 mm/yr) in the descending image, indicating an eastward component of ground deformation during 2003-2010. The northeastern part of Nisyros has positive LOS velocities (0.6 to 1.8 mm/yr) on both images, with an inconsistent pattern of ground deformation in the northern part due to dense vegetation. The Yali islet shows no consistent deformation pattern between acquisition geometries, except in the northeastern part with relatively stable to small negative LOS velocities. Differential motion between the northeastern and southwestern parts may be due to differing geological characteristics: obsidian in the northeast and pumices in the southwest.
For the period 2018-2022 interferometric results were obtained by the European Ground Motion Service (EGMS, https://egms.land.copernicus.eu/). The data of Ascending and Descending orbital geometries were initially calibrated using the permanent station in Mandraki, and then decomposed on East-West and Vertical component (Figure 4).
To perform the calibration of the InSAR data in the island the velocity vector of the continuous operating GNSS station NISY has been taken into consideration. Initially, the GNSS velocity vector was estimated for the time period that the EGMS product covered, and it was projected into the LOS direction, for both ascending and descending orbital geometries. As a second step, from the EGMS products the LOS velocity vector in both geometries for the “Data Points” located close to GNSS station were compared to the GNSS projected LOS vector, and the difference between the GNSS LOS projected vector and the InSAR LOS vector was estimated. Finally, the difference was “added” to the rest of the “Data Points” to obtain the GNSS calibrated LOS velocity fields. The new calibrated LOS velocity maps on both geometries were combined in order to decompose the LOS vector into the Vertical and the East-West components.

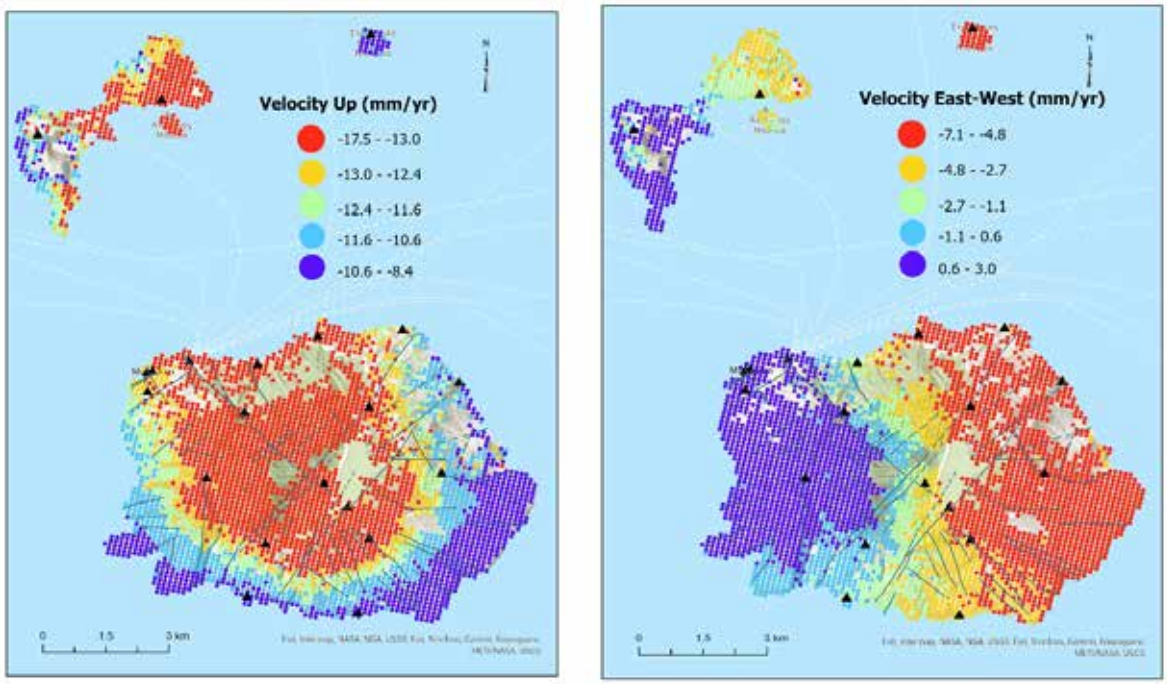

Figure 4. Vertical (left panel) and East-West (right panel) velocity field calibrated using the continuous GNSS station in Mandraki area.

The local calibrated and decomposed EGMS interferometric product show small velocities values for both components, indicative of linear type of deformation. The vertical velocity field highlights and confirm the velocity field deduced by the GPS technique, showing intense subsiding motion in the central and northern part of island (up to -17 mm/yr), but smaller subsidence in the southern Nisyros. The East-West component also clearly depicts the diametrical opposition between the eastern and western part of Nisyros and Yali. The western part exhibits positive velocity values, consistent to eastward motion, while the eastern flanks show negative velocities, indicative of westward motions. A feature that rises observing the East-West velocity field is that changes on the sign of motion coincide with the main tectonic zones that cross-cut the island.

Discussion

During the “unrest” period from 1996 to 2000, strong ground non-linear deformation was observed, which was explained using a model that included two MOGI Point Sources: one offshore and one inland. Interferometric results

(SqueeSAR™) for the subsequent period from 2003 to 2010 showed linear deformation along major faulting zones that cross-cut the island. This deformation included a significant vertical component (subsidence) mainly in the central and northern parts, and a considerable horizontal component in the eastern, western, and southeastern parts. Differential GPS measurements for the period from 2002 to 2023, and interferometric products for the period 2018-2022 indicated intense subsidence at all stations, with a horizontal component pointing towards the central part of Nisyros. The observed deformation may be explained as a result of combined volcanic and tectonic activity, including a decrease in pressure in the possible magma chambers beneath and offshore of Nisyros Island, and possible tectonic motions along the trough offshore north of Nisyros and south of Yali Islet. Notably, there was an absence of any significant shallow seismic activity during the period from 2002 to 2023 in the vicinity of Nisyros.

Acknowledgements

SqueeSAR™ processing was performed by TRE company. Part of this research was supported by the project “Provision of services regarding the implementation of an integrated solution for the continuous and necessary microseismic monitoring of the island of Nisyros, with emphasis on the area of Agia Irini, highlighting the parameters required for geothermal projects” funded by the Public Power Corporation Renewables SA (PPCR) (Special Account for Research Grants of NKUA, project).

EXTENDED ABSTRACT 279

Comparison of dermal bioaccessibility of Cu, Pb, and Hg between modern and ancient cosmetics

Samothraki M-I.[1], Kypritidou Z.[1], Argyraki A.[1]

(1) Department of Geology and Geoenvironment, National and Kapodistrian University of Athens, Panepistimiopolis, Zographou, 15784, Athens, Greece

Introduction

This research highlights the severe health risk that the ancient populations faced by applying raw minerals as cosmetics on a daily basis, following the risk assessment methodology used in modern cosmetics.

In each century, facial cosmetics fulfilled a specific purpose. Since ancient times, the use of cosmetics has been a way of making a statement, an element of culture, as well as an example of scientific development in the field of health. Both men and women in ancient Egypt, Greece and Rome (14th century BCE) used cosmetics not only during religious rituals, but as a daily-care routine to show their social status and prestige. Black-coloured eyeliners were the most common facial cosmetics, which were produced by grinding galena or stibnite (Murube J., 2013, Perez-Arantegui J., 2021). Green, grey, white, red and bluish eyeshadows were prepared by malachite, galena, cerussite, and chryssocolla powders, respectively (Murube J., 2013). Red ochre, cinnabar and minium were used to blush their cheeks. Cerussite and white marl were often used as skin whiteners.

It is reported that cerussite and cinnabar were used until the 16th century BCE by royalty as skin whiteners, lipsticks, and blush (McMullen & Dell'Acqua, 2023; Welcomme *et al*., 2006). However, these natural cosmetics consist of highly toxic elements such as Pb, Sb, Cu, As and Hg, causing serious health effects in ancient populations (Olson K., 2009). Anemia, neurological disorders, kidney failure, liver damage, miscarriage and cancer, are some of the health impacts induced upon ingestion or inhalation of mineral dust containing the above elements. However, references regarding the effects of dermal exposure to these elements (except for exema) and their bioaccessibility through the skin, are scarce.

The aim of this study was the comparison of the potential dermal bioaccessibility of Pb, Cu and Hg contained in ore minerals (such as those used in antiquity) and modern cosmetics. The specific objectives of the study were the determination of: (a) the pseudo-total and sweat extractable elemental concentration, (b) the bioaccessible metal content, and (c) the examination of the systematic exposure and hazard from these elements, in both minerals and cosmetics.

Materials and Methods

Four minerals and the respective commercial cosmetics were selected and studied for their dermal bioaccessible content of toxic elements. The selected minerals include galena, cerussite, malachite, and cinnabar, which were used as eyeliner, foundation, eyeshadow, and blush respectively. By analogy to these minerals, the respective modern cosmetics include foundation, blush, eyeliner, and eyeshadow, purchased from local stores (Table 1). The mineralogical composition of the samples (minerals and cosmetics) was examined through X-ray Diffraction spectroscopy in randomly oriented mounts, from 3-65^{o} 2-theta, with a scanning rate 1^{o}/min (Cuka radiation, 40kV, 40mA, SIEMENS D5000).

Table 1. The associated minerals and cosmetics, and the respective analyzed element of the current study

Mineral	Modern cosmetics	Associated element
Galena	Eyeliner	Pb
Cerussite	Foundation	Pb
Malachite	Eyeshadow	Cu
Cinnabar	Blush	Hg

The pseudo-total elemental composition of minerals and cosmetics was identified by aqua regia digestion. Specifically, about 0.1g of mineral or 1g of cosmetic powders were digested in 1:3.5 HNO3:HCl mixture, for 2hrs in a sandbath (~110^{o}C) following the procedure as described by Irfan *et al.* (2022). The dermal bioaccessible elemental concentrations were determined by extracting the solids with an artificial sweat solution. The extraction solution was composed of 0.5% NaCl, 0.1% urea and 0.1% lactic acid according to EN 1811:2023. The pH 6.5 was adjusted by drops of NH_3. About 0.4g of solid was dispersed in 40ml solution following the assumption that the solid/sweat ratio that is deposited on the face daily is 1mg/0.1ml per skin surface area (Anselm et al., 2022). The suspensions were mixed for 2 hours in the thermal chamber under the constant temperature of 37 Celsius (similar to the human body). Then, followed centrifugation for 5 minutes. Due to the high concentrations level, the aqua regia samples were diluted by 1: 10 ml ratio of sample and 2% HNO_3, whereas, dermal samples were diluted by 1:10 ml ratio of dermal sample and half of the amount of sweat solution with 2% HNO_3. Each sample (mineral and cosmetic) was analyzed in dublicates, and the mean and relative percent difference were calculated. Blanks were also included in each analytical batch. The

extracted solutions were stored at 4°C prior to analysis with F-AAS and ICP-MS, for Pb, Cu, and Hg.
The dermal bioaccessibility of Pb, Cu, and Hg (D_{dermal}, %) from each mineral and/or cosmetic was calculated by dividing the sweat extracted concentration (C_{sweat}, mg/kg) with the pseudo-total concentration (C_{AR}, mg/kg) obtained by aqua regia digestion (Eq 1):

$$D_{dermal}(\%) = \frac{C_{sweat}}{C_{AR}} \times 100 \qquad \text{(Eq. 1)}$$

The systematic exposure dose (SED, mg/kg bw/d) of each element from minerals and cosmetics was calculated according to the European Scientific Committee on Consumer Safety (SCCS, 2023) (Eq. 2):

$$SED = \frac{E_{prod}}{BW} \times \frac{C}{100} \times \frac{D_{abs}}{100} \qquad \text{(Eq. 2)}$$

where E_{prod} is the effective exposure per product (mg/kg/d), BW is the body weight of the consumer (60 kg), C is the elemental concentration (%wt) in the product, and Dabs is the dermal absorption factor (%). E_{prod} values were 0.005 for galena/eyeliner, 0.51 for cerussite/foundation, 0.02 for malachite/eyeshadow and cinnabar/blush, and 0.4 for orpiment/waxing cream respectively (SCCS, 2023).
The risk to human health by application of minerals and modern cosmetics onto the skin on a daily basis, was assessed by calculating the Hazard Quotent (HQ) for each element as (Eq. 3):

$$HQ = \frac{SED}{RfD} \qquad \text{(Eq. 3)}$$

Where RfD is the reference dermal dose for each element. The established RfD for Pb, Cu, and Hg are $1.6*10^{-4}$, $5*10^{-1}$, and $2.3*10^{-4}$ mg/kg bw (Irfan *et al.*, 2022). The sum of HQ for minerals and cosmetics defines the Hazard Index (HI), with an accepted value less than one, when no hazard is induced.

Results & Discussion

The mineralogical analysis of minerals revealed that cerussite and malachite were free of impurities, whereas cinnabar contained minor quartz and galena traces of wurtzite (Fig. 1a). The examined cosmetics (blush, foundation, eyeshadow) consisted mainly of talc, kaolinite and micas. Blush contained also chlorite, smectite and anorthite, whereas the foundation contained zincite and anatase (Fig. 1b).
The pseudo-total elemental concentrations in minerals range from 11.3% wt Hg in cinnabar to 47%wt Pb in cerussite (Fig. 2a), exceeding by far the EU limits for metals in cosmetics (2 mg/kg Pb and 0.1 mg/kg Hg). The respective concentrations in cosmetics range from 6.4 mg/kg Hg in blush to 134 mg/kg Pb in eyeliner, also exceeding the regulatory values.

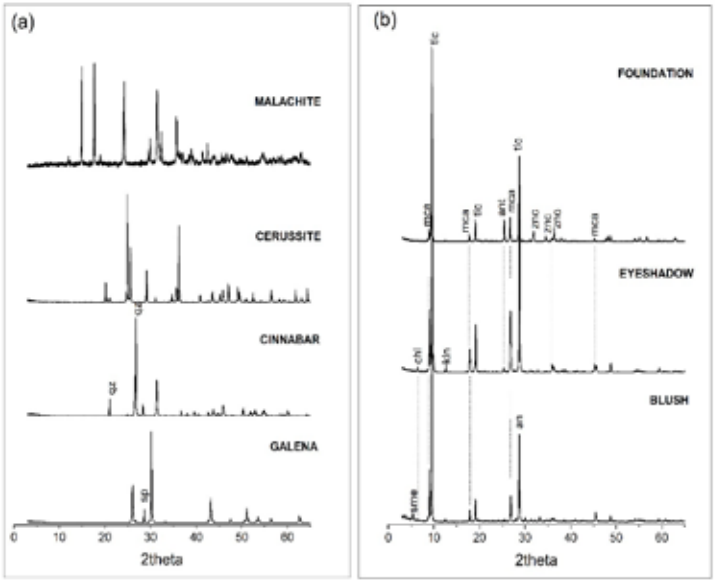

Figure 1. XRD patterns of minerals and cosmetics. The non-annotated peaks in (a) are assigned to the corresponding main mineral phases (i.e. galena, cerussite, cinnabar and malachite). Mineral symbols after IMA (Warr, 2021) (anorthite (an), anatase (ant), chlorite (chl), kaolinite (kln), mica (mca), talc (tlc), quartz (qz), smectite (sme), sphalerite (sp), zincite (znc))

The elemental concentrations extracted by the artificial sweat are much lower in minerals, showing a relative stability to dissolution (Fig. 2b). Particularly, the sweat-extracted concentrations range from 78 mg/kg Hg in cinnabar to 2299 mg/kg Pb in cerussite. The dermal bioaccessibility of minerals is less than 2%. The respective sweat-extracted concentrations in cosmetics range between 0.5 mg/kg Hg in blush and 108 mg/kg Pb in eyeliner. However, the dermal bioaccessibility of the elements is high, following the order: Cu (eyeshadow, 100%)> Pb (eyeliner, 81%)>Pb (foundation, 67%)>Hg (blush, 7%). This shows that, although the sweat extracted concentrations in cosmetics are much lower compared to minerals, they are readily bioaccessible. This is explained by the fact that these elements are bound onto the clay surfaces of cosmetics (smectite, micas) and are easily exchanged by sodium (the major cation in sweat solution).

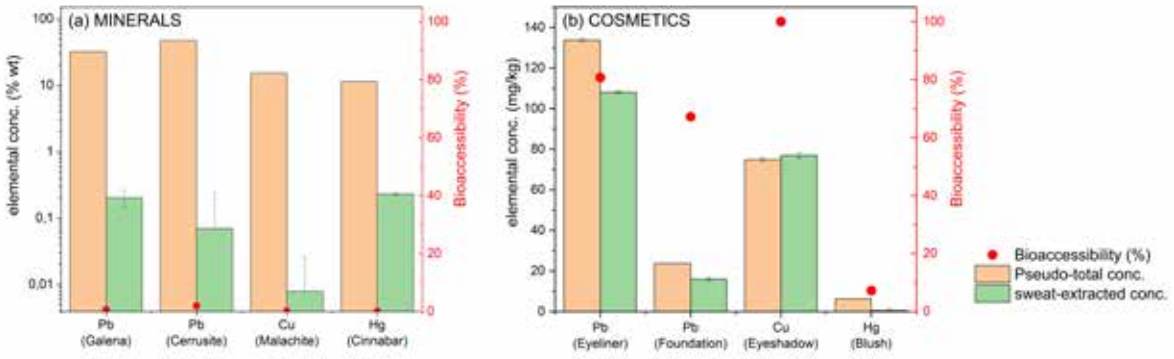

Figure 2. Pseudo-total and sweat extracted concentrations of Pb, Cu, Hg and As from (a) minerals and (b) cosmetics, and their bioaccesibilities

The exposure of consumers to various ingredients contained in cosmetics is assessed based on the systematic exposure dose (SED) as established by SCCS (2023). The SED values for Pb, Cu and Hg were calculated for both minerals and cosmetics, by examining two bioaccessibility scenarios. The first (worst case) scenario assumed that 100% of the pseudo-total concentration of each element is bioaccessible (D_{abs}=100%), whereas the second scenario assumed that only the sweat-extracted elemental concentrations are bioaccessible (D_{abs}=D_{dermal}%). The obtained SED values are given in Table 2.

Table 2. SED values (mg/kg bw/d) as calculated for each element contained in minerals and cosmetics for the two bioaccessibility scenarios

Element	Mineral	D_{abs}=100%	D_{abs}=D_{dermal}%
Pb	Galena	$2,68*10^{-2}$	$1,68*10^{-4}$
Pb	Cerussite	$9,61*10^{-1}$	$1,95*10^{-2}$
Cu	Malachite	$1,57*10^{-1}$	$2,32*10^{-4}$
Hg	Cinnabar	$5,09*10^{-2}$	$2,62*10^{-5}$

Element	Cosmetic	D_{abs}=100%	D_{abs}=D_{dermal}%
Pb	Eyeliner	$1,12*10^{-5}$	$9,00*10^{-6}$
Pb	Foundation	$2,02*10^{-4}$	$1,36*10^{-4}$
Cu	Eyeshadow	$2,49*10^{-5}$	$2,57*10^{-5}$
Hg	Blush	$2,13*10^{-6}$	$1,67*10^{-7}$

As expected, the SED values elements in minerals are much higher than those in cosmetics. The 100% bioaccessibility scenario gives the highest SED values especially for minerals. However, these cosmetics (ancient and modern ones) are applied together onto the face skin on a daily basis, therefore a cumulative systematic exposure should also be calculated. The cumulative SED value ranged from 0.02 to 1.2 mg/kg bw/d in minerals, and $1.7*10^{-4}$ to $2.4*10^{-4}$ mg/kg

bw/d in cosmetics. It is evident that the ancient populations were systematically exposed in high metal concentrations compared to today on a daily basis by applying the raw minerals onto their faces.

The Hazard Quotent and the Hazard Index (HI) for minerals and cosmetics were also calculated for each element in each bioaccessibility scenario. Specifically, at the 100% bioaccessibility scenario the HI for minerals is 2700, whereas for cosmetics 0.16. Additionally, when the dermal bioaccessibility is considered as the exposure scenario, the HI for minerals is 6.22 and for cosmetics 0.05. In either case the HI values of minerals is much higher than 1, implying that the high hazard due to application of ancient cosmetics.

In the 100% bioaccessibility scenario, Hg is the most hazardous element, contributing 63.7% and 89.8% to the total hazard in ancient and modern cosmetics respectively (Fig. 3). On the contrary, when dermal bioaccessibility is considered, Pb is the more hazardous element, contributing over 70% in total HI. This shows that, although Hg is more toxic and carcinogenous, it is less hazardous due to its lower penetration through the skin. It is documented that, among the mercuric substances, cinnabar is insoluble in water with low oral bioaccessibility (~0.2%) (Liu et al., 2009). Moreover, studies on dermal contact between cinnabar-rich sands and workers, showed that Hg was not bioaccessible through skin (Cegolon et al., 2022). However, Pb has high bioaccessibility, explaining the various health effects induced during ancient times. Among lead compounds, lead released from cerussite is more bioavailable than from galena, due to its higher solubility. Considering that cerussite is more easily dissolved and applied as a foundation in a larger surface area, the expected health impacts are more severe, compared to the other elements.

Figure 3. Contribution of each element to the total HI obtained by applying minerals and modern cosmetics, in the two bioaccessibility scenarios

Conclusions

Minerals have been extensively used as cosmetics from ancient times since the 16th century BCE, due to their variety of colours, such as galena, cerussite, cinnabar and malachite. However, these phases are primary ore minerals for the extraction of Pb, Cu and Hg, elements of high toxicity for living organisms. Although numerous in vitro and in vivo toxicological studies have been carried out regarding the bioaccessibility of these elements, most of them involve artificial organic compounds (mostly present in commercial products) with different physicochemical properties compared to natural mineral phases. Moreover, these studies refer to bioaccessibility due to inhalation and/or ingestion of these compounds, which is much higher compared to the penetration through skin. In this study we tried to assess the bioaccessibility of elements contained in ancient cosmetics following the risk assessment procedure of modern cosmetics. The results indicate that the ancient populations were exposed to severe health risk due to the application of raw minerals onto their skin on a daily basis.

Research Highlights

This project constitutes the first systematic documentation of Greece's water resources, with a focus on both qualitative and quantitative groundwater characteristics.
The project data, combined with the Daniel storm in the Thessaly Region, demonstrated its contribution to aquifer management in the affected area and to mitigating the impacts of severe weather.

Introduction

Water is a heritage that must be protected. Both internationally and in Greece, the pressures on water resources are increasing, because of the growing demand from various users for sufficient quantity and quality of water.
Boreholes constitute a critical parameter in the management of water resources, particularly groundwater. The large number of boreholes as well as uncontrolled abstractions have created and accumulated several problems of mismanagement, either in the form of salinization of coastal aquifers or depletion of aquifers. The extensive operation of boreholes in Greece, many of which remain undeclared, significantly affects water balance calculations, the quantitative assessment of groundwater systems, and the evaluation of water usage and needs.
The SAMY Project is carried out by the Hellenic Survey of Geology and Mineral Exploration (H.S.G.M.E.). Project main activities in Greek Territory are: (a) borehole inventory by recording drilling technical data and on-line measurements, (b) database production based to all recorded data and (c) groundwater abstraction related to groundwater resources in ground water bodies. During fieldwork, data recording includes geographical coordinates, operational status, and technical borehole characteristics (depth, drill hole diameter, casing diameter, and pump type). Also, borehole usage such as irrigation, drinking water, stock farming are basic features of recording data with details of pumping.
Based on inventory data final reports are drawn up for all Ground Water Systems in the field including also geomorphological, geological, hydrogeological conditions, land use area, statistics with processing of all recording raw data, drawing water estimation and aquifer water balance.
The result of the inventory program with the systematic counting of boreholes in all the Ground Water Systems (GWS) and the recording of the extractable quantities of water, contributed to the effective implementation of the Water Framework Directive 60/2000, but also to the formulation, implementation and control of policies (water saving, programs of measures, etc.) concerning the rational management of water resources.
The annual volume of groundwater which is used from an aquifer system is one of the two basic factors of the 'equation' required to achieve its rational exploitation in each case. The other factor concerns the recording and mapping of the hydrogeological and hydrological characteristics of a groundwater table, some of which require a "one-time" recording and mapping, such as geological and hydrolithological structures. The establishment of such an information platform, alongside the development of an institutional mechanism for continuous data updating, is essential for effective groundwater management.

Materials and Methods

This study represents the first systematic documentation of water resources in Greece. The program created an extensive database far beyond that of the hydrogeological management of the country's groundwater systems, such as: irrigation needs in different areas for the same crops, energy costs for the same pumping quantities but from different depths in the various rural areas, etc.
A total of 108,092 boreholes of various uses were inventoried and the information collected for this project is:

- geographical and topographic data of the project location
- data of the owner and user of the project
- data of the use of the project (duration, water supplies, type of use)
- hydrological data (average precipitation of at least 20 years, and evapotranspiration), utilizing the information of the 3rd Community Support Framework (CSF) Program of the H.S.G.M.E, which was implemented in all water compartments simultaneously during the period 2006-2012)

- on-site data of the technical characteristics of the boreholes, in particular with regard to the depth of borehole and extraction, duration of extraction / year, yields / hour
- physicochemical data of water (conductivity, temperature, pH)

The high density of collected data, particularly in plains with a significant number of boreholes, facilitated both precise estimations of annual and peak-period water consumption and the detailed analysis of specific hydrogeological parameters. The detailed mapping whose information may be useful beyond hydrogeology.

The methodology for processing large-scale aquifer data included: (a) aquifer system delineation based on Management Plan boundaries, (b) assessment of infiltration and evapotranspiration parameters, and (c) analysis of meteorological data spanning at least 20 years.

For the compilation of the maps, the same methodology was followed in terms of processing the measurements in "non-pumping" conditions and not in dynamic conditions. This is because, as is known, for example, both the level and the conductivity can vary significantly in pumping conditions, resulting in the mapping presenting irregular local variations.

The collection of annual groundwater consumption data and withdrawal rates facilitated not only the total volume estimation but also the assessment of the groundwater systems' overall transfer capacity during the same period. The Project provided important hydrogeological information regarding the supply capacities of a groundwater system or a large part of it is under universal intensive exploitation, as occurs during the period when irrigation is at its peak. During this period and in whatever groundwater systems the inventory work was in progress, it became possible to capture the dynamic salinization conditions in coastal groundwater systems with an "open" hydraulic front to the sea, as well as the overall dynamic retreat of the hydrostatic level.

Results and discussion

The project's results support the General Directorate of Water of the Ministry of Environment & Energy in strengthening national water policy, ensuring both water quality and quantity while aligning with EU Directives (60/2000/EC, 118/2006/EC, and 91/676/EEC).

The total number of recorded boreholes is 108,092. Also, the technical reports include statistical analysis and processing to draw conclusions on all basic parameters as they arise from the registration of the inventory forms, the recording of all parameters on thematic maps and the assessment of the water balance components with the characterization of the Ground Water System (G.W.S.) as Surplus or Deficit. From the preparation of the Technical Reports, it emerged that the large G.W.S. that concentrate the largest number of active boreholes are characterized as deficient.

Figure 1. The total of boreholes in Greece by SAMY Project.

SAMY and DANIEL storm

Following the devastating DANIEL storm, the SAMY Project played a key role in identifying water points within the flooded areas and monitoring underground aquifers in the Thessaly Region. During the SAMY Project, more than 21,894 boreholes have been recorded in Thessaly Region.

Based on the boundaries of the flooded areas of the DANIEL storm (as produced by the Copernicus program - 11/09/2023) and the data of the SAMY, the following results emerge:

- Within the boundaries of the flooded areas, 4,452 boreholes are located, which correspond to approximately 20% of the total boreholes in Region Thessaly.
- More specifically, within the flooded areas, the rate of 87.1% (3,876 boreholes) are active and main use for irrigation, 12.1% (539 boreholes) are inactive/unexploded, 0.5% (22 boreholes) for domestic water 0.3% (15 boreholes) for livestock water and 297 abandoned boreholes have been inventoried.
-

Table 1. Number of boreholes in Thessaly Region

Municipality	Boreholes	Flood zone	Boreholes
Sofades	1,160	Larisa- Stefanovikeio	843
Palama	1,060		
Larisa	383	Trikala – Karditsa - Palamas	3,617
Trikaion	345		
Farsala	299		
Kileler	281		
Farkadonas	186		
Tirnavos	183		
Tempi	181		
Dokomos	173		
Riga Feraioy	61		
Mouzaki	120		
Karditsa	20		

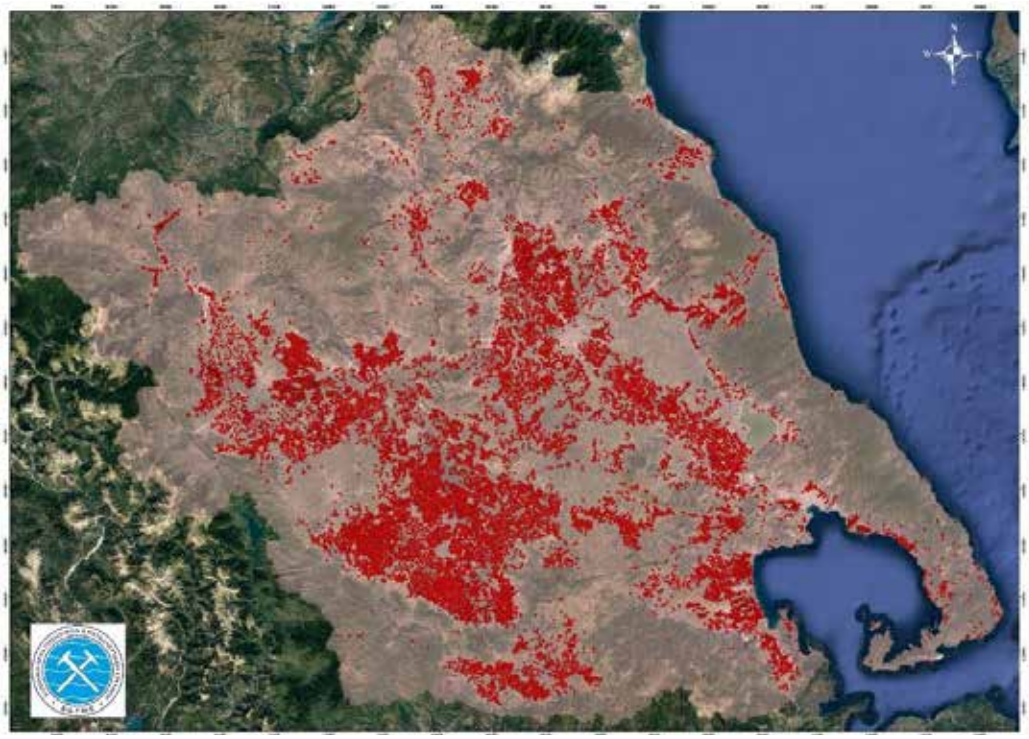

Figure 2. Boreholes in Thessaly aquifer

The functionality of the boreholes located within the flooded areas may have been affected to a very large extent due to the reverse infiltration of water and the subsequent deposition of fine clay material (mud) within the permanent piping of the boreholes, resulting in the non-functionality of the filter pipes and submersible pumping units due to blockage (clogging). Extensive damage is also expected to the accompanying facilities such as sheds, electrical supply panels, pumping units, etc.

Table 2. Number of each use and operational function of boreholes in Thessaly Region

Operational function	Boreholes	Main Use	Boreholes
Active	3,921	Irrigation	3,876
Unexploited	297	Domestic water	22
Inactive	242	Livestock uses	15
		Industrial use	8

Also, from the total available quantities in the entire Water District of Thessaly, it emerged that approximately 90% is used to cover irrigation needs, 6.7% for livestock farming, 1.6% for water supply and 1.7% for industrial and other use.

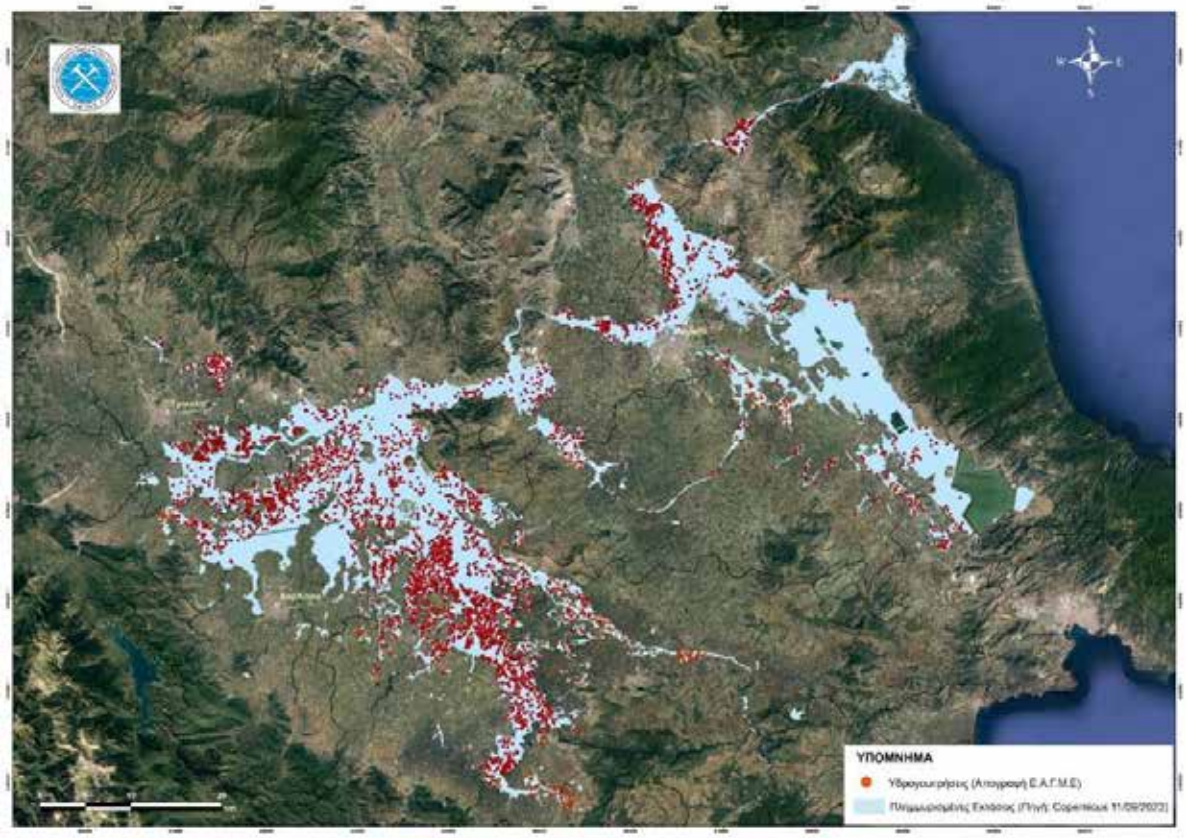

Figure 3. Borehole distribution and flooded areas in the Thessaly Region

Conclusions

This study presents an overview of Greece's water resources. The SAMY Project is a key tool in the effective management of water abstraction and the protection of groundwater systems from over-pumping. The volume of water abstraction is an important parameter for the calculation of water balances, helping to assess the status of Groundwater Systems and the pressures they are exposed to take appropriate measures, as well as to achieve the goal of their rational management. For the first time, we integrate temporal and spatial groundwater data with geological, hydrogeological, land use, and other relevant information to provide a comprehensive analysis. Our key findings are:

- Rational management of the country's water resources and thereby ensuring sustainable development,

benefiting the entire population of the country. This will significantly contribute to the correct decision-making on water resources management by the competent decision-making centers.

- Achieving social consensus and citizen support, allowing them to understand the importance of the entire project by helping to collect data, as well as the benefits that will arise with a direct impact on productive and social life.
- Informing local communities, through a mechanism that will promote dialogue, to learn about the possibilities of the Aquifer System from which they are supplied and thus have knowledge about the possibilities of its exploitation, or even the need to contain and protect the reserves. In both cases there is a social benefit for the integrated and sustainable management of water systems.
- Approval of a strategic plan for the exploitation of the country's water resources by implementing specific actions, to ensure the needs of society and the economy for sustainable water, while at the same time raising awareness among citizens and making them stakeholders in the rational management of available water resources.
- Provision of the National Water Abstraction Register with points/data that will result from the implementation of this project in accordance with Directives 60/2000/EC, 118/2006/EC & 676/91/EEC.

Finally, the continuous update and integration of groundwater data are fundamental for sustainable management in Greece. Furthermore, establishing a Strategic Water Policy will be crucial in addressing future demands and mitigating climate change impacts. The establishment and operation of an Entity, that will utilize the experience and data of the SAMY Project. Also, it ensures the continuation of the flow of this information is the only way for the rational management of water resources.

Introduction

Santorini Island is located in the central part of the Hellenic Volcanic Arc, which lies in the back-arc region of the Hellenic subduction zone. The majority of identified faults in Santorini exhibit a SW-NE orientation (Heiken & McCoy, 1984). Similarly, Santorini's main volcanic centers, including the Christiana Islands and the submarine volcano Columbo (located 7 km northeast of Santorini), are aligned along two seismic fault lines: the Kameni Line and the Columbo Line. These lines intersect the caldera in a northwest-southeast direction. Santorini is predominantly composed of volcanic rocks, except for a pre-volcanic substratum in the southeastern region, consisting of Mesozoic and Cenozoic metamorphic limestones and schists (Nicholls, 1971; Druitt et al., 1989).

The most significant eruption of the Santorini volcano, known as the Minoan eruption, occurred approximately in 1600 BC. In 1650, Santorini Island suffered significantly from the explosive eruption of the Columbo submarine volcano, The last recorded eruption occurred in 1950. The most intense seismic activity in this region has been observed along the NE–SW trending Santorini–Columbo volcano-tectonic line (Druitt et al., 1999).

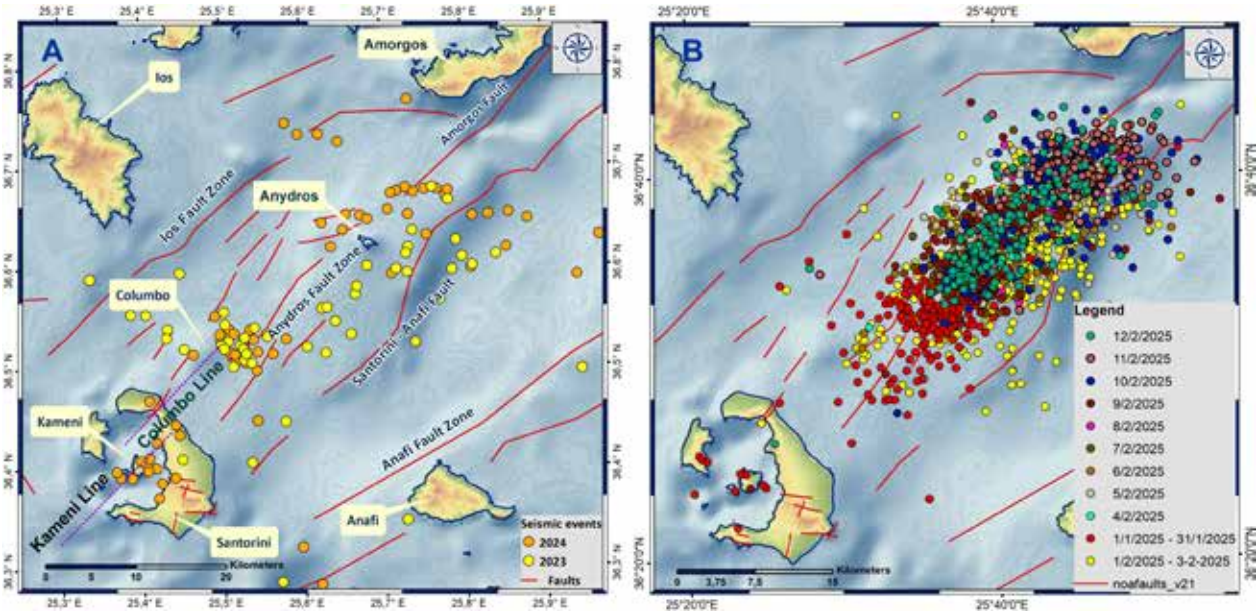

Figure 1. (A) Seismicity in the broader area of Santorini Island during the period 2023-2024. (B) Spatiotemporal distribution of the earthquake swarm during the first period of temporal distribution.

Since January 2025, weak to moderate earthquakes have occurred north – east of Santorini (Figure 1A). However, in early 2025, Santorini Island experienced a significant seismic swarm, recording over 4,000 earthquakes (Figure 1B). The largest earthquake had a local magnitude of M_L 5.3 on February 10, 2025. This seismic activity initiated in the caldera area of Santorini and progressively migrated northeast, offshore the island, between Santorini and Amorgos. In this study, we examine the spatiotemporal distribution and the computed Coulomb stress changes resulting from each earthquake of moment magnitude $M_w \geq 4.7$ that occurred during the 2025 Santorini - Amorgos swarm. Additionally, we determined the Coulomb stress changes at each focus of the following significant earthquakes, defined as those of moment magnitude $M_w \geq 4.7$. Finally, a modified Wadati method was used to determine the average V_p/V_s ratio for the Santorini-Amorgos area.

Seismic Data and Methodology

To investigate the spatiotemporal distribution and the computed Coulomb stress changes during the 2025 Santorini earthquake swarm, we used data such as the earthquake catalog from January 1, 2025, to February 28, 2025, and the available CMT (Centroid Moment Tensor) focal mechanism solutions from the National Observatory of Athens (https://bbnet.gein.noa.gr/HL/seismicity/mts). The earthquakes that were selected for the period from February 3rd to 18th have a moment magnitude M_w greater than or equal to 4.7 (Table 1).

Numerous studies on major earthquakes have demonstrated a strong correlation between positive Coulomb stress changes and the spatial evolution of seismic events (King et al., 1994; Vallianatos & Pavlou, 2021). Research has shown that Coulomb failure stress changes (ΔCFS) triggered by large earthquakes can either accelerate or delay the occurrence of subsequent seismic events. Additionally, these Coulomb stress changes can influence and control their temporal and spatial distribution (Stein, 1999; Kilb et al., 2002). Specifically, a positive ΔCFS transfer to a receiver fault brings it closer to failure, whereas a negative ΔCFS indicates a delay in failure.

The calculation of Coulomb Failure Stress changes (ΔCFS) under undrained rock conditions is based on the Coulomb failure criterion, which quantifies the proximity to failure. It is expressed by the following equation (Scholz, 2019):

$$\Delta CFS = \Delta_T - \mu' \Delta_\sigma$$

where Δ_T represents the changes in static shear stress, Δ_σ denotes the changes in effective normal stress, and $\mu\mu$' is the coefficient of friction (Cocco, 2002).

The ΔCFS changes were calculated using the Coulomb 3.3 software (Toda et al., 2011) in an elastic half-space, assuming a uniform slip on the rupture planar surfaces that imposes an "ideal" stress redistribution around the seismic faults. The software was used to model the Coulomb failure stress changes (ΔCFS) with a mean friction coefficient of μ' = 0.4. Additionally, the empirical relations of Wells and Coppersmith (1994) were employed to determine the width and length of the subsurface faults for each modeled earthquake (Lin & Stein, 2004; Toda et al., 2005).

Table 1. The most significant 2025 Santorini seismic events

No	Date -Time	Latitude	Longitude	Depth	Mw	Strike	Dip	Rake

17	18/2/2025 4:46	36,6199	25,8577	5,0	4,9	39	46	-110

Furthermore, the present study used the best-located hypocentral solutions (~1600 earthquakes) to improve hypocentre depth estimates. This subset of events was recorded in stations with both P- and S-wave arrival time picks at epicentral distances <200 km. An average $V_p/V_s V_p/V_s$ ratio was determined for the Santorini-Amorgos area using a modified Wadati method (Chatelain, 1978). This method is based on the differences in body wave arrival times P_i and P_j and S_i and S_j for an event k recorded by two stations (i, j) at hypocentral distances x_i and x_j, respectively, $DT_p = P_i - P_j = (x_i - x_j)/V_p$ and $DT_s = S_i - S_j = (x_i - x_j)/V_s$. Thus, $DT_s/DT_p = V_p/V_s$, and a plot of versus DT_p indicates a V_p/V_s ratio of 1.76 for the broader region (Figure 2). Konstantinou et al. (2013) estimated the Vp/Vs ratio between February 2011 and June 2012 at Santorini caldera. The average Vp/Vs ratio was 1.54 ± 0.17, much lower than the regional background value of 1.77. This led the authors to conclude that the involvement of gases was the

main factor that influenced the evolution of that swarm. On the contrary, Andinisari et al. (2021) estimated that Vp/Vs ratios varied from 1.74 to 1.91 during the 2011 to 2019 time period.

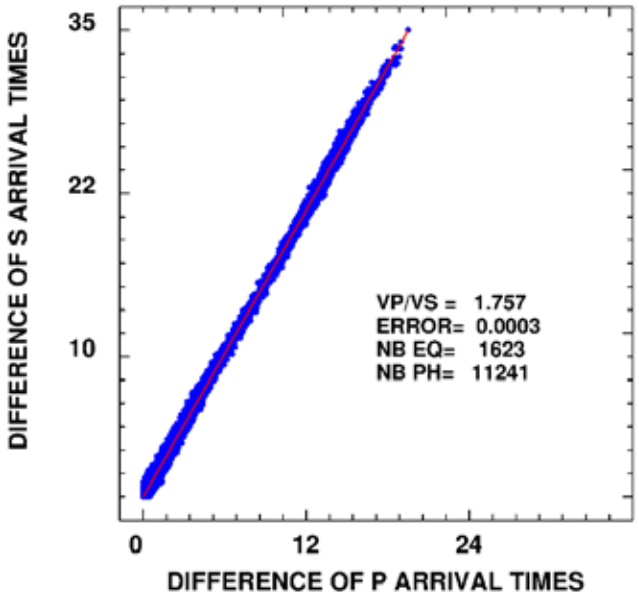

Figure 2: Vp/Vs ratio in the Santorini-Amorgos area using a modified Wadati diagram.

In the same study, the authors estimated the Vp/Vs ratio between 1.77 and 1.86 in the area to the NE, between Santorini and Amorgos, near the region that was activated in this period that we have examined.

Results and Discussion

The seismic swarm began with small seismic events in January 2025. However, on February 3, 2025, three earthquakes of magnitude M_w 4.8 occurred. In the following days, specifically until February 18, 2025, another 15 seismic events of a magnitude M_w greater than 4.7 took place in the Santorini-Amorgos area. Hence, to understand the evolution of the earthquake sequence, the co-seismic static Coulomb stress changes for each of these earthquakes, which occurred at depths ranging from 5 to 15 km (Table 1), were calculated.

Figure 3 depicts the first two significant earthquakes on February 3, 2025, at 9:25 and 12:17, both of a magnitude M_w 4.8 and at depths 13.7 km and 10.5 km, respectively. The spatial distribution of the ΔCFS reveals a stress decrease towards the NW and SE and a stress increase towards the NE and SW. Earthquakes that occurred up to February 18, 2025, are represented by white dots, and their spatial distribution follows the fault strike with a significant concentration in positive lobes. Cross-section AB, which illustrates the seismic events in the seismically activated area, shows that the subsequent events following the mainshock occur in regions with positive values of Coulomb stress changes (red lobe). These positive values indicate that the transfer of Coulomb stress changes due to the occurrence of the first strong event may have triggered the following events.

Additionally, the ΔCFS values at the hypocenters of the following seismic events were estimated. The results indicate a stress increase of +1.425 bar from the earthquake on February 4, 2025, at 13:04 to February 17, 2025, +0.314 bar from the earthquake on February 4, 2025, at 13:04 to February 10, 2025, at 20:16, +0.196 bar from the earthquake on February 4, 2025 at 13:04 to February 7, 2025, and +0.173 bar from the earthquake on February 9, 2025 to February 12, 2025 at 9:15. It is worth noting that while the co-seismic Coulomb stress changes were modeled assuming pure double-couple (DC) sources, recent studies (Zahradnik et al., 2025) have shown that several events within the 2025 Santorini–Amorgos swarm exhibit significant non-double-couple components. These components may locally alter the stress field beyond what is captured by DC-only modeling.

The spatial distribution of the static Coulomb stress changes for earthquakes with a magnitude greater than or equal to M_w 4.7 reveals a stress increase towards NE and SW. The migration of seismicity in the Santorini-Amorgos region closely aligns with the Coulomb stress transfer results, confirming that stress redistribution played a crucial role in triggering subsequent earthquakes. The initial scattered seismicity in late January intensified in early February, with a clear NE migration until February 5. This pattern corresponds to areas of increased Coulomb Failure Stress (ΔCFS), indicating that the stress changes induced by earlier earthquakes facilitated the activation of nearby faults.

The return of seismicity to the broader Anydros region after February 6 and the secondary NE shift on February 10–11 further support the influence of stress transfer on the sequence's evolution. These findings underscore the strong correlation between seismic migration and Coulomb stress changes, highlighting the importance of stress redistribution in controlling the evolution of the sequence.

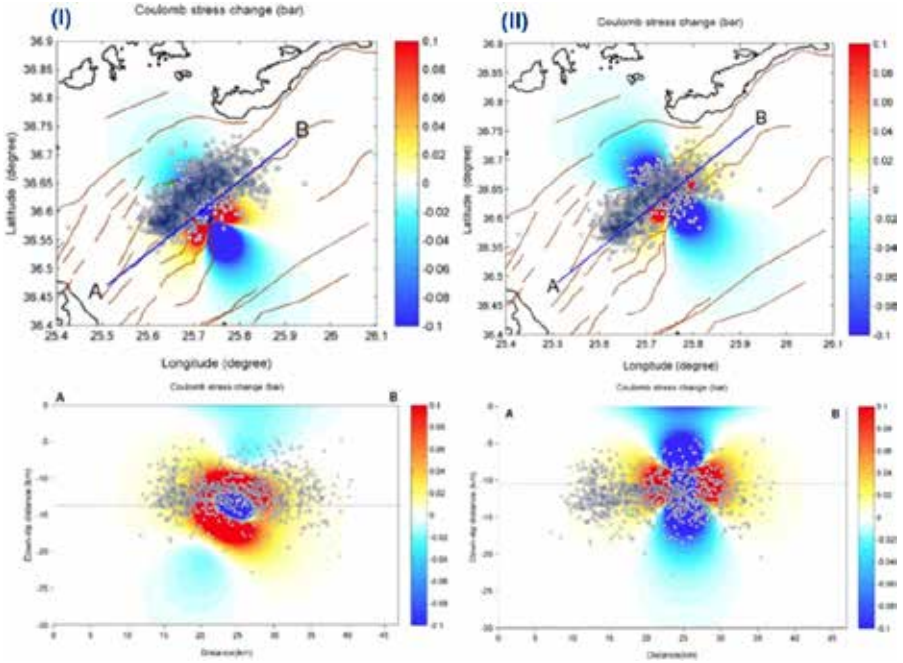

Figure 3: Coseismic Coulomb stress change distributions resulting from (I) the M_w 4.8 earthquake on February 3, 2025, at 9:29 and (II) the M_w 4.8 earthquake on February 3, 2025, at 12:17, with centroid depths of 13.7 km and 10.5 km, respectively. The white circles represent the hypocenters of the swarm until February 18, 2025. Cross-sections AB illustrate the changes in Coulomb stress (ΔCFS) relative to depth related to these seismic events.

Stabilisation of volcanic rock slopes in traditional settlements. The case of Petra, Lesvos Island

Saroglou C. [1], Kallimogiannis V.[2], Tsirogianni A.[3], Klironomou G.[4]
(1) National Technical University Athens, Greece, saroglou@central.ntua.gr (2) Civil Engineer, MSc, PhD NTUA (3) Civil Engineer, MSc, (4) Civil Engineer.

Introduction

Rock slope instabilities pose a significant problem to cultural heritage sites in Greece (Saroglou, 2012a and Saroglou *et al*., 2012b). The paper presents the assessment of rock slope stability of the volcanic rock cliff in the village of Petra in Lesvos Island, on which the Church of the Koimisi of Theotokos is founded (Figure 1). The rock cliff has almost vertical slopes with height up to 40 m and is formed by an andesitic rockmass, fractured by four discontinuity sets. The predominant kinematic instability is wedge or toppling failures of medium-sized rock blocks. The problem of potential rock instability of the volcanic slope in Petra has been investigated in the past (Apostolopoulos & Koukis, 1979) and rock fall episodes have occurred mainly triggered by intense rainfall. Due to the weathering and deterioration of the andesitic rockmass, the risk of rock instability has increased in the last two decades and it was deemed necessary to protect the foundation of the monument as well as the surrounding settlement and visitors from potential rockfalls. Stabilisation measures were proposed to minimize the risk of rockfalls and protect the foundation of the Church.
Similar problems of rock instabilities have been identified in many sites in Greece (Saroglou, 2019) but also near the study area at Mythimna Castle (Marinos *et al*, 2002). Saroglou (2012a) has studied the engineering geological behaviour of the volcanic formations in the northern part of Lesvos Island and highlighted the controlling factors of different types of slope instabilities, including landslides and rockfalls. The properties of the volcanic formations and their long-term behaviour in slopes are strongly controlled by the degree of weathering and the mineralogy of clay components when totally weathered (Irfan, 1999).

Figure 1. Volcanic rock cliff of Church of the Koimisi of Theotokos, Lesvos Island

Geological setting

Geologically the northern part of Lesvos Island consists of 400 m thick Neogene volcanic formations, formed by the Upper Miocene to the Middle Pliocene volcanic activity in the northeast Aegean Sea. These formations can be further distinguished in an upper lava unit and lower lava unit of Stypsi (Pe-Piper,1978). The upper lava unit consists of rhyodacitic, latitic and latiandesitic lavas, which are strong and hard formations, usually highly fractured, characterized by the magmatic pseudolayering, and intensely altered at places (kaolinitized) due to hydrothermal

activity. Two fault zones exist in the wider area, the main one with a WNW-ESE strike forming the tectonic graben of Petra and the secondary one with a NE-SW strike. As a result of compressive strains, the structure of rhyodacitic and latiandesitic lavas is characterized by two perpendicular joint systems which are vertical and intersect the pseudo bedding of lavas, thus forming orthogonal rock blocks. The rock cliff consists of rhyodacitic and latiandesitic lavas of the upper lava unit.

Rockmass conditions

The rock slopes surrounding the cliff were divided into eight distinct areas and the kinematic analysis of each area was analysed separately according to the discontinuity geometry and properties and the prevailing mechanism of failure (Figure 2). The volcanic rock appears massive in most places but locally is intensely fractured with a dense discontinuity network which forms wedges and rock pillars. The rockmass of the southern cliff appears extensively fractured and highly weathered, resulting in cavities. Due to the inaccessibility of the cliff, the rock slopes were mapped with UAV and LiDAR survey producing a point cloud and digital terrain model was created for the entire study site (Figure 3).

Figure 2. Plan view of the study site with designated slope areas

The discontinuity geometry was assessed using Discontinuity Set Extractor (Riquelme, 2015) which processes the point cloud data and then classifies points into planes (discontinuities) with similar orientation (dip/dip direction). The rockmass is intersected by three main discontinuity sets, as presented in Figure 4. The joint spacing was calculated as less than 1m (ranging from 0.3 to 0.7m), thus most blocks have a maximum volume of 0.5m^3.

Kinematic stability and rockfall analysis

Based on the mechanism of kinematic analysis (planar sliding, wedge sliding or toppling) in each area of the cliff, stability analysis was carried out for all the slope sections to define the factor of safety against each type of failure and determine the appropriate stabilisation measures. The analysis was performed in static conditions, with presence of water pressure in joints and under seismic loading.

The principal failure type is rockfall due to toppling, mainly in areas where large cavities are formed by the combined effect of weathering of the volcanic rock and the presence of discontinuities. Secondly, there are planar and wedge sliding failures in specific slope areas. The slope angle ranges between 55° and 88° and the steepest slopes are found in Areas 3,4 and 7, while the slope height ranges from 7 to 18m, with the highest slopes found in Areas 1, 3 and 4.

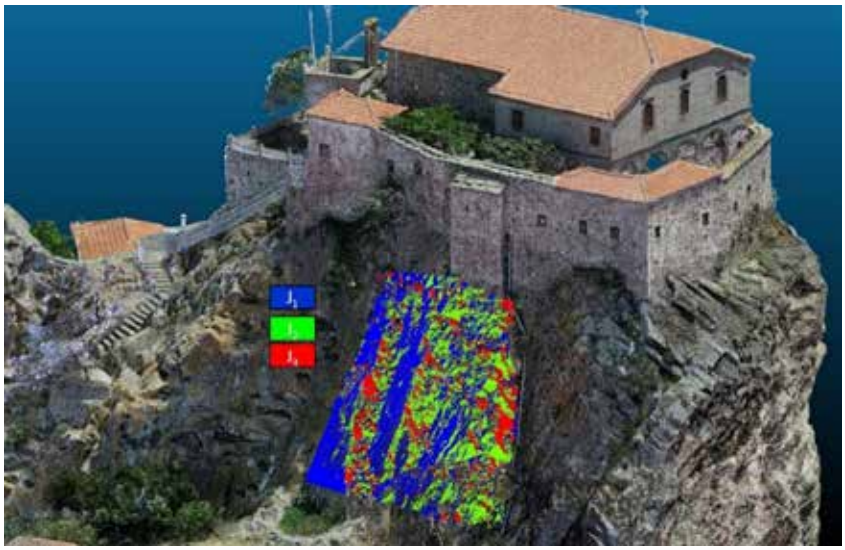

Figure 3. Digital terrain model and discontinuity mapping in the south side of the cliff

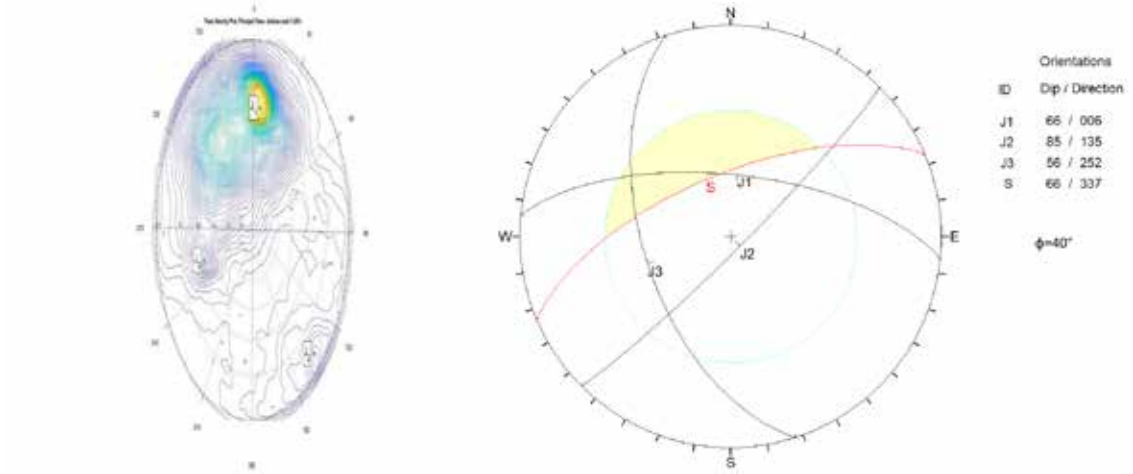

Figure 4. a) discontinuity pole density (from DSE), b) Stereographic plots with main sets in south cliff side.

In Area 1 (south side), toppling failure prevails due to a discontinuity set with NE-SW strike, as presented in Figure 4. In Area 2, planar sliding could occur along a discontinuity set with NW-SE strike. In Area 3, potential wedges are formed by the intersection of discontinuity sets of NW-SE and WE strike. In Areas 4 and 5, no systematic presence of discontinuity sets was observed. In Area 6, toppling failure prevails due to a discontinuity set with NNW-SSE strike, while in Area 7 toppling failure prevails due to a discontinuity set with N-S strike. In Area 8, planar sliding could occur along a discontinuity set with N-S direction and wedge failures could occur with a conjugate joint system. The determined factors of safety were not acceptable in many cases and therefore installation of rock bolts was considered necessary.

Rockfall analyses were performed for certain slope sections under different loading conditions. The critical locations of potential detached blocks were selected based on in-situ observations and the 3D terrain model of the slope and were used in the rockfall analysis performed in RocFall (Rocscience Ltd). The normal and tangential coefficients of restitution for the andesitic slope surfaces were taken equal to 0.45 and 0.85, respectively, based on experience from previous studies (Saroglou et al.,2012). The height of block detachment was defined in the range of 17 to 29 m above the slope base, with a maximum of 29 m in Area 1 (Figure 5a). The analysis shows that Areas 1, 4 and 5 are the most critical sections due to impact of falling rocks on houses and on the street which is around the cliff. In Area 1, the majority of falling blocks impact the houses with a maximum kinetic energy of 110 kJ. In Area 4 certain blocks reach the houses with a maximum kinetic energy of 160 kJ (Figure 5b). In Area 5 most falling blocks reach directly the residential zone with a maximum kinetic energy of 90 kJ and significant bouncing heights. On the contrary, there

are areas that are considered as lower risk, such as Area 2, where falling blocks stop at a plateau located near the base of the slope and Area 3 where most rocks reach the base of the slope with a maximum kinetic energy of 80kJ.

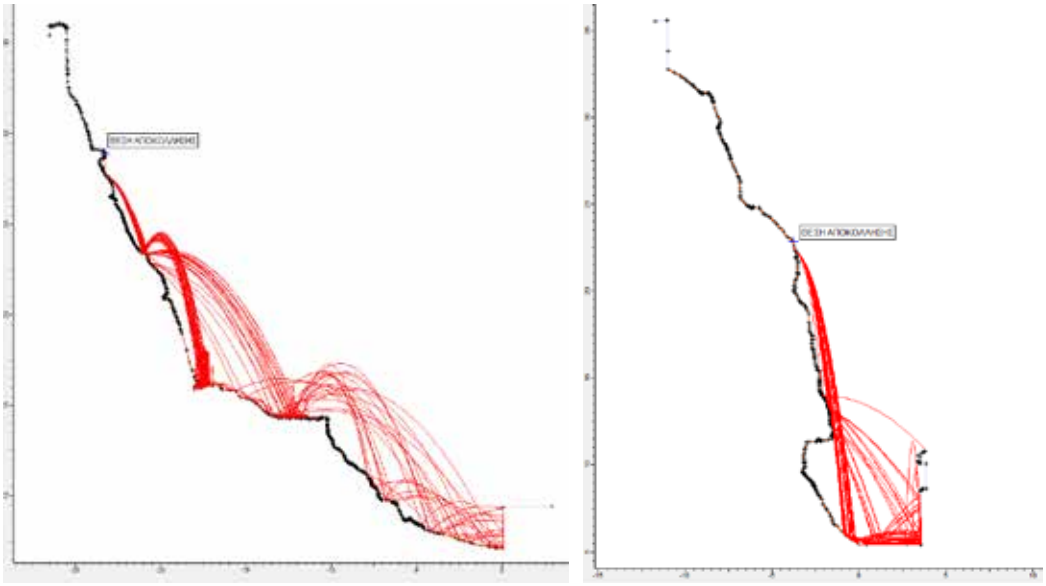

Figure 5. a) Rockfall analysis in Area 1 (south cliff) and b) in Area 4 (north cliff)

Stabilisation measures

Based on the stability analyses it was considered necessary that active support measures (rock bolts, anchored wire mesh) are installed to minimise the risk of rock blocks falling from the upper parts of the slopes, instead of installing passive measures (rockfall barriers). The option of installing rockfall barriers on the slope was not acceptable to due to achieve the minimum impact on the cultural heritage site.

The proposed rock stabilization works aimed to enhance the overall stability and reduce the risk of further rock falls. The stabilization measures are summarised below, and an example is presented in Figure 6.

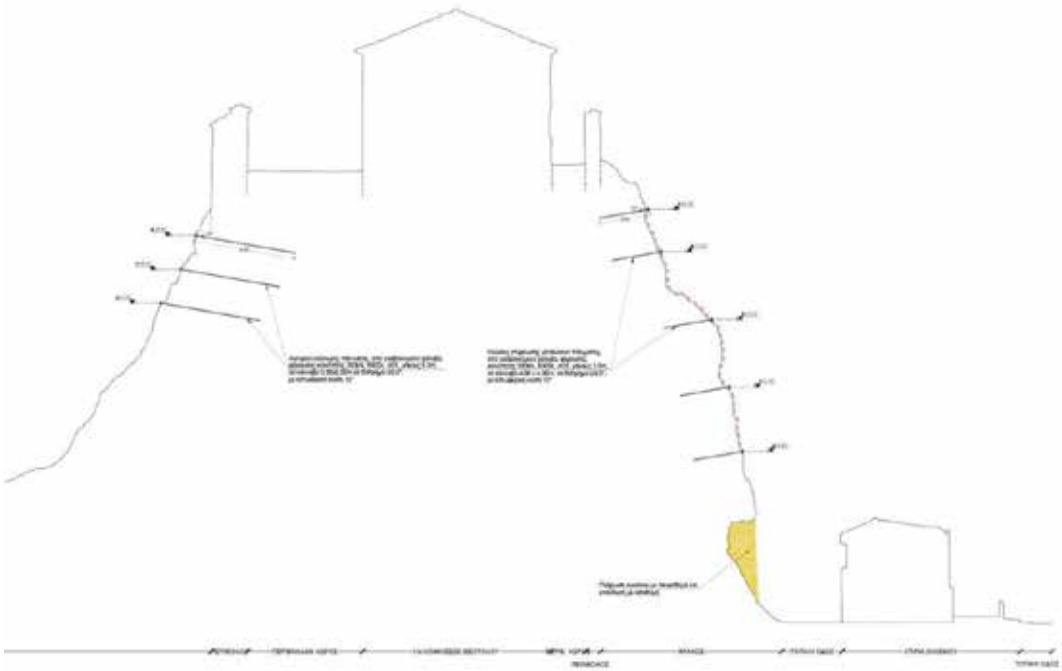

Figure 6. Section with proposed stabilisation measures in Area 1 (south) and Area 4 (north)

The main measures were:
1. Installation of spot bolts for anchoring individual relatively small rock blocks and pattern bolting for anchoring of larger blocks. The aim of this measure was to support potentially unstable blocks and improve the stability conditions of the upper part of the cliff below the foundation of the Church.
2. Installation of a steel wire rope net, anchored with fully grouted bolts in order to control further loosening of the rock mass in areas where it is fractured.
3. Filling of voids in specific locations with sprayed concrete or reinforced concrete, depending on their location, geometry and size. The intention was to minimise the enlargement of voids due to weathering and support the overhangs of rocks.

Conclusions

The stabilisation of steep rock slopes in areas where human activities are impacted is a very challenging task. The case of Church of the Koimisi of Theotokos in Petra is such an example, which demonstrates the difficulty to stabilise a rock slope in inhabited area, while at the same time respecting the cultural heritage character of the monument.
In this study, a methodology was presented which is based on identifying the engineering geological behavior of the volcanic rock formations and determining the prevailing failure mechanisms in different sections of the slope to propose the appropriate stabilisation measures. The advantage of technologies, such as UAV and LiDAR and use of software for automatic detection of discontinuities was demonstrated to enhance the assessment of kinematic stability analysis and protection of the monument.

EXTENDED ABSTRACT 283

Mapping pyroclastic formations at the Lesvos Petrified Forest, Greece the Akrocheiras hill pyroclastic sequence

Savvelos L.[1, 2] and Zouros N.[1, 2]
(1) Natural History Museum of the Lesvos Petrified Forest
(2) Department of Geography, University of the Aegean, Greece

Introduction

The Lesvos Petrified Forest is a unique natural monument located in western Lesvos. It is the geological heritage treasure with international significance of the Lesvos Island UNESCO Global Geopark. It is also included in the 100 first Geological Heritage sites of the International Union of Geological Sciences (IUGS). The Lesvos Petrified Forest includes massive assemblages of silicified tree trunks located in situ within the Sigri pyroclastic formation of Lower Miocene (Velitzelos and Zouros 1997, 1998, Pe-Piper et al. 2019, Zouros 2021).The Natural History Museum of the Lesvos Petrified Forest is conducting scientific research, excavation and conservation works in the Lesvos Petrified Forest during the last 30 years. Excavations in the Lesvos Petrified Forest reveled a large number of standing and lying silicified tree trunks, root systems, brunches, leaves and cones that belong to conifer and angiosperm tree species. The composition of the forest ecosystem represents subtropical climatic conditions (Velitzelos and Zouros 1997, 1998, Pe-Piper et al. 2019).

Silicification of the Lesvos Petrified Forest is related with the volcanic activity in Lesvos during Lower Miocene (Pe-Piper et al. 2019b, 2024). The perfect preservation of the fossils is due to the circulation of hydrothermal fluids rich in silicon dioxide SiO_2, (Pe-Piper et al. 2019b).

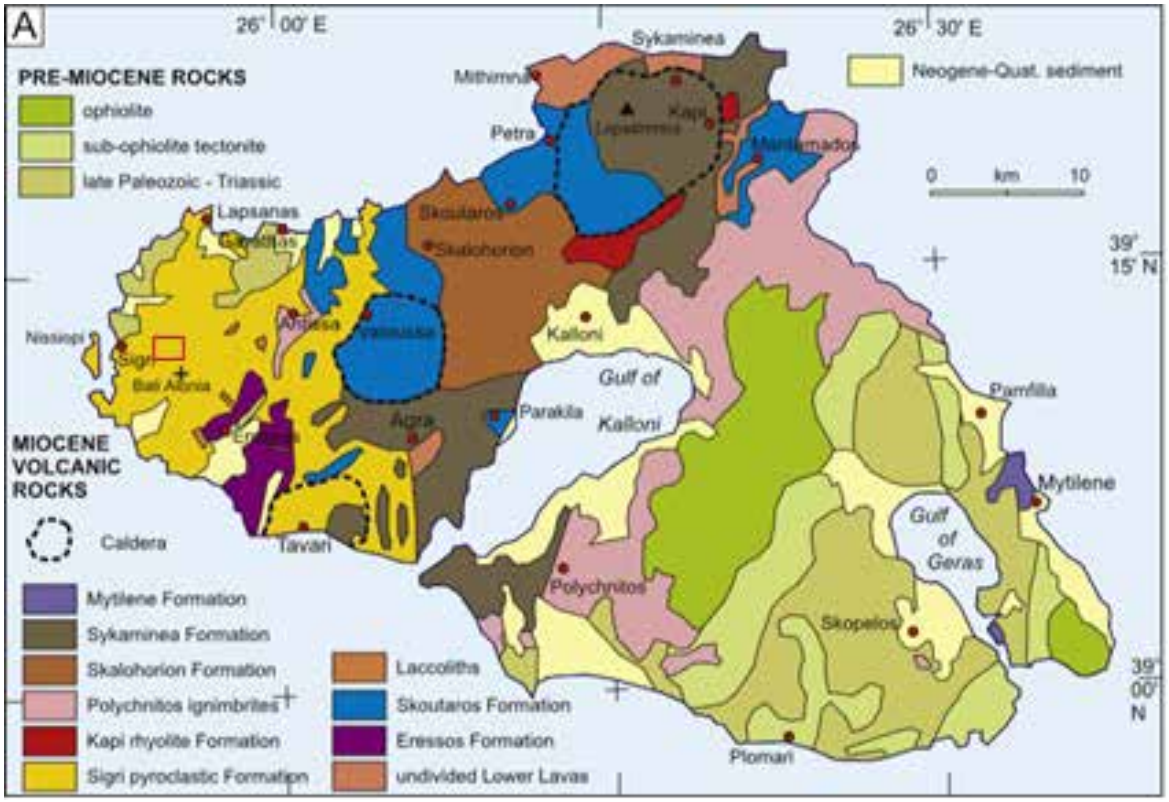

Figure 1: Geological Map of Lesvos Based on Hecht (1972-1976), modified by Pe-Piper (1992). Red rectangle indicating the study area of current research

Since 2014 extensive rescue excavation works were carried out by the Natural History Museum of the Lesvos Petrified Forest due to the construction of the Kalloni - Sigri, road crossing the protected area of the Lesvos Petrified Forest. As a result large amounts of new data in a number of significant fossil sites were collected (Zouros et al. 2015, Zouros 2021, Pe-Piper et al. 2019b, 2024).

As several significant fossil sites are located on the northern flanks of the Akrocheiras hill, a detailed mapping project in the area of Akrocheiras hill was carried out, in order to archive a better understanding of the stratigraphy of the pyroclastic sequence. Therefore the main objective of the current study is the identification and mapping of successive fossiliferous horizons associated with different volcanic eruptions that led to the preservation of the fossilized forests

Study Area

The protected area of the Petrified Forest of Lesvos spans at the western peninsula of the island covering 15.000 ha. Throughout the area, silicified trunks can be found at various depths. Akrocheiras hill lies in the center of the protected area, 7 km east of Sigri village (Fig. 2), reaching an altitude of 370 meters above sea level and covering an area of approximately 1.2 km². Recent rescue excavations conducted in the area along the Kalloni-Sigri road uncovered thousands of petrified trunks along the road, which were showcased and preserved in situ through the efforts and acts of the Natural History Museum of the Lesvos Petrified Forest. Additionally, hundreds of fossils were uncovered and preserved on the hilltop, due to rescue excavations for the re-construction of the Sigri windmill farm, where the longest fallen petrified trunks were excavated, along with a large number of standing in-situ and lying silicified tree trunks.

The study area is entirely covered by the Sigri pyroclastic formation (Figure 1), featuring a variety of volcanic deposits that covered and preserved fossiliferous horizons (Pe-Piper et al., 2019b). The Sigri pyroclastic formation is several hundred meters thick and consists of tuffs and coarse-grained volcanic materials. Stratigraphically, it overlies the Gavathas and Eresos formations and underlies the younger Skoutaros formation (Pe-Piper et al., 2019b).

Following the deposition of this formation, the intrusion of the Moni Ipsilou dome occurred, dated to approximately 17.9 million years ago. The Sigri pyroclastic formation in several sites is covered by recent deposits.

This description highlights the geological complexity and significance of the area, particularly in the context of preserving the fossilized forest and understanding its volcanic history.

Methodology

To achieve the identification of successive fossiliferous horizons associated with different volcanic eruptions and the evaluation of volcanic episodes that preserved fossilized forests, detailed mapping was conducted in the study area (Fig. 5). The mapping included fossil sites with standing in-situ petrified tree trunks, root systems, and fallen petrified tree trunks in direct contact with pyroclastic material, as well as occurrences of volcanic sequence of pyroclastic formations marking the onset of deposition from a volcanic eruption (Fig. 5).

The standing petrified tree trunks (Fig. 2, Fig. 4), being fossilized in their original position, serve as significant evidence to define a fossiliferous horizon. When the root system of the trunk is a marker of the original layer where a dense subtropical forest once thrived.

The fallen petrified trunks are displaced from their original position by pyroclastic flows. The composition of the clasts and orientation of the fallen trunks provide significant information on the origin of the pyroclastic flows involved in the silicification of the trees.

Coarse-grained horizons of volcanic conglomerates with clasts of diameter <2m are found throughout the area(Fig. 3a). These usually contain polygenetic volcanic pebbles, consisting of flows—volcanic conglomerates or debris flows —and appear to have been formed by water-driven flows that filled a complex network of paleo-river channels of that time (Pe-Piper et al., 2019b). This formation was created during a relatively calm period, meaning it was not driven by eruptions, unlike the tuffs found in the area. This feature provides insights into how the region's morphology developed between eruptions.

Therefore, the fine-grained pyroclastic horizons, the tuffs, whose creation and deposition are processes closely linked to the various volcanic eruptions, are expected to appear in the field as stratigraphically overlying on the previously formed substrate of the area—in this case, the debris flow. Thus the fine-grained formations simultaneously act as markers of deposition from a volcanic eruption.

Vitric tuff (Figure 3b) is a volcanic tuff primarily composed of fragments of volcanic glass that have undergone alteration (Pe-Piper et al., 2019b). It forms during an eruption and the rapid cooling of magma (Sparks & Walker, 1977; Pe-Piper et al., 1980). The binding material of the tuff consists of volcanic ash and contains fragments of pumice and small pieces of lava ejected during the eruption (pumice-lithic lapilli) (Pe-Piper et al., 2019b). It is deposited from the air (Sparks & Walker, 1977) directly onto already formed substrate of the area and serves as a strong indicator of the onset of deposits from a volcanic eruption.

Lithic tuff is pyroclastic sediment (Figure 3c). It consists of a primary binding material (matrix) made of volcanic ash with a grain size of ~2 mm and fragments of andesitic-dacitic lava <64 mm, which are shattered from pre-existing surrounding rocks and spread during the eruption (Pe-Piper et al., 2019a).

Figure 2 a, b, c, d: Standing in situ petrified trunks at the north and south flanks of Akrocheiras

Its deposition is closely linked to the volcanic eruption. It usually exhibits variability in the distribution of clasts due to the varying intensity of the eruption that caused its deposition (Pe-Piper et al., 2019a). Additionally, the deposition of this formation usually in the most cases succeeds that of Vitric tuff. In many cases though, in the field the two formations are found together, with lithic tuff being the base and vitric tuff overlying on top, directly on the already formed substrate (Pe-Piper et al., 2019a). Consequently, lithic tuff also serves as an important indicator for the onset of deposits from a volcanic eruption.

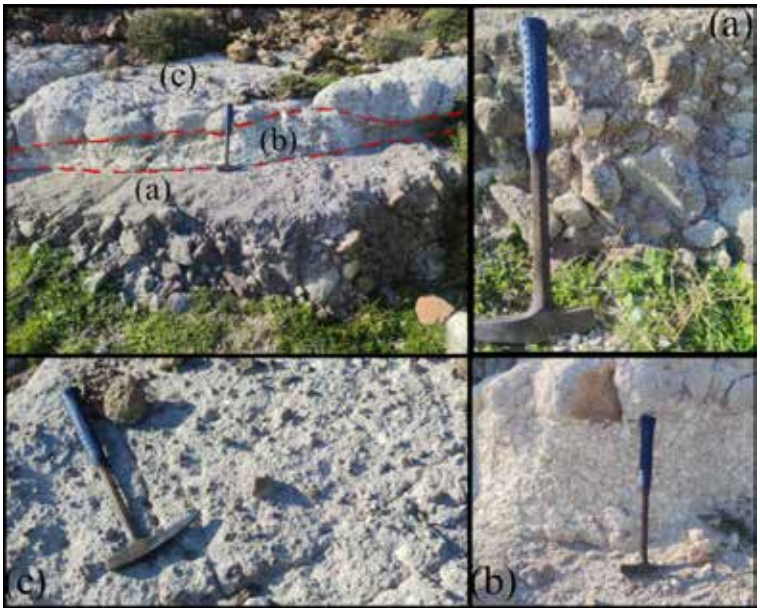

Figure 3: Appearance of the main sequence marking the deposition of a new volcanic eruption, where: a: Coarse-grained pyroclastic flow (Debris flow). b: Vitric tuff, deposited directly from the air; the vitric tuff forms during the eruption due to the rapid cooling of magma and serves as a critical marker indicating the onset of a new volcanic sequence. c: Lithic tuff, a pyroclastic sediment containing volcanic tuff and andesitic-dacitic clasts.

The formations mentioned above (debris flow, vitric tuff, lithic tuff) constitute a representative stratigraphic volcanic sequence (Figure 3), which is observed in the field and marks the onset of deposits from a volcanic eruption. The identification of locations where the whole sequence or parts of it appear is crucial for understanding and evaluating

the fossiliferous horizons and volcanic episodes hosted by Akrocheiras.
The occurrence of the primary volcanic sequence or parts of it containing vitric and lithic tuff, and the extent to which it repeats upstream on the slopes of Akrocheiras is the key element distinguishing fossiliferous horizons from one another, as well as different volcanic episodes.
The main and primary indicator is vitric tuff, as mentioned earlier, since it forms during the rapid cooling of magma during a volcanic eruption. It is deposited from the air directly onto the already formed topography of the ground surface, which supports a subtropical forest. Therefore, it is expected that the vitric tuff horizons represent the main fossiliferous horizons.
In the field, petrified trunks and root systems that protrude directly from vitric tuff (Fig. 4) are encountered, and in such cases, the recognition of the fossiliferous horizon is facilitated. However, even in cases where the formation is found without the presence of fossils, this does not mean that fossils are absent, they simply do not happen to be visible at the specific location.

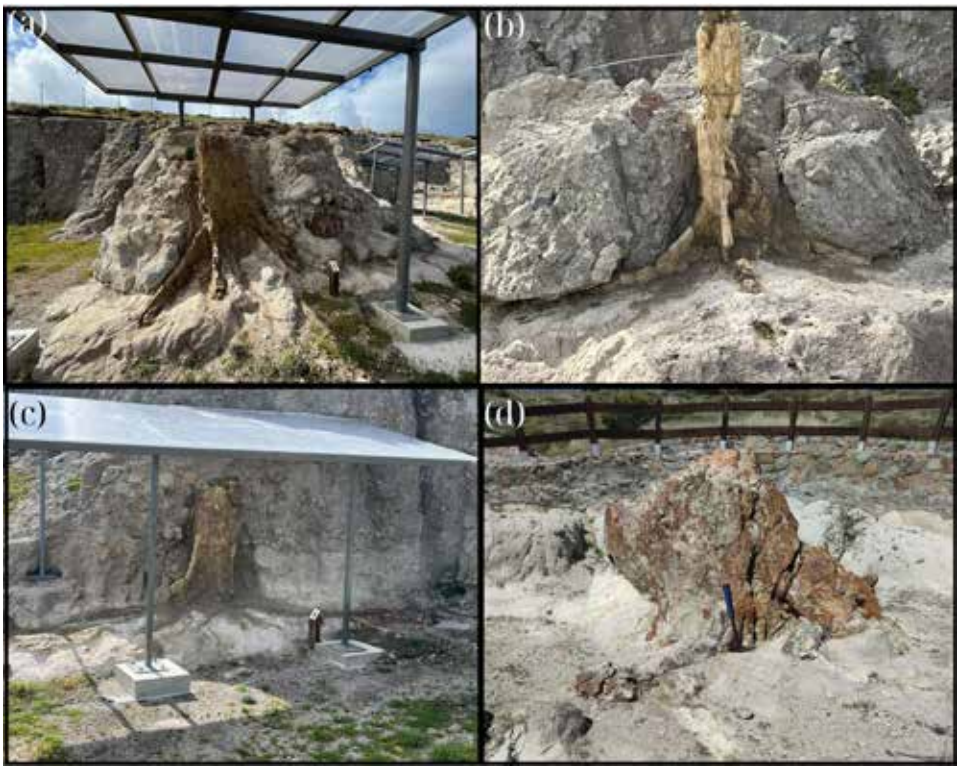

Figure 4 a, b, c, d: Standing in situ petrified trunks at the broader area of Akrocheiras illustrated with their roots systems spreading in the air fall vitric tuff and a, b, c also covered by coarse-grained volcanic conglomerates.

Results

The primary objective of this study is the identification and evaluation of successive fossiliferous horizons associated with different volcanic eruptions, as well as the assessment of volcanic episodes that preserved fossilized forests.
By combining the locations of standing petrified trunks that display their root systems, along with the occurrences of the entire volcanic sequence or parts of it featuring vitric tuff or lithic tuff, the following map is produced (Figure 5).
Documented locations (Figure 5) indicate that the Akrocheiras hill hosts at least 11 successive fossiliferous horizons associated with different volcanic eruptions. This represents the minimum number that can be established based on the evidence and their respective locations.

Conclusions-Discussion

Akrocheiras hill is covered by the Quaternary deposits and low vegetation, which makes the mapping effort very challenging. Detailed mapping curried out in Akrocheiras hill provide evidence for the presence of at least 11 successive pyroclastic horizons representing successive volcanic eruptions.
If we consider that only in the “Ioannis Toumpelekis Park”, at the northeastern edge of the Akrocheiras Hill, where the soil horizon has been removed and the volcanic formations are fully exposed, at least 8 fossiliferous horizons have been documented, it becomes evident that the Akrocheiras hill hosts dozens of petrified forests.

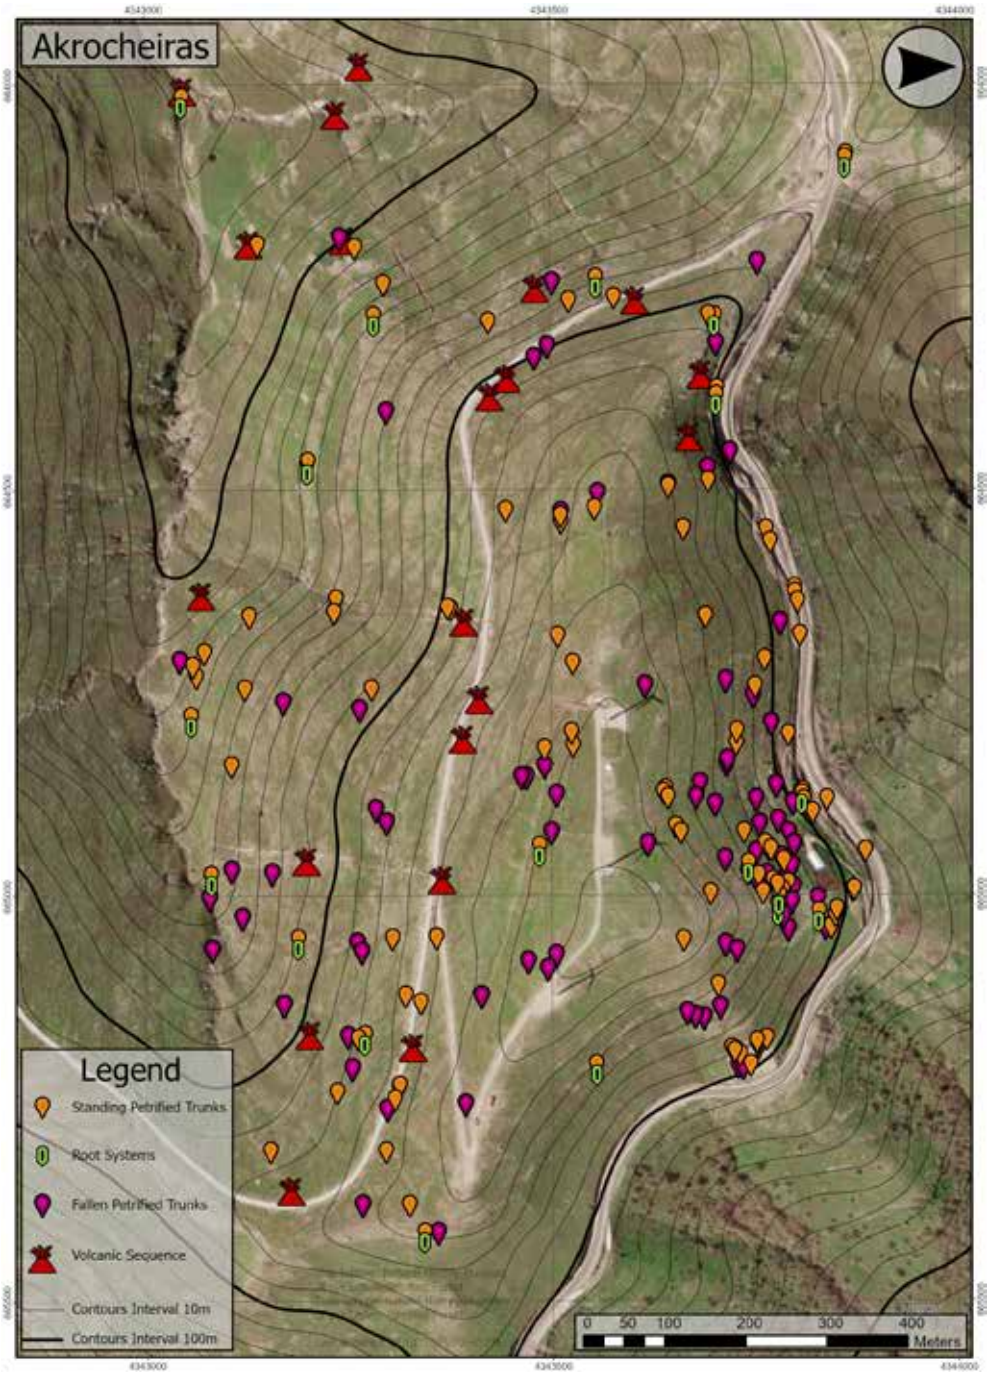

Figure 5: Result of the mapping of the plant fossils (standing, petrified tree trunks, lying petrified tree trunks , root systems) and volcanic horizon contacts conducted in the Akrocheiras area, within the protected area of the Lesvos Petrified Forest.

Additionally, the fact that the volcanic sequence in the northern part of the hill, along with the significantly higher density of fossil concentrations (see Figure 6), are phenomena that require further scientific investigation. These are possibly directly linked to the geomorphology of the area during the deposition of the Sigri pyroclastic formation. Finally, the primary objective of this study is a topic that requires much more research. This initial approach and estimation open a significant scientific discussion regarding the minimum number of successive fossiliferous horizons associated with different volcanic eruptions and the assessment of volcanic episodes that preserved fossilized forests, initially for the Akrocheiras hill and, by extension, for the broader recognized area of the Petrified Forest of Lesvos.

Mapping petrified tree trunks and pyroclastic formations at the Lesvos Petrified Forest, Greece, case study of the Bali Alonia area

Savvelos L.1, 2 and Zouros N.1, 2
(1) Natural History Museum of the Lesvos Petrified Forest
(2) Department of Geography, University of the Aegean, Greece

Introduction / Background

The Lesvos Petrified Forest constitutes a distinctive natural monument situated in the western region of Lesvos. It represents a geological heritage asset of considerable international importance within the Lesvos Island UNESCO Global Geopark. Additionally, it is recognized among the first 100 Geological Heritage sites designated by the International Union of Geological Sciences (IUGS). The Lesvos Petrified Forest encompasses extensive assemblages of silicified tree trunks that remain in situ within the Sigri pyroclastic formation, dating back to the Lower Miocene epoch (Velitzelos & Zouros 1997, 1998; Pe-Piper et al. 2019; Zouros 2021). The Natural History Museum of the Lesvos Petrified Forest has been engaged in scientific research, excavation, and conservation efforts within the Lesvos Petrified Forest for the past 30 years. Excavations conducted in the Lesvos Petrified Forest have unveiled a substantial quantity of both standing and fallen silicified tree trunks, root systems, branches, leaves, and cones attributable to coniferous and angiosperm tree species. The composition of the forest ecosystem reflects subtropical climatic conditions (Velitzelos & Zouros 1997, 1998; Pe-Piper et al. 2019).

The silicification process of the Lesvos Petrified Forest is intricately associated with the volcanic activity that transpired in Lesvos during the Lower Miocene epoch (Pe-Piper et al. 2024). The exceptional preservation of the fossils is attributed to the circulation of hydrothermal fluids that were enriched in silicon dioxide (SiO2) (Pe-Piper et al. 2019).

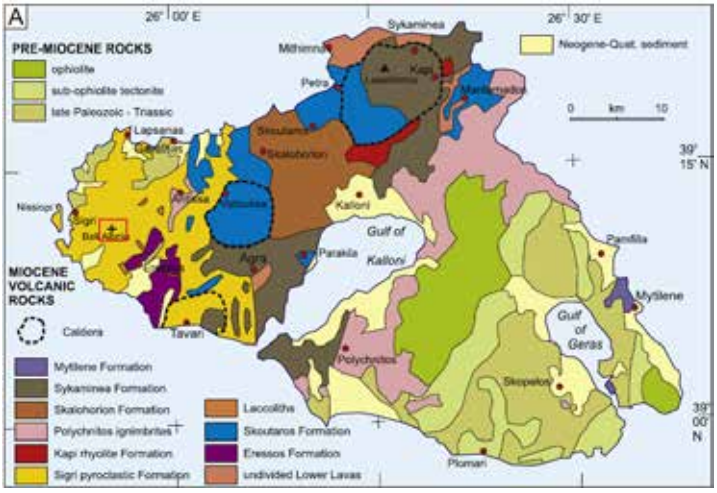

Figure 1: Geological Map of Lesvos Based on Hecht (1972-1976), modified by Pe-Piper (1992). Red rectangle indicating the study area, Bali Alonia broader area.

Since 2014, extensive rescue excavation initiatives have been conducted by the Natural History Museum of the Lesvos Petrified Forest in response to the construction of the Kalloni - Sigri road, which crosses the designated protected area of the Lesvos Petrified Forest. Therefore, a considerable amount of new information has been collected from various notable fossil locations (Zouros 2021; Pe-Piper et al. 2024).

Due to the presence of several prominent fossil sites inside the fenced area of “Bali Alonia Park”, an extensive mapping initiative was conducted within this region to meticulously identify and document fossil-bearing locations. Consequently, the primary aim of the present investigation is the identification and cartographic representation of standing tree trunks, fallen tree trunks, root systems, as well as vitric and lithic tuffs. By determining the precise locations of these fossils, we can more effectively safeguard and analyze the Petrified Forest. The mapping effort has also facilitated an enhanced comprehension of the stratigraphy associated with the pyroclastic formations.

Study Area

The Petrified Forest of Lesvos spans an area on the western edge of the island of Lesvos. Within this area, with the efforts of the Natural History Museum, accessible parks have been established where visitors can view the in situ petrified tree trunks. Approximately 10 km away from the settlement of Sigri lays the area of Bali Alonia (Fig. 2). Historically, this is where the first petrified tree trunks were protected and showcased. Subsequently, a section of the area was fenced and protected, leading to the creation of the first park of the Petrified Forest, named the Main Fossil area or the Bali Alonia Park. Fossilized in situ trunks can be found both within the fenced section and in the broader area of Bali Alonia

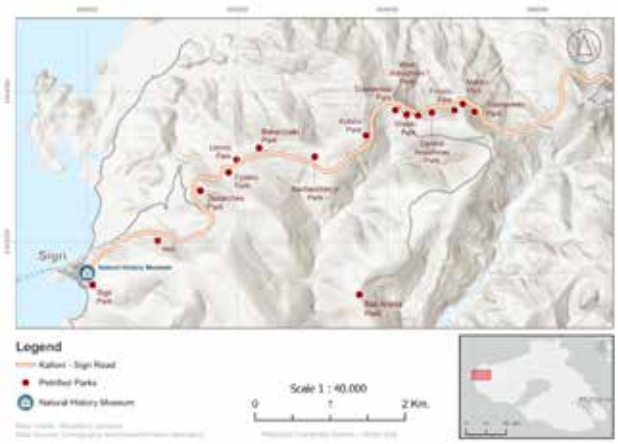

Fig 2: Regional map indicating locations of significant fossil parks along the Kalloni-Sigri road, also the main fossil area petrified forest park Bali Alonia.

For the purposes of this specific study, the broader area, covering approximately 7 km², was designated as the study area (Fig. 1). From the lowest point at an elevation of ~60 meters to the highest point of the study area at ~300 meters above sea level, standing tree trunks, fallen tree trunks, root systems and vitric and lithic tuffs are distributed.

The geographical region under investigation is comprehensively enveloped by the pyroclastic formation of Sigri (Fig. 1), which is distinguished by a diverse array of volcanic deposits that have effectively covered and preserved petrified forests in different strata (Pe-Piper et al. 2018). The Sigri pyroclastic formation exhibits a thickness of several hundred meters and is composed of tuffs alongside coarse-grained volcanic materials. From a stratigraphic perspective, it is situated above the Gavathas and Eresos formations while being positioned beneath the more recent Skoutaros formation.

Subsequent to the deposition of this geological formation, the intrusion of the Moni Ipsilou dome transpired, with a temporal attribution of approximately 17.9 million years ago. The majority of the Sigri pyroclastic formation is obscured by more recent deposits, with only the coarse-grained materials, lava flows, and volcanic domes emerging above these overlying layers. In select regions, tuffs are also present, exhibiting formations characterized by grain sizes of less than 2 mm (Pe-Piper et al. 2018).This exposition emphasizes the intricate geological attributes and importance of the region, especially concerning the conservation of the petrified forest**s** and the comprehension of its volcanic past.

Coarse-grained materials characterized by clasts with a diameter of less than 2 meters are prevalent throughout the region. These formations are typically distributed, consisting of overcompressed flows—specifically volcanic conglomerates or debris flows (Fig. 5a)—and appear to have originated from water-induced flows that infiltrated a complex network of paleo-river channels from that period (Pe-Piper et al. 2018). This formation emerged during a relatively tranquil epoch, between volcanic episodes, indicating that it was not a result of volcanic eruptions, in contrast to the tuffs present in the vicinity. This characteristic offers valuable insights into the morphological evolution of the region between volcanic events.

Consequently, the finely textured pyroclastic materials known as tuffs, whose formation and deposition are definitely associated with volcanic eruptions, are anticipated to be found in the field as stratigraphically overlying layers on top

the pre-existing substrate of the region—in this instance, the debris flow or volcanic conglomerate. Therefore these layers concurrently function as indicators of deposition resulting from a volcanic episode.
Vitric tuff is a type of volcanic tuff that is predominantly contains volcanic glass fragments that have experienced alteration (Fig. 5b) (Pe-Piper et al. 2019). It is generated during an eruption and the quick cooling of magma (Sparks & Walker 1988; Pe-Piper et al. 1980). The matrix of the tuff comprises volcanic ash and includes fragments of pumice and small lava pieces expelled during the eruption (pumice-lithic lapilli) (Pe-Piper et al. 2018). It is deposited as air fall formation (Sparks & Walker 1977) directly onto the pre-existing substrate of the region and serves as a main indicator of the initiation of deposits resulting from a volcanic eruption.

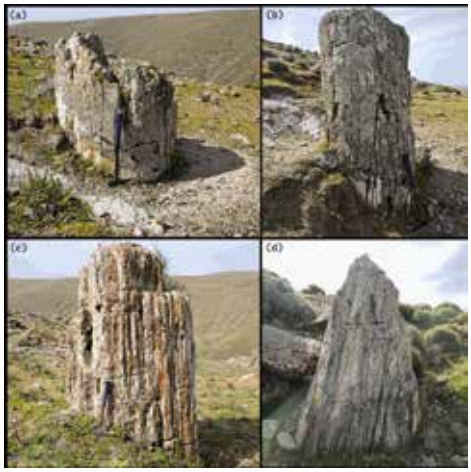

Figure 3 a,b,c,d: Standing in situ petrified trunks stable in their original position. . a: 663,737.98E 4,340,605.91N m, b: 663,709.15E 4,340,596.20N m, c: 663,617.72E 4,340,502.68N m, d: 663,692.56E 4,340,621.39N m,

Lithic tuff is classified as pyroclastic sediment. It comprises a primary binding material (matrix) consisting of volcanic ash with a grain size of approximately 2 mm, along with fragments of andesitic-dacitic lava measuring less than 64 mm, which are fragmented from pre-existing surrounding rocks and disseminated during the eruption (Fig. 5c) (Pe-Piper et al. 2018). The process of its deposition is intricately associated with volcanic eruptions. Typically, it displays variability in clasts distribution, a consequence of the differing intensities of the eruptions responsible for its deposition (Pe-Piper et al. 2018). Moreover, the deposition of this formation generally follows, on top, that of Vitric tuff. Nevertheless, in numerous instances, both formations are observed in situ, with Lithic tuff acting as the substrate and Vitric tuff overlaying it directly upon the pre-existing substrate (Pe-Piper et al. 2018). Consequently, lithic tuff serves as a significant indicator of the initiation of deposits resulting from a volcanic eruption.
This description highlights the geological complexity and significance of the area, particularly in the context of preserving the fossilized forest and understanding its volcanic history.

Methodology

The research encompassed a thorough cartographic endeavor within the specified study region, employing a methodical field survey methodology. The principal objective was to precisely identify and document fossiliferous sites, including both upright and fallen petrified tree trunks. To achieve this, we also delineated the stratigraphy of the pyroclastic deposits, with particular focus on the tuff horizons (both vitric and lithic tuff).
Field investigations were executed utilizing the FieldMove Clino Version 3.0.6 application, which afforded precise geospatial coordinates and enabled real-time data recording. In advance of data acquisition, the application underwent calibration in accordance with the manufacturer's specifications to guarantee measurement precision and dependability. Special attention was directed towards mapping regions where tuffs were exposed, particularly along the stream valleys that define the study area.
Subsequent to the identification of each relevant site, positional data was systematically documented through the

FieldMove Clino application, along with further site-specific observations recorded manually. These observations encompassed geological and geomorphological attributes. Data points were collected at locations deliberately selected during the mapping process to maximize spatial resolution and reliability.
The KMZ file format was chosen for its intuitive usability and compatibility with ArcGIS Pro, coupled with its ability to include location-specific images, thus considerably improving the data processing and interpretative phases. Data accuracy and consistency assessments were conducted to ensure the quality of the gathered dataset.
The standing petrified tree trunks (Fig. 3, Fig. 4), being fossilized in their original position, serve as significant evidence to define a fossiliferous horizon. The root systems of these trunks are markers of the original layers where a dense

Figure 4 a, b, c, d: Standing in situ petrified trunks at the broader area of Akrocheiras illustrated with their roots systems spreading in the air fall vitric tuff and a, b, c also covered by coarse-grained volcanic conglomerates. a: 663,805.18E 4,341,410.44N m located in the Park Bali Alonia, b: 663 770,269E 4,343,366,122N m, c: 663 777,896E 4,343,388,585N m, d: 664,396.99E 4,343,703.54N m. Trunks b, c, located at the Park Kotsini and d located at the Park Vrysaki.

Figure 5: Appearance of the main sequence marking the deposition of a new volcanic eruption, where: a: Coarse-grained pyroclastic flow (Debris flow). b: Vitric tuff, deposited directly from the air; the vitric tuff forms during the eruption due to the rapid cooling of magma and serves as a critical marker indicating the onset of a new volcanic sequence. c: Lithic tuff, a pyroclastic sediment containing volcanic tuff and andesitic-dacitic clasts. Coordinates of the locality: 664,134.57E 4,341,600.77N m

Figure 4 illustrates the distinctive geological formations of the Bali Alonia region previously discussed (debris flow, vitric tuff, lithic tuff) that have been observed in situ and signify the commencement of deposits resulting from volcanic activity. The discernment of sites where the interrelationship among the pyroclastic layers is evident is essential for comprehensively understanding and assessing the fossiliferous stratas and volcanic episodes present in the broader area of Bali Alonia.

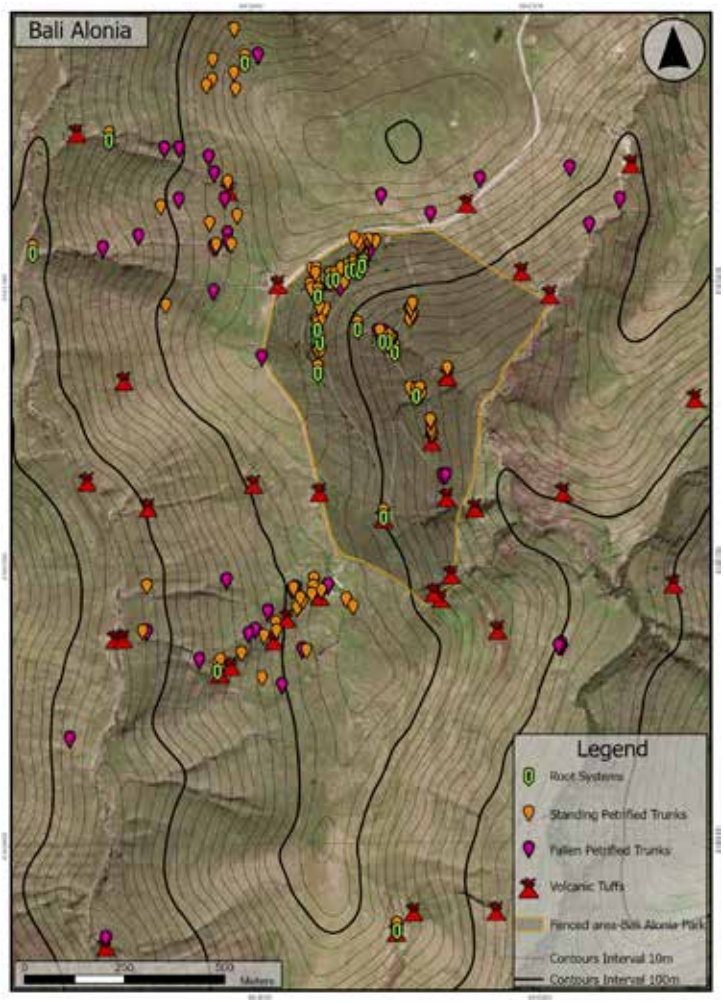

Figure 6: Result of the mapping of the plant fossils (standing, petrified tree trunks, lying petrified tree trunks , root systems) and volcanic horizon contacts conducted in the Bali Alonia area, within the protected area of the Lesvos Petrified Forest.

Results

The principal aim of this research is to identify and delineate standing tree trunks, fallen tree trunks, root systems, also vitric and lithic tuffs, which are instrumental in pinpointing successive fossiliferous horizons linked to distinct volcanic eruptions. By integrating the geographical coordinates of upright petrified trunks that exhibit their root systems, in conjunction with the occurrences of vitric tuff or lithic tuff, the resultant map was generated (Fig. 6).

The recorded locations (Fig. 6) suggest that the Bali Alonia region contains multiple successive fossiliferous horizons corresponding to various volcanic eruptions.

Discussion

Bali Alonia broader area is characterized by its coverage of quaternary deposits and sparse vegetation, which complicates the mapping endeavors significantly. Comprehensive mapping conducted on Bali Alonia region has furnished substantial evidence for the existence of multiple successive pyroclastic layers that

signify a series of volcanic eruptions.
The excavation activities undertaken by the Natural History Museum of the Lesvos Petrified Forest have resulted in the removal of quaternary deposits and soil profiles, thereby fully exposing the volcanic formations at the excavation sites along the Kalloni Sigri thoroughfare. It is noteworthy that within the confines of "Ioannis Toumpelekis Park" located at the northeastern periphery of Akrocheiras Hill, a minimum of 8 fossiliferous layers have been documented. This finding underscores the notion that the study area is home to numerous successive fossiliferous horizons.
Empirical observations reveal that petrified tree trunks that have fallen are predominantly located at lower elevations, embedded within debris flow deposits, while standing trunks with visible root systems are typically found protruding from tuff layers at higher altitudes. This observed distribution implies that the occurrence of fallen trunks within debris flow deposits does not directly correlate with volcanic eruptions. Rather, these trunks likely represent fragments of previously standing trees that were displaced and subsequently deposited during debris flow events. These flows, influenced by hydrological factors during non-eruptive intervals, transported tree remnants alongside volcanic materials, embedding them within coarse-grained deposits. The consistent vertical and spatial arrangement of standing trunks above fallen trunks is recurrently observed along Bali Alonia broader Area. Consequently, the distribution of fallen trunks in these instances is indicative of prolonged natural transport mechanisms rather than direct volcanism; however, this pattern does not universally apply across the entirety of the study area, as in other locations the distribution of fallen trunks is directly associated with volcanic activity.
Furthermore, the instant correlation of the petrified trunks hosted in the fenced area, the Bali Alonia Park at the West side of the hill, with the numerous trunks at the East of the hill (Fig. 6), it is a subject that demands furthermore research. These occurrences are potentially directly associated with the geomorphological characteristics of the region during the deposition of the Sigri pyroclastic formation and of course will provide very important additional information to the main objective of the current study.
Ultimately, the principal aim of this research represents a subject that warrants extensive further investigation. This preliminary analysis and assessment catalyze a substantial academic discourse concerning the distribution of petrified tree trunks and volcanic tuffs, which contribute to the identification of successive fossiliferous horizons correlated with diverse volcanic eruptions and the evaluation of volcanic episodes that have preserved fossilized forests, initially focusing on Akrocheiras hill and subsequently extending to the broader recognized expanse of the Petrified Forest of Lesvos.

Research Highlights

- Greek travertines are dominated by calcite with aragonite, hydromagnesite, hematite and clay minerals;
- Chemical composition of travertines shows high concentrations of some potentially toxic elements (e.g. As, Ba, Cu, Cr, Ni, Pb, V).

Introduction

Travertine, also known as *Lapis Tiburtinus* by ancient Romans, is a type of "chemically precipitated continental limestone" which consists of calcite or aragonite minerals. (Pentecost, 2005). The precipitation of carbonate minerals occurs primarily through the degassing of carbon dioxide from a groundwater source, resulting in calcium carbonate supersaturation (Pentecost, 2005). The occurrence of travertine deposits has been observed around both cold springs (i.e. tufa or meteogene travertine) and warm-hot springs (i.e. travertine or thermogene travertine), suggesting two distinct origins of travertine. The distinction between these two types of deposit can be determined based on features of parent waters and on the source of CO_2 (e.g. Pentecost and Viles, 1994; Ford and Pedley, 1996). Meteogene travertines are formed from parent waters that are characterized by lower temperature and neutral pH values (7-8). CO_2 has a meteoric and/or biogenic origin and shows carbon isotope compositions that range mostly from about -11 to 0 ‰, reflecting the depleted ^{13}C of soil CO_2 (Deines, 1980). On the other hand, thermogene travertines form from parent waters with high temperatures and lower pH values. The CO_2 in this case has mostly a geogenic source, with a $\delta^{13}C$ range of -4 to +8 ‰ (Pentecost and Viles, 1994), resulting from the interaction between host rocks and deep CO_2-rich fluids, such as mantle fluids or metamorphic decarbonation reactions (Ohmoto and Rye, 1979). In addition, while meteogene travertines display low deposition rates (<10 mmol cm^{-2} a^{-1}), thermogene travertine show very high deposition rate of hundreds of mmol cm^{-2} a^{-1} (D'Alessandro *et al.*, 2007).

An increased interest in studying travertine deposits is driven by their potential applications in paleoclimatic and paleoenvironmental studies, as well as in hydrogeological studies, rock and oil exploitation. Thermogenic travertine deposits also allow for the evaluation of any endogenic processes. Additionally, travertine deposits facilitate the estimation of paleo CO_2 fluxes associated with their deposition (Mancini *et al.*, 2019).

Travertine deposits are widespread in Greece, with the most studied being found in Northern Euboea and Eastern Central Greece. These areas are characterised by a high geothermal gradient, which leads to the presence of several thermal springs. In some of these thermal springs are depositing thermogene travertine, as a result of the cooling and degassing of thermal waters, leading to the rapid precipitation of calcium carbonate (Kanellopoulos *et al.*, 2017 and references therein).

In this research, we present data about the mineralogical and geochemical compositions of 39 travertine samples collected along the whole Hellenic territory from thermal, cold–gas-rich, acidic and hyperalkaline springs, in order to better investigate the possible differences between different type of parent waters.

Methods

Thirty-nine travertine samples were collected along the whole Hellenic territory (Fig.1 and Table 1) from a variety of springs, including thermal, cold–gas-rich, acidic and hyperalkaline springs. Samples were analysed for their mineralogical and geochemical composition. Information on the physico-chemical parameters and the chemical composition of the parent waters were taken from (Li Vigni *et al.*, 2022, 2023).

Samples were, firstly, pulverised in an agate mortar and then, subdivided in two aliquots. The first aliquot was used for the investigation of mineralogical composition by X-ray powder diffraction (XRPD). The XRPD analysis was being carried out at the laboratories of the Department of Earth and Marine Sciences of the University of Palermo, using a PANanalytical X'PERT PRO diffractometer. The second aliquot was mineralized to obtain the chemical composition of the samples. About 100 mg of dried sample were dissolved in a polypropylene bottle with a solution of 1 mL of ultrapure HCl (37%), 0.5 mL of ultrapure HNO_3 (65%) and 50 mL of milliQ water. The obtained solutions were analysed for major cations (Ca, K, Mg, Na, P, S, Si) by Inductively Coupled Plasma Optical Emission Spectrometry

(ICP-OES; Jobin Yvon Ultima 2), whilst 26 trace elements (Li, Be, B, Al, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Se, Rb, Sr, Mo, Cd, Sn, Sb, Cs, Ba, Tl, Pb, and U) were analysed by Inductively Coupled Plasma Mass Spectrometry (ICP-MS; Agilent 7800). Results are expressed as μg g^{-1} of solid. Pre-treatment procedures were carried out at the laboratories of the Department of Earth and Marine Sciences of the University of Palermo, and analysis were carried out at laboratories of the Istituto Nazionale di Geofisica e Vulcanologia (INGV-Palermo).

Results

X-ray diffraction analyses were carried out on 13 travertine samples. The analysis revealed that the main mineral phases show close similarities. The samples are predominantly composed of calcite (Fig. 2), with a very low percentage of aragonite in few samples. Traces of halite and hydromagnesite were also found. Further investigations are underway to verify their presence. Moreover, traces of hematite were found in travertine samples of Mesochori (GR01) and Giotrisi (GR02), whereas traces of clay minerals were found in Archani (GR20).

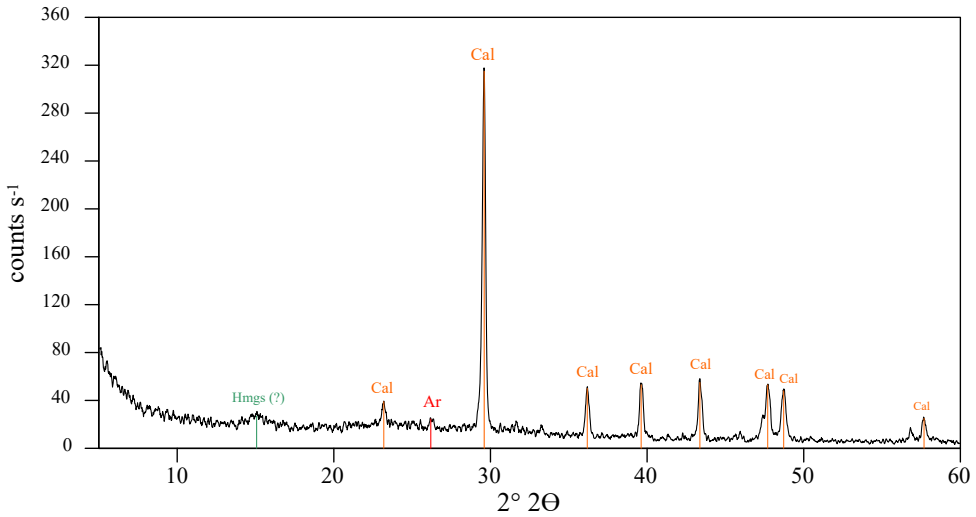

Figure 2. X-ray diffractogram of the travertine sample of Nea Kessani. Hmgs = Hydromagnesite; Cal = Calcite; Ar = Aragonite.

The results of the geochemical analyses are summarised in the boxplot in figure 3, which shows a wide range of concentration, generally, exceeding three orders of magnitude. Calcium is the dominant cation in all the samples,

with concentrations ranging from 94,800 μg g^{-1} to 462,000 μg g^{-1}. The elements can be categorized, based on their median concentrations, into minor elements (Mg, S, Na, Fe, Sr, Si), which show a median values between 1% and 0.1%, and into trace elements (Mn, Ba, P, B, Zn, As, Li, Ti, Ni, Cr, Cu, V, Pb, Rb, Co, Be, U, Cs, Sb, Mo, Se, Cd, Sn, Tl) with median concentrations below to 0.1%.

Thermogene travertine samples of Thermopyles (GR23, GR24, GR25), Ilion (GR26, GR27) and Edipsos (GR37, GR38) have been compared with literature data (Kanellopoulous et al., 2017), showing a similar composition. Elements such as Fe (Thermopyles up to 265 μg g^{-1}, Ilion up to 285,800 μg g^{-1}, Edipsos up to 9280 μg g^{-1}) and As (Thermopyles up to 156 μg g^{-1}, Ilion up to 15,360 μg g^{-1}, Edipsos up to 90.6 μg g^{-1}) displayed concentrations within the range reported by the same authors. According to them, the lithogeochemistry of these ore-bearing travertines reflects the geochemical composition of the parent hydrothermal fluids, which are enriched in Fe and As, particularly in the case of Ilion. The presence of metal(loid)s in thermogenic travertine can be attributed to a primary magmatic source and to reduced and low-sulfidation state of the hydrothermal fluids (Kanellopoulous *et al.*, 2017). However, other travertine samples exhibit enrichment in some metal(loid)s, including Mesochori (GR01), Giotrisi (GR02, GR12) and Skra (GR04).

All these trace elements may be incorporated in the mineral structure of the carbonates substituting for Ca or precipitate as constituents of secondary minerals or be adsorbed onto the surface of the forming crystals or amorphous phases. Therefore, further studies are required to ascertain both the origin and water-rock interaction processes, such as the precipitation of secondary minerals, that took place.

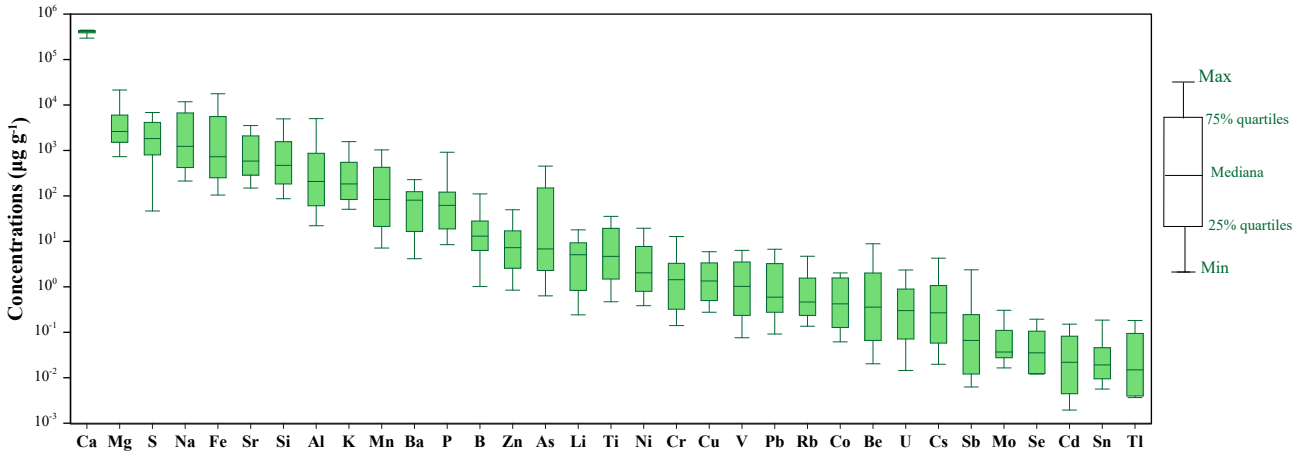

Figure 3. Boxplot of major ions and trace elements of collected travertine samples.

Conclusions

Despite the widespread presence of travertine in Greece, few studies can be found in the scientific literature. Their geochemical and mineralogical characterization may provide important information on water-rock interaction processes, dissolution and precipitation patterns, the origin of CO_2 and the genesis of travertines themselves. These preliminary data show both their mineralogical phases associated dominantly with calcite although traces of aragonite, hydromagnesite, hematite and clay minerals are sometimes found. From a geochemical perspective, calcium is the predominant element. Nonetheless, their chemical composition comprises a large number of trace metals, including some potentially toxic elements (e.g. As, Ba, Cu, Cr, Ni, Pb, V) and some strategical industrial elements like Li and B. Further steps of this preliminary study will be to investigate the relationship between travertine samples and their parent waters in order to better understand water-rock interaction processes.

The Upper Devonian sequence of the Noravank and Ertych geosites in Armenia: stratigraphy and geotouristic potential

Serobyan V.[1], Danelian T.[2], Grigoryan A.[1]

(1) Institute of Geological Sciences of the National Academy of Sciences of the Republic of Armenia, 24A, Marshal Baghramyan Avenue, Yerevan 0019, Republic of Armenia, (2) University of Lille, CNRS, UMR 8198- Evo-Eco-Paleo, F-59000 Lille, France

Introduction / Background

Upper Devonian sequences crop out in the southern part of central Armenia (Fig. 1). They are relatively thick and rich in fossils, especially brachiopods, a fact that has been acknowledged since mid-19th century, at the time of the first geological expeditions in the region by Hermann Abich, considered as “the Father of Caucasian Geology”. Interest on these sequences and their brachiopods was revived after the end of World War II, when at the time of the Soviet Union, extensive stratigraphic and mapping efforts were conducted by the Institute of Geological Sciences of the National Academy of Sciences of the Republic of Armenia. The rich brachiopod fauna was studied by Abrahamyan (1957); it allowed her to recognize a number of stratigraphically succeeding brachiopod assemblages that served as a foundation for the stratigraphic understanding and mapping of the Upper Devonian and Lower Carboniferous sequences of Armenia (Arakelyan, 1964). Following this phase of extensive mapping the sequences were considered as relatively well known. In the framework of the preparation of the IGCP n° 491 meeting (*Devonian Vertebrates of the Continental Margins*), held at Yerevan in May 2005, some identifiable conodonts and chondrichthyan microremains were found in limestones processed by Araiyk Grigoryan (Ginter *et al.*, 2011). However, comprehensive and systematic studies of these Upper Devonian sequences in Armenia, with deployment of modern approaches and techniques, only began in earnest with the launch of the co-tutorial PhD work of Vahram Serobyan, which focused on a revision of the taxonomy and biostratigraphy of the Brachiopods recovered from the Frasnian and lower Famennian sequences of Armenia (Serobyan, 2021).
Previous studies conducted in Armenia and Nakhichevan would suggest that some of the Upper Devonian outcrops could include sedimentary sequences deposited during the late Frasnian and early Famennian interval; however, detailed stratigraphic studies were missing. The Frasnian–Famennian transitional interval bears a particular significance for the evolution of marine ecosystems, since the diversity of the marine biosphere was affected profoundly during the Kelwasser mass extinction event. Although the study of Serobyan (2021) was mainly focused on the brachiopods, it allowed to clarify stratigraphic relationships of the Noravank section, which takes its name from the presence of the famous Noravank monastery constructed on top of the Upper Devonian sequence (Fig. 2). This section was correlated with the better-exposed Ertych section (Fig. 1). The correlations established by Serobyan (2021) were based not only on revised brachiopod assemblages, but also on lithostratigraphy. His PhD study confirmed the interest of these sequences as potentially containing the transition between the Frasnian and the Famennian stages, with the possibility of documenting a regional record of the Kelwasser mass extinction in the Lesser Caucasus. This latter part is currently one of the objectives of the ongoing GREATPAL project (*Deciphering the Global vs Regional record of Environmental chAnges in The PALeozoic mountains of Armenia*), funded by the Higher Education and Science Committee of Armenia. We here present recent biostratigraphic results obtained in the framework of this project and discuss the potential of these sections to become geotouristic destinations in Armenia, especially the Noravank geosite, given that the Noravank monastery is one of the most visited touristic attractions in Armenia.

Stratigraphic and palaeogeographic setting

The Upper Devonian sedimentary sequences in Armenia are over 1,000 m-thick; they represent the earliest part of the depositionary history of the Paleozoic sediments that are present in the region. These sedimentary sequences accumulated in a tropical shallow-water platform that was positioned on the northern margin of Gondwana, facing the Paleotethys to the North. This part of Gondwana was individualized afterwards, during the Triassic, as the South-Armenian Block, after it started migrating northwards as a result of the opening of Neotethys further to its South.
In Armenia, the known Frasnian–Famennian sequences crop out essentially on the flanks of a deep valley that has been formed along the Gnishik river, where the Noravank monastery is located, and on the southern bank of the Arpa river, ca. 8.5 Km east of the village of Areni, near the ruins of the ancient village Ertych (Fig. 1). Both sections display a similar lithostratigraphic succession (Fig. 3) and can be subdivided into four lithostratigraphic intervals. The lower and upper parts of the sections are represented by two distinct carbonate intervals that are composed essentially of marly/sandy limestones. The older (lower) carbonate interval is rich in brachiopods characteristic of the *Ripidiorhynchus gnishikensis–Angustisulcispirifer arakelyani* assemblage zone, which have been directly correlated with the latest early

to late Frasnian interval, based on conodonts characteristic of the *transitans* to late *rhenana* conodont zones (Serobyan *et al.*, 2023). It is stratigraphically overlain by an interval dominated by black shales that are intercalated by relatively thin sandstone beds. They are in their turn overlain by thick mature sandstones, in which we may find occasionally some intercalations of shales. Finally, the younger (upper) limestone interval is also rich in brachiopods characteristic of the *Aramazdospirifer orbelianus–Tornitospirifer armenicus* brachiopod assemblage. Conodonts identified by Ginter et al. (2011) in this limestone interval correspond to the lower Famennian *Palmatolepis crepida* conodont zone.

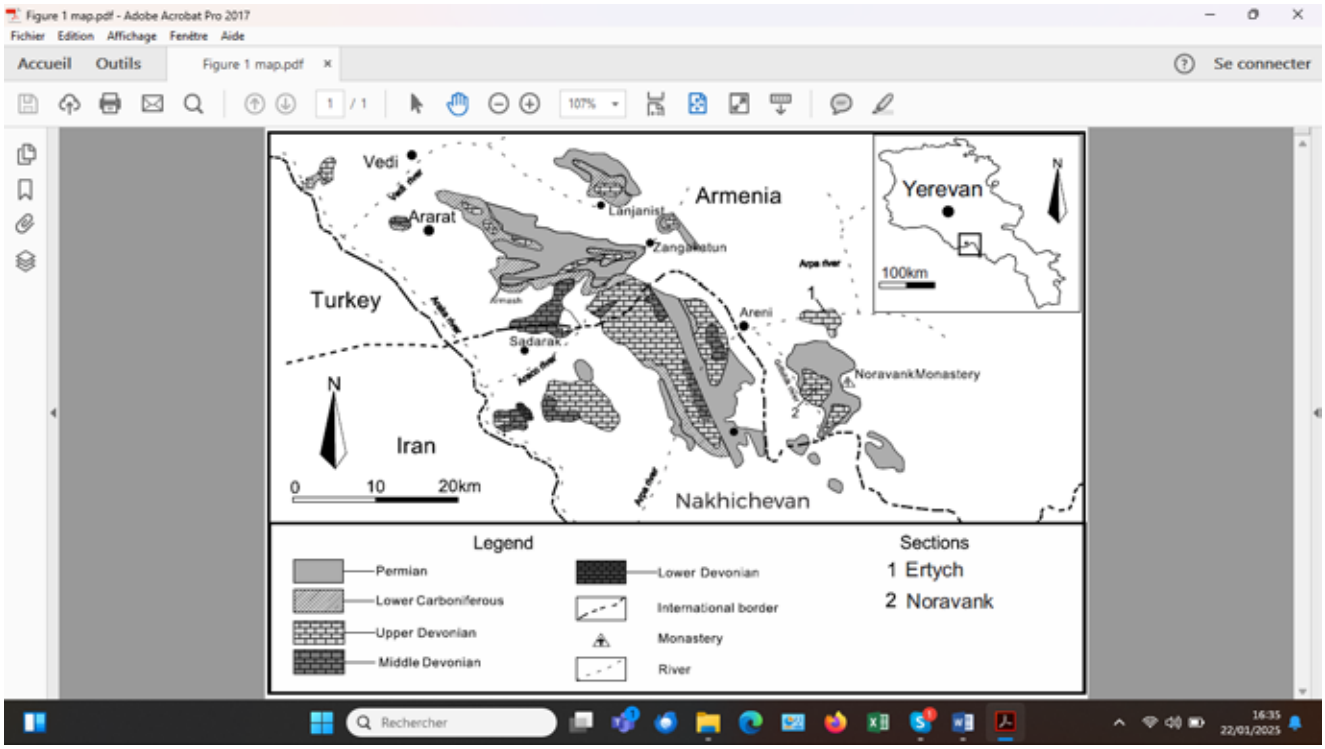

Figure 1. Schematic geological map of the Middle-Upper Palaeozoic sequences in the Lesser Caucasus (Central Armenia and Nakhichevan), with localization of the Noravank and Ertych sections discussed in this study.

Stratigraphy: recent palynological results and correlations

The Upper Devonian sequences of Armenia are indeed rich in fossils; more particularly, they contain a diverse and well-preserved brachiopod fauna (Serobyan *et al.*, 2023). However, they also contain chondrichtyan microremains and conodonts (Ginter *et al.*, 2011), tentaculitides (Vinn *et al.*, 2025), rare bryozoans (Ernst *et al.*, 2024), corals and trilobites (unpublished data). However, since terrigenous siliciclastic sediments, devoid of any carbonate beds, are intercalated between the lower and the upper limestones, the critical Frasnian–Famennian transitional interval has largely remained unzoned. Nevertheless, major biostratigraphic progress has recently been achieved for this interval thanks to the initiation of palynological studies. Indeed, Khachatryan *et al.* (2025) discovered abundant and diverse palynomorphs from the entire terrigenous interval. These authors document for the first time miospore assemblages recovered from eleven samples of the Ertych section. The presence of the miospore species *Teichertospora torquata*, found present in most of the examined samples, suggests that the entire terrigenous siliciclastic interval should be attributed to the *torquata-gracilis* miospore zone, indicating a late Frasnian to early Famennian age. Interestingly, this terrigenous interval contains also the species *Acinosporites lindlarensis*, which corresponds to the spores of the herbaceous lycophyte *Leclerquia*, for which it is well established that it went extinct at the end of the Frasnian. Thus, the miospore record suggests that the age of the black shales and mature sandstones should be limited only to the late Frasnian. In addition, acritarchs, prasinophytes and chitinozoans are also found in the same samples, which establishes that these terrigenous sediments were accumulated in a marine depositional environment (Yeghiazaryan *et al.*, 2025).

Geotouristic potential: where history meets palaeontology, stratigraphy and the topic of mass extinctions

Noravank has an immense historical and touristic significance for Armenia. The geosite hosts a monastery that is composed of a church built initially during the 9th and 10th century. The existing church was re-built during the 12th, 13th and 14th centuries to become the mausoleum of the Orbelian royal family, as it represents one of the most notable monasteries constructed by the Orbelian dynasty.

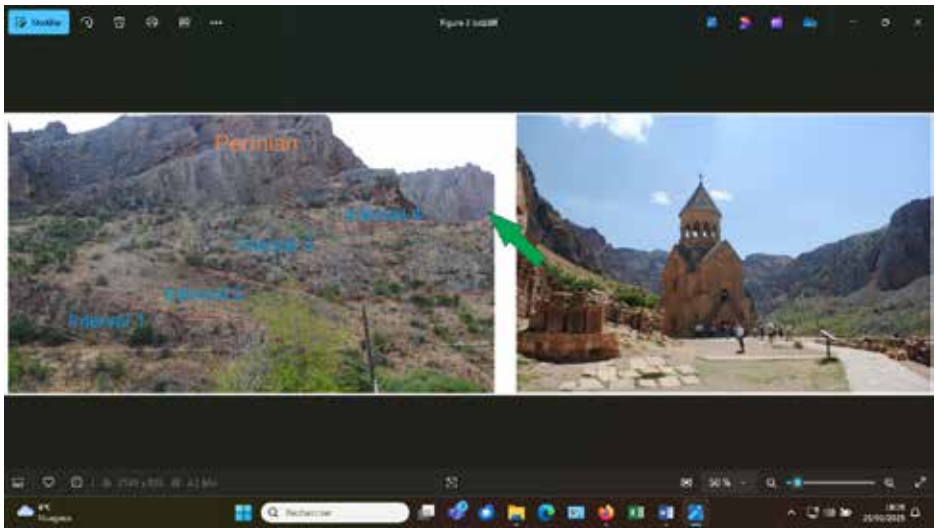

Figure 2. Left: Field photograph of the Noravank section. Right: the Noravank monastery.

The area surrounding the Noravank geosite has been studied since the 19th century by Abich (1858). Born and educated in Germany, he spent most of the time of his life in Russia. He travelled for 30 years different regions of the Lesser Caucasus and more particularly in the current and historic Armenia.

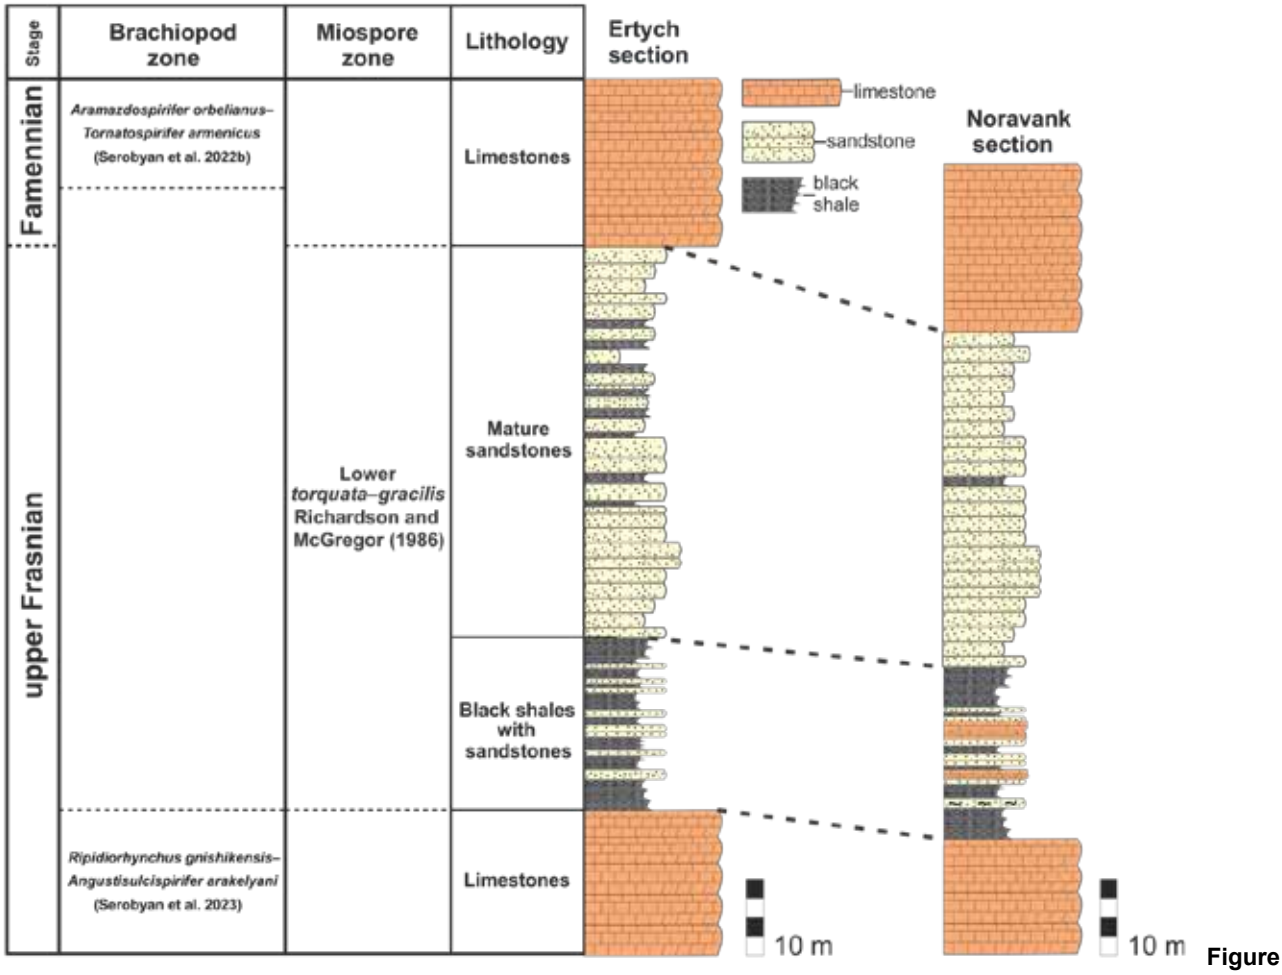

Figure 3. Lithostratigraphic columns and biochronostratigraphic framework of the Upper Frasnian–lower Fammenian sedimentary sequences of the Ertych and Noravank sections.

At Noravank, he found a new brachiopod species, which he dedicated to the Orbelian dynasty, one of the most prominent in medieval Armenia; he named it *Spirifer orbelianus* Abich, 1858. The Orbelian family has had a long-lasting political influence in Armenia and this has been materialized in numerous inscriptions found in different constructions throughout southern Armenia, namely the Vayotz Dzor and Syunik regions. Although Abich did not explicitly mention where exactly he had found the holotype of this species, we believe that it was found in the lower Famennian marly limestones cropping out just below the Noravank monastery (see Serobyan *et al.*, 2022, for more details). During his PhD, V. Serobyan re-examined new specimens of this species (Fig. 4), which he collected from the type locality (the Noravank section). He studied the internal structure of this brachiopod species based on numerous serial thin sections. He found out that this species should be assigned to a new genus, which he introduced under the genus name *Aramazdospirifer*, in honor of Aramazd, the chief god in pre-Christian Armenian mythology. It is obvious that all these palaeontological and stratigraphic elements are of great potential interest for a touristic visit. The Noravank, but also Ertych geosites, may be considered as open-air geological museums for tourists interested in geoeducation.

Marble as an educational fabric interweaving cultural and geological heritage, the case study of ancient Philippi site rock art, Kavala, Greece

Sideridis A.[1], Koutsoumpis E.[1], Mytakidou K.[2], Boumpouka M.[3], Anevlavi V.[4], Rousopoulos P.[5]
(1) Krinides Gymnasium, Kavala, Greece, alkisside@sch.gr (2) 4th Gymnasium of Kavala, Kavala, Greece (3) 1st elementary school of Nea Peramos, Kavala, Greece (4) Austrian Archaeological Institute, Austrian Academy of Sciences, Vienna, Austria (5) Kupa Ceramics, Kavala, Greece

Introduction

The educational system is dealing with ever-changing classrooms in constant need of contemporary teaching methodologies. Due to technological advancements and changes in the perception of the world, students are not efficiently responding to traditional teaching methods. Most prefectures in Greece combine both interesting Geology and Archaeology and these make up for great educational tools, especially when combined with alternative teaching methods and an interdisciplinary approach. As detailed below, the paradigm of the ancient Philippi site will be presented.

Geology of Ancient Philippi site

The area around the Philippi site belongs to the Rhodope massif and, more specifically, to the lower tectonic unit (Pangaion unit). The latter consists of marbles, gneisses, schists and amphibolites of upper greenschist-lower amphibolite metamorphic facies (Eleftheriadis and Koroneos, 2003; Papanikolaou and Panagopoulos, 1981) and later underwent retrograde greenschist metamorphism (Mposkos and Liati, 1993). NE of the archaeological site (Figure 1A, B, C), small occurrences of the Philippi middle Oligocene granitoid intrude in marbles and gneisses of the Pangeon unit (Tranos et al., 2009), inducing local contact metamorphism. The Philippi Plain comprises quaternary sediments. Local geo-materials such as clay, granite and coarse-grained marble were used in the ancient Philippi site. Marbles from Thasos and ophicalcite from Larissa have also been used.

Historical background

Philippi's inclusion on the UNESCO World Heritage list in 2016 underscores the site's cultural and archaeological significance (Delev, 2018). These monuments, comprising relief images, etchings, inscriptions, and niches, have historically been documented on the acropolis slopes (Figure 1C, D). The predominant depiction among these carvings is a youthful huntress, commonly identified as Artemis/Diana (Figure 1D), which suggests an emphasis on themes of popular religion from the Roman era (Graml et al., 2024). The origins of these carvings, however, extend beyond the Roman period. Some are attributed to the Thracian Hedones tribe, dating from the Late Bronze Age to the Early Iron Age (Dimitriadis, 2008). Despite the rise of Christianity in the region, many of these pagan carvings persisted, reflecting the endurance of earlier religious traditions (Abrahamsen, 1988).

Educational methods and results

Regarding the subject of Geology-Geography in public Greek schools, this is only being taught sparsely in primary schools and for two years in middle school, a time not sufficient to ingrain basic geoscience concepts with the current educational form. Considering the needs of a classroom consisting of Generation Z and Alpha students (born between 2012-2018) the following methods have been adapted: a) Interdisciplinary education (subjects of technology, arts, history), b) Education Through Art and Storytelling, c) Nature-Culture Trails and d) Working groups and reverse classroom (Politis, 2019). This methodology is based on the environmental projects of the Philippi Centre of Environmental and Sustainability Education and was modified to meet the needs of the students. A trail was planned leading to the site. Along the way, students were introduced to the local geology, identifying lithologies and understanding their physical properties and potential uses. Reaching the site and the rock art monuments, students either etched or photographed the carvings and listened to stories related to rock art. Moreover, they tried to identify the lithologies within the Philippi site and discuss rock-provenance and uses. In the classroom, students working in teams tried to interpret the carvings and produce their own rock art on pieces of clay, inspired by their everyday life. The questionnaire results demonstrate that students were able to better grasp the geological and local history and make links between the local geology and other disciplines such as technology, commerce, and architecture. More importantly, they developed their environmental consciousness through the environmental trail and interaction with nature. Art proved to be an effective method for increasing student engagement while nurturing fine motor skills.

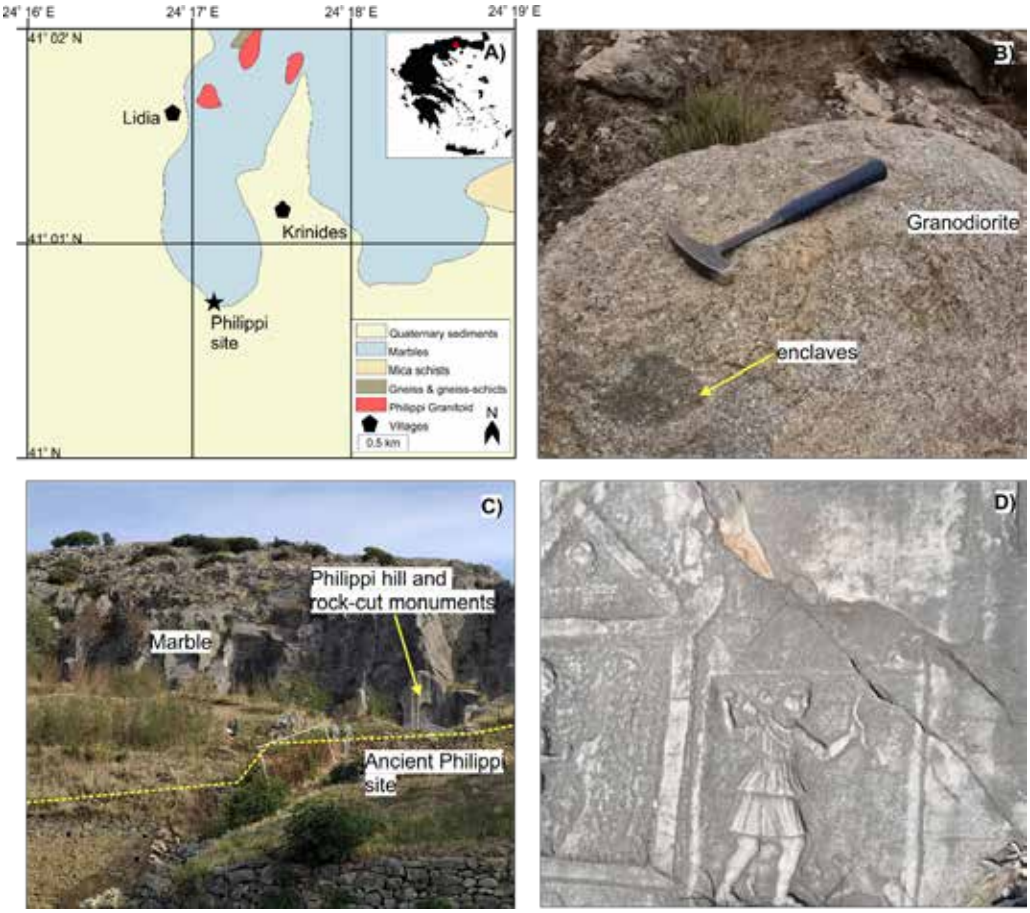

Figure 1 A) Simplified geological map of the studied area; B) Granodiorite occurrence adjacent to the site of Philippi; C) 'Contact' between the natural environment and the ancient Philippi site; D) relief image of hunting Artemis.

Conclusions

To conclude teaching of geosciences can make use of the following methods: a) Interdisciplinary education, b) Education Through Art and Storytelling, c) Nature-Cultural Trails and d) Working groups and reverse classroom. Better engagement, interdisciplinary and syllogistic reasoning, introduction to sustainability and differentiated expression through art are a few of the outcomes. The adapted plan is especially feasible for schools in the Greek countryside that have archaeological sites in their vicinities.

First record of pockmarks in the North Aegean Trough

Sklavounaki P.[1], Tzafaridi V.[1], Hasiotis T.[1], Missias S.[2], Paleokrassas A.[2]
(1) Department of Marine Sciences, University of the Aegean, Mytilene, Greece, mar21053@marine.aegean.gr, (2) Akti Engineering, Piraeus, Greece

Research Highlights

Discovery of small depressions in the North Aegean Trough that probably contribute to the Limnos oil seep cluster

Introduction

Pockmarks are crater-like depressions of the seafloor where underlying fluids in the sediment pores escape to the water column. They have been discovered in numerous environments all around the world: in shallow areas, along continental margins, and in deep environments (Judd and Hovland, 2007), even in lakes (i.e., Toker and Tur, 2021). The records of pockmarks in Greece are numerous as well (Papatheodorou *et al.*, 1993), mostly found in shallow areas, like the pockmark fields in Patra and Corinth gulfs (Christodoulou *et al.*, 2003). During a marine survey for the laying of a power cable between Thrace and Limnos Island, numerous small depressions resembling pockmarks were discovered along a narrow corridor in the North Aegean Trough (NAT) (Figure 1a,b). NAT is a main geotectonic and morphological feature in the North Aegean Sea. It has a complex bathymetry containing three main basins (Limnos, Athos and Sporades). The tipping point of the most important fault system that characterizes the region, the dextral strike-slip fault known as the North Anatolian Fault (NAF), is differentiating the SW part of the NAT (Sporades and Athos basins) from the NE part of the NAT (Limnos basin) (Sakellariou *et al.*, 2016). The basins have small dimensions and steep slopes, and they are isolated and separated from each other by bathymetric highs (Roussakis *et al.*, 2004). The bathymetric high between Athos and Limnos Basins is the area under consideration for this study. Recently, Jatiault *et al.* (2024) discovered numerous oil seeps in the wider NAT region probably related to leakage from the broader fault system (Figure 1b). The western part of NAT (to the west of north Limnos), including the survey area, was mapped by Papanikolaou *et al.* (2002), however, pockmarks were not discerned. Thus, the objective of this study is to describe the distribution, morphology, size and density of the observed depressions and examine their potential relation with the oil seeps reported by Jatiault *et al.* (2024).

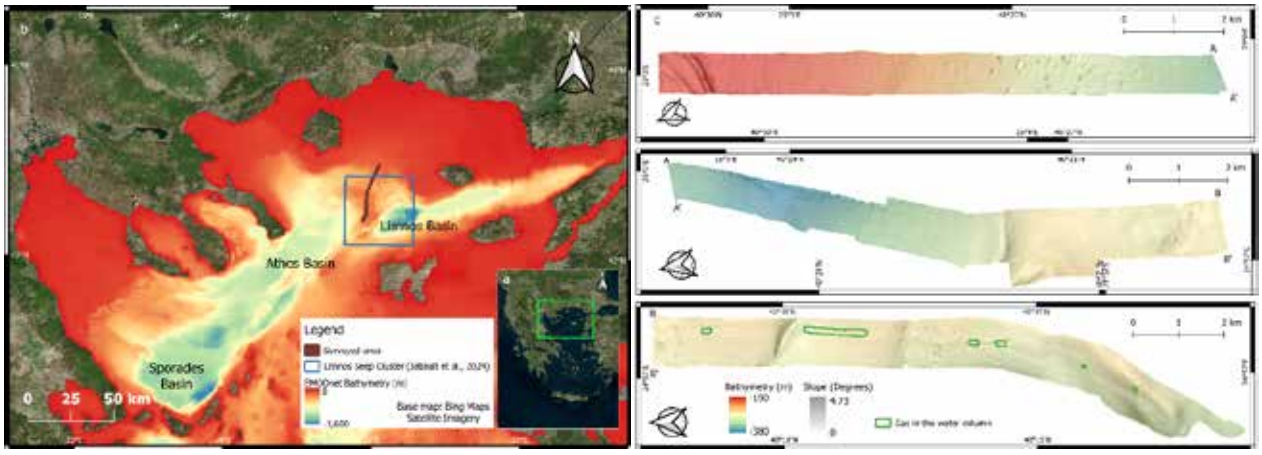

Figure 1. (a) Location of the broader study area (in green), (b) general bathymetric map of the North Aegean and location of the surveyed area (brown line) and of the Limnos seep cluster (blue box) studied by Jatiault *et al.* (2024), (c) bathymetry of the surveyed area overlaid by slope (selected layer transparency: 40%), clipped to 3 subregions for better visualization.

Methods

The survey was conducted during June 2024, along a corridor that was pre-selected by the Independent Power Transmission Operator (IPTO) of Greece, to pass along a bathymetric high in-between Limnos and Athos basins, so as to limit the depth of cable laying and burial. The distance between the survey lines was approximately 250 m. For bathymetry an R2Sonic 2026 (170-450 kHz) multibeam echosounder (MBES) was used. A Valeport Midas profiler was utilized for sound velocity profiles. Data acquisition was performed using the NaviScan and R2Sonic controller software packages. For the morphological survey, an EdgeTech 2050 Side Scan Sonar (SSS) was deployed, able to

scan simultaneously the seafloor with a lower (230 kHz) and a higher frequency (540 kHz). A Sonardyne Ranger-2 USBL system was used for the towfish position. Survey speed was maintained at approximately 3-4 knots. Subbottom profiler records and sediment cores were also collected but are not presented in this study. MBES processing was performed utilizing EIVA, whilst for the SSS data processing and analysis and the production of high-resolution georeferenced sonar mosaics (pixel size of 0.25 m), the Chesapeake Technology SonarWiz software was used. QGIS was used for (i) mapping purposes (bathymetry cell size of 1 m), (ii) the descriptive measurements of the depressions, (iii) slope extraction and (iv) the creation of shaded relief imagery.

Results

Water depths in the study area range between 194 and 373 m. The northernmost part of the surveyed area is relatively shallow but gradually towards the south, the depth increases, reaching its maximum value (Figure 1c) with the deepest region occupying only a small part of the corridor. After this area and towards the southernmost part of the surveyed area, the depth is maintained at approximately 260 m. Slopes gradients are mild, not exceeding ~4.5°.

Throughout the surveyed area, numerous depressions were easily observed. Most of the pockmarks appear in the northern and southern parts of the surveyed zone, whilst along the deepest part depressions rarely occur. A total of 136 depressions were recognized and mapped (Table 1). Although relatively small (average spatial extent of ~1830 m^2) and shallow (1-3 m deep) they appear in a variety of shapes, and they were categorized following the definitions of Judd and Hovland, (2007) for pockmark morphologies. 90 resemble “asymmetrical pockmarks”, lacking a well-defined rim, something that made their recognition difficult in the bathymetric maps. 40 were categorized as “well-defined circular”, and 6 appeared as “composite pockmarks”, implying merging of two or more smaller depressions.

Table 1. Summary of pockmarks’ main characteristics.

	Minimum	Maximum	Average
Occurrence water depth (m)	197	370	282.4
Pockmark depth (m)	1	3	1.3
Perimeter (m)	15.8	675.8	149.9
Area (m^2)	16.6	21414.9	1831.2

The SSS records revealed a uniformly low reflectivity seabed, which indicates the presence of fine-grained sediments. Abundant crossing longitudinal marks suggest intense trawling fishing creating sharp scars on the soft seabed. Upon comparing the pockmarks detected in the bathymetric data with the SSS observations, it was evident that numerous depressions observed in the bathymetrical survey were not observed in the morphological survey, and SSS navigation errors produced discrepancies in the pockmark positions. Thus, unlike the bathymetric data, the SSS images discerned only 104 pockmarks, 28 in both SSS frequencies, 53 only in the low frequency, 11 only in the high frequency, whilst for 12 only low-frequency data were available, thus they could not be compared with the higher frequency information that was missing. Also, along specific areas towards the southern part of the surveyed area, anomalous reflections were recognized in the water column of the SSS records, probably due to fluid seepage (Figure 1c).

Jatiault *et al.*, (2024) studying Sentinel-1 data, reported oil seepage on topographic highs located west of Limnos trough and close to the NAF that coincides with the area under consideration. Fluid leakage was attributed to upward fluid migration through the local fault zone that displaces the shallow sedimentary structure.

Discussion and Conclusions

The study area is located within a topographic high of NAT, separating Limnos and Athos basins and has depths that do not exceed 370 m. The observed pockmarks are so far the deepest observed in the Greek maritime region, even if they have small dimensions. It must be mentioned that since the surveyed corridor spreads only for 1.1-1.2 km, pockmarks are obviously expected to occur in the wider area. This is also supported by the fact that the Limnos oil seep cluster (Jatiault *et al.*, 2024) extends over ~40 km, in water depths ranging from 140 to 1200 m. Leakage in the water column is fueled through faults from deeper sedimentary strata, however, fluid seepage may also take place through pockmarks, and this process might have likewise contributed to their formation. Yet, the fact that leaking fluids in the water column, as observed in the SSS images, were not detected over the entirety of the pockmark field, possibly indicates that seeping activity through pockmarks is sporadic, and that probably only some of the observed pockmarks contribute to the fluid leakage in lower concentrations. Although the wider area is characterized by relatively high sedimentation rates (Roussakis *et al.*, 2004) the topographic high where pockmarks occur probably corresponds to an area of lower sediment accumulation rates, thus ensuring the more stable conditions also needed for pockmark formation (Judd and Hovland, 2007). Finally, at least the surficial sediments are fine-grained, as observed in SSS images, a fact that contributes to the variety of pockmark morphologies that can be found in certain fields (Judd and Hovland, 2007).

Introduction

Nowadays, global environmental regulations require industrial production to align according to principles of sustainable development. In cement industry it consists of priority, since optimizing raw material use and energy efficiency are crucial for reducing environmental impact. Limestone is a key raw material in cement production, primarily serving as a source of calcium carbonate (CaCO□) for clinker formation. Its mineralogical composition and structural characteristics significantly influence both grinding efficiency and thermal behavior during calcination (Nuhu et al., 2020).

This preliminary study focuses on the petrographic characteristics of different limestone types and their effects on the critical stages of grinding, calcination and clinker formation. A deeper understanding of these variations enables a more targeted selection and design of the initial raw material mixture, improving grinding and calcination efficiency as well as ensuring a stable, high-quality clinker product. Such improvements can lead to reduced production costs, lower energy consumption, and enhanced process control, all contributing to a more sustainable cement manufacturing process.

Materials and methods

This study consists of part of a project in progress in cooperation with TITAN Cement Company S.A. (Drepano plant, Patras, Greece). Under this project rrepresentative limestone samples were collected from the quarries of the company in Drepano, Achaia. These samples, were delivered from TITAN to the Department of Geology, University of Patras, in order to be studied regarding their mineralogical and petrographic characteristics.

The characterization of the samples was conducted by the following techniques and methodology:

- XRD (X-ray diffraction)

The mineralogical analyses of the studied samples were carried out by an X-ray diffractometer, Bruker D8 Advance type, equipped with a copper cathode with nickel filter and fast, high-resolution detector (Lynxye). The scan area was in the range of 2–70o 2θ, with a resolution step of 0.3 s / 0.015o. Before the analyses, the powdered samples placed in the special container and flattened by a glass in order to ensure uniform surface. Identification of these phases was done using DIFFRACplus EVA12® software (Bruker-AXS) and the accompany ICDD Powder Diffraction, PDF- 2 2006, EVA database, which compares the data to a database of known crystal phases. The semi-quantitative analysis was performed using the TOPAS 4.0® software (TOPAS MC Inc., Oakland, CA, USA), based on the Rietveld method. Finally, ccorrections of the semi-quantitative results were performed by chemical analyses.

- Petrographic microscope

A Leitz Ortholux polarized light petrographic microscope was used for the petrographic study of the samples, while thin sections of representative samples were prepared for observation.

- SEM (Scanning electron microscope)

A JEOL 6300 SEM was used to observe the microstructure and perform microanalyses. The microscope is equipped with an X-ray Energy Dispersive Spectrometer (EDS), which was utilized for elemental analysis. The analyses were performed on carbon-coated thin sections.

Results and discussion

Mineralogical study

During the analyses of limestone samples using XRD, the amount of calcite ranges from 88% (sample 3) to 97% (sample 4), (Figure 1, Table 1). Additionally, small amounts of quartz (max of 8% in sample 3) were detected, along with low amounts of clay minerals and opaque in the detection limit of technique (max 4% in sample 3), (Figure 1, Table 1)

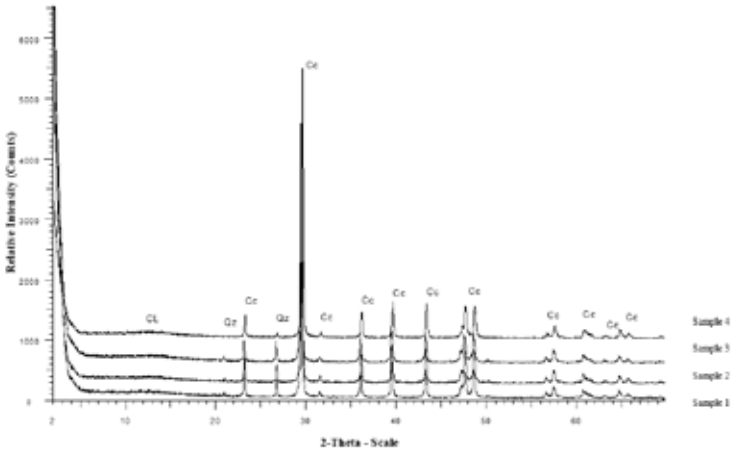

Figure 1. X-ray diffractogram of limestone samples.
Abbreviations: Cc: Calcite, CL: Clay, Qz: Quartz.

Table 1. Qualitative and semi-quantitative phase analysis results obtained through Rietveld refinement, with corrections based on chemical analyses, for the analyzed limestone samples. GOF Good of Fitness (GOF) is 1.25 and error is below 1%.

Mineral phases / Samples		Sample 1	Sample 2	Sample 3	Sample 4
Calcite	**$CaCO_3$**	91%	93%	88%	97%
Quartz	**SiO_2**	6%	4%	8%	2%
Clay/Opaque	**Al-Si minerals/ Fe oxides or hydroxides**	3%	3%	4%	tr*

Abbreviation: tr: traces

Overall, considering the results and the potential impact of impurities in the primary limestone material, such as silicate, clay minerals and opaque, sample 4 exhibits the purest calcite composition in contrasts to sample 3, which contains the highest percentage of quartz and opaque minerals (such as oxides and hydroxides, see Table 1), is the least favorable raw material for cement.

Petrographic study

Examination of the samples under a petrographic microscope proves that these are sedimentary rocks classified as biochemical limestones.

Figure 2. The analyzed limestone samples (Sample 1, Sample 2, Sample 3, Sample 4).

Sample 1 shows micritic to microsparitic and locally oolitic texture (Figure 3). Carbonate veins with sparitic material

are sometimes partially oriented. Also, porosity is low in the form of mostly individual pores. The shape of the crystals is hypidiomorphic to anhedral. Minerals that prevail in this sample are calcite with accompanying minerals of quartz, muscovite or other clay minerals and opaque (as iron oxides/hydroxides) in low percentages.

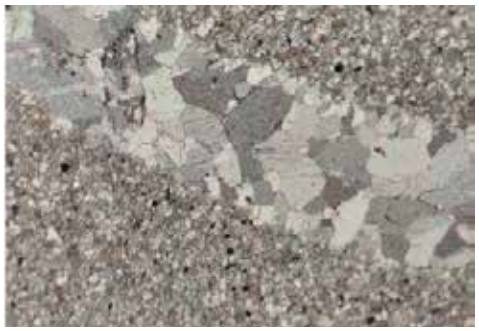

Figure 3. Microstructure in the polarizing microscope of sample 1 (Nicols vertical with magnificence 100x). Sparitic vein with isometrical calcite crystals developed in a mainly micritic microstructure.

Sample 2 exhibits micritic to locally oolitic texture. Moreover, sparitic veins and microveinlets filled with hypidiomorphic to adhedral grains occur (Figure 4). Porosity is low and sometimes capillary channels (i.e. microcracks) appear. The primary mineral in this sample is calcite, and it coexists with minor amounts of quartz, muscovite and plagioclase.

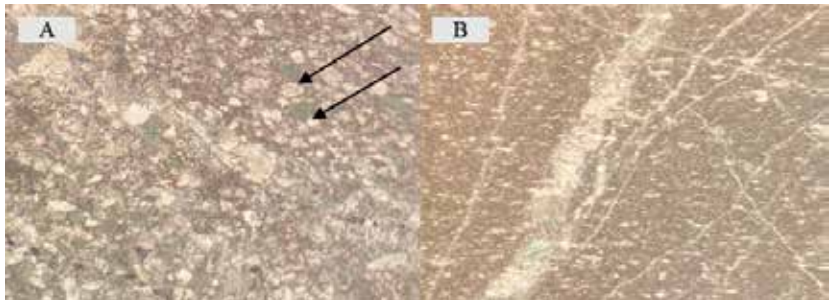

Figure 4. Microstructure in the polarizing microscope of sample 2 (Nicols vertical with magnificence 100x). A. Locally oolitic texture (spheroidal shaped grains). B. Micro veinlets filled with carbonate material of sparitic texture within a micritic main mass.

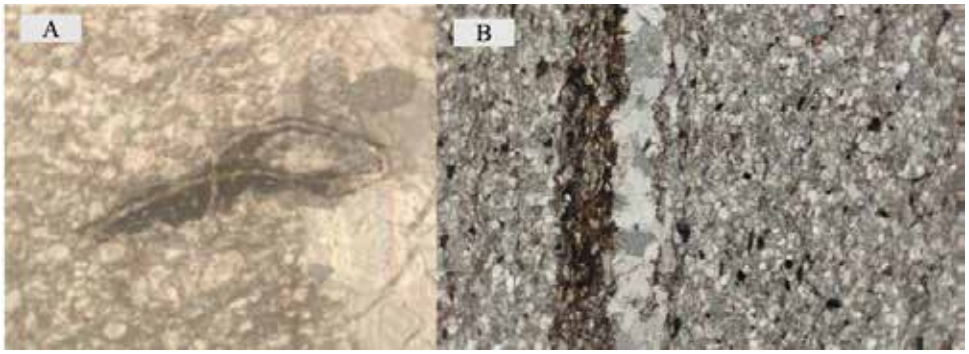

Figure 6. Microstructure in the polarizing microscope of sample 3 (Nicols vertical with magnificence 100x). A. Presence of fossil material. B. Sparite vein composed of calcite and opaque minerals. Polarization colors range from brown and red-brown to black, corresponding to calcite, clay minerals, and opaque phases. Gray coloration is associated with silicate minerals, including quartz and feldspars.

Sample 3 is characterized by micritic texture, locally oolitic, with the presence of scattered veins (Figure 5). The

porosity forms capillary-shaped or even larger channels. The presence of opaque minerals, partially in an oriented distribution, is common. The primary minerals of this sample are calcite, while feldspars, microcrystalline quartz and muscovite appear more often than in the other samples. Opaque, most iron oxides and some fossils are observed too (Fiure 6).

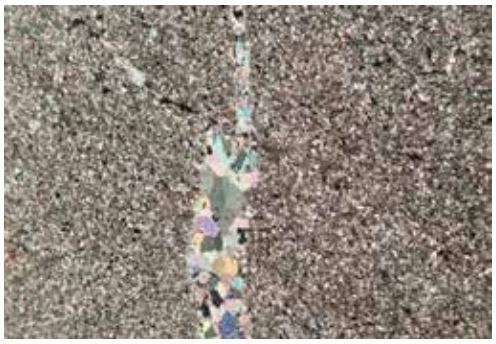

Figure 5. Microstructure in the polarizing microscope of sample 3 (Nicols vertical with magnificence 100x). Presence of sparitic vein in a micritic mass with calcite.

Sample 4 appears a more homogeneous mineral composition and microstructure compared to the others. Specifically, it is appeared fine-grained with a micritic to locally oolitic texture and low porosity. The mineralogical composition consists of calcite and low amounts of quartz. However, micro-areas filled with carbonate material and veins of various sizes and orientations were identified.

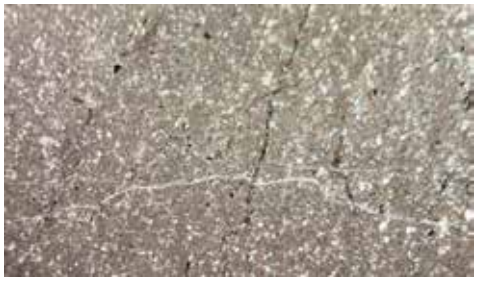

Figure 7. Microstructure in the polarizing microscope of sample 4 (Nicols vertical with magnificence 100x). Homogeneous microstructure with micritic texture.

Influence of petrographic characteristics of limestone to the grinding and calcination processes

Grinding and calcination are critical processes in cement production and are significantly influenced by the physical and mineralogical characteristics of raw materials (Soltan & Serry, 2011). Understanding these characteristics is essential for the optimizing processes in cement production regarding the energy cost, environmental impact in accompany with the quality of final product. The main mineralogical and petrographic features of the limestones, along with their potential effects on the two crucial parameters mentioned above, are summarized in the table below (Sousa, 2021).

The desired characteristics for grinding are:

- **Micritic texture**: It is the fine-grained texture of the calcite material, which facilitates the milling process, as the smaller and uniform crystal sizes require less milling time.
- **Reduced number of veins:** Micro micritic veins contribute less to the inhomogeneity of the structure than the larger ones or/ with the occurrence of veins filled with sparite (He et al., 2022).
- **Homogeneous structure and mineralogical composition:** A uniform distribution of fine-grained structure and minerals are expected to promote the efficient of grinding. Moreover, homogeneity would positively influence some crucial parameters such as hardness and plasticity. Minor amounts of quartz, opaque minerals, feldspars, and soft phyllosilicates are not expected to affect significantly the process.

Likewise, for calcination:

- **Micritic texture – microcrystalline:** Having a fine-grained and microcrystalline texture facilitates uniform heating and consistent sintering performance.
- **Reduced number of veins:** The reduced presence of veins limits the possibility of uneven heating and the occurrence of failures in the material during the firing process (He et al., 2022).
- **Homogeneous structure and mineralogical composition:** The stable structure and uniformity in mineral composition ensure isomeric heating and predictable reactions, which is critical to creating high-quality end products.
- **Fossils:** The presence of fossils of a non-calcic composition is not desirable because it can affect the thermal behavior of the material and lead to inhomogeneities or to the formation of undesirable by-products during firing.
- **Porous in the form of channels:** Having pores in the form of channels can favor heating as it facilitates air circulation, improving calcination efficiency (Freire-Gormaly et al., 2015).
- **Impurities of other minerals:** Low percentages of quartz and opaque minerals could have a positive or neutral effect during

the firing process (Sandström et al., 2024).

Based on the above characteristics, the analyzed samples are categorized and presented in Table 2. In particular, the sample 4 presents the smallest grain size, the most suitable mineralogical composition and high homogeneity of microstructure. Micro veinlets, porosity or even fossils are sometimes present in the microstructure but they do not alter significantly the prevalence of the micritic texture.

Sample 1 exhibits the desired characteristics in terms of grain size, mineralogical composition and homogeneity, although it falls slightly short compared to sample 4. The micritic texture is satisfactorily developed. It has high porosity and a small percentage of veins, but the presence of fossils is more rare compared to that in sample 4.

Sample 2 has a relatively fine grain size but exhibits significant heterogeneity, which may cause issues during processing. The predominance of sparitic texture makes it less desirable, as its involvement in the formation of new phases is expected to be delayed. Its relatively high porosity may contribute to improved combustion efficiency.

Sample 3 has characteristics that place it lower in the overall evaluation. Even it exhibits the lowest porosity and contains few fossils, it is the most heterogeneous in terms of grain size and mineralogical composition. Although it displays veins less frequently than the other samples, the larger grain size of its mass may prolong the heating time or potentially cause inhomogeneity during calcination.

Table 2. Summary table including the most favorable characteristics for cement production observed for each limestone sample.

Grain Size	Mineralogical Composition	Homogeneity	Micrite-Sparite	Veins	Porosity	Fossils
Samples	4, 1, 2, 3	4, 1, 2, 3	4, 1, 3, 2	4, 1, 3, 2	3, 1, 4, 2	3, 4, 2, 1

Conclusions

- Sample 4 is the purest compositionally with the most homogenous structure of predominantly micritic character, while porosity channels and veins of carbonate material are present in its structure.
- Sample 3 is the most mineralogically inhomogeneous with microsparitic main texture. In addition, it presents the highest percentage of quartz, opaque minerals and porosity in the form of channels.
- Samples 1 and 2 appear an intermediate mineralogical composition compared to the above, low porosity in the form of isolated pores and microsparitic-micritic oolitic texture.
- Sample 4 is considered as the most favorable material, as it gathers the most desirable characteristics. It is followed by samples 1, 2 and 3 in terms of suitability.

Although no significant differences were observed in the suitability of the different limestone types for cement production, variations in their grinding and calcination behavior could impact energy consumption, cost, and time during production, as well as clinker phase formation. More homogeneous raw materials, in terms of texture and mineral composition, are expected to facilitate grinding and reduce energy and time consumption. These characteristics also promote sintering, enabling more efficient phase formation.

Despite their general suitability, micro-scale differences in the limestones may influence the final material properties and should be considered. Ongoing experiments on clinker production from different raw materials and grinding processes will further optimize raw material mixtures and process parameters, with results to be presented in a future work.

EXTENDED ABSTRACT 290

The role of the epikarst zone in the influx of water and the manifestation of humidity at the Holy Monastery of Kleiston, Mount Parnitha, Attica, Greece

Skourtsos E[1], Filis, C.[1], Vassilakis, E.[1], Konsolaki, A.[1], Kotsi E.[1], Lekkas, E.[1]
(1) National and Kapodistrian University of Athens, Department of Geology and Geoenvironment, Athens, Greece

Introduction

The epikarst zone represents an essential facet of karst landscapes, positioned at the boundary between the soil and the underlying bedrock. This area, distinguished by its high porosity, plays a significant role in the hydrology and ecology of karst systems.

Originally defined by Mangin (1974), the term “epikarst” has undergone a nuanced evolution in its interpretation. Williams (1983) characterized it as “subcutaneous”, highlighting its importance as the karst morphology of the rock layer directly beneath the soil. As noted by Bakalowicz (2004), the epikarst can be envisioned as the “skin” of the karst system, implying its function as a protective and interactive layer that governs water infiltration, drainage, and the overarching dynamics of the karst environment.

At the Holy Monastery of Kleiston which is situated on Mount Parnitha in Attica, localized points of water and humidity intrusion manifest in several buildings and functional spaces, particularly during the winter months and following rainfall of considerable intensity and/or prolonged duration, as well as snowfalls. The issues of humidity display greater persistence, even becoming evident in the summer months. The localized sites of water and humidity intrusion include the following:

- The Catholicon of the Holy Monastery of Kleiston (Holy Monastery of the Dormition of the Theotokos).
- The storage facility of the Holy Monastery of Kleiston, located within a cavern (to the north of the Catholicon).
- The building of the cells situated immediately before the entrance to the Catholicon (to the south of the Catholicon).
- The edifice housing the old cells of the Fathers, in addition to various common areas (the reception hall, the dining room, the kitchens, etc.) (to the east of the Catholicon).
- The Church of the Holy Cross.

This work outlines the epikarst in the region of the Holy Monastery of Kleiston, and analyzes its role in the aforementioned phenomena of water and humidity intrusion.

Morphology and Geological Setting

The Holy Monastery of Kleiston is situated within the gorge of the Giannoulas stream, which divides the mountainous mass of Strati to the west from the peaks of Korifoula, Koromilia, and Alogorachi to the east. The gorge has an average orientation from north to south and features steep slopes primarily composed of carbonate rocks. These steep to nearly vertical slopes attain heights of up to 400 m. The Monastery is founded on the edge of a narrow “terrace” on the western slope of the valley, at an elevation of 450 m, rising approximately 80 m above the valley floor.

The region of Monastery is composed of geological formations belonging to the Sub-Pelagonian or unmetamorphosed Pelagonian Unit (Dounas, 1971; Katsikatsos et al., 1986). Specifically, it comprises clastic and volcanic rocks from the Upper Paleozoic to the Lower Triassic (P-Ti.tf), as well as limestones and dolomites dated Lower Triassic to Lower Jurassic (Ti-Ji.k,d).

The lower stratigraphically volcanosedimentary formation exhibits an elongated outcrop that originates to the north of the Monastery, passes west of it, and is observable along the road leading to it. This consists of keratophyres and keratophyric tuffs, sandstones, and argillaceous schists. The thickness of the formation varies from 10 m near the Church of the Holy Cross and reaches 50 to 60 m to the north and south of the Monastery.

The carbonate rocks consist of platy to thick-bedded, locally massive limestones dolomitic limestones and dolomites. The upper strata are mainly thin-bedded to platy carbonates with intercalations and nodules of chert.

To the north-northwest of the Monastery, the appearance of the volcanosedimentary formation is obscured by debris and scree (H.cs,sc) composed of breccias and carbonate blocks of various sizes. This formation originates from the overlying limestones, where carbonate fragments were dislodged from their original positions-potentially due to erosion-and subsequently rolled downstream.

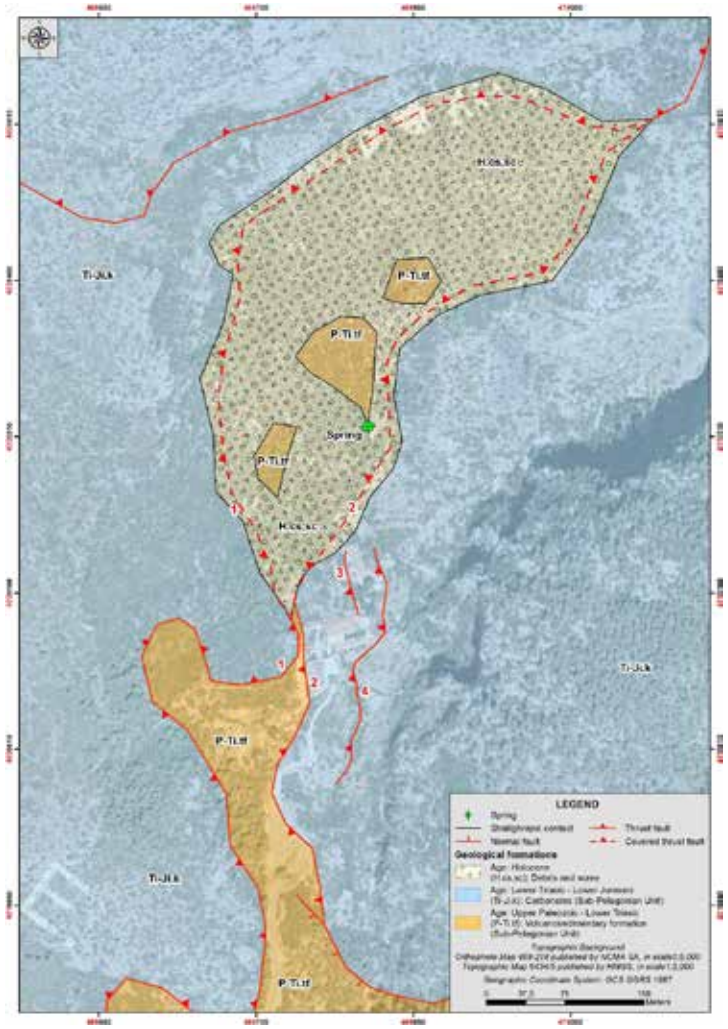

Figure 1. Geological map of the area of the Holy Monastery of Kleiston.

The formations of the Sub-Pelagonian Unit are in contact with one another via reverse faulting (thrusts) and steep normal faults, resulting in the lower clastic formations being thrust upon and overlain by the carbonate rocks. This deformation can be attributed to at least two tectonic episodes, one during the Middle Jurassic to Lower Cretaceous and another during the Middle Eocene to Lower Miocene. Subsequently, steeply dipping normal to oblique-normal faults led to the fragmentation of the earlier structures, constituting a third tectonic episode, which remains active in the broader region to this day (e.g., the Fili earthquake).

Through detailed mapping in the vicinity of the Holy Monastery of Kleiston, the following tectonic contacts were identified:

- Upper thrust (No 1, Figure 1 & Figure 2), which places the carbonate rocks above the volcanosedimentary rocks. This tectonic contact is characterized by a gentle slope, generally dipping towards the south-southwest, as the elevation of the contact gradually decreases in that direction.
- Lower thrust (No 2, Figure 1 & Figure 2), which positions the volcanosedimentary formation upon the carbonate rocks. The trace of this fault is sub-parallel to the upper thrust. The lithologies of the overlying volcanosedimentary formation along the tectonic contact are markedly faulted, brecciated and schistose.

Within the footwall of the lower thrust and within the carbonate rocks, successive tectonic surfaces can be observed, many of which have developed along or sub-parallel to the bedding of the carbonates. These are sub-horizontal to gently and moderately dipping surfaces, occasionally flat but also slightly undulating, anastomosed surfaces that primarily incline towards the north-northwest and southwest, though locally they may trend in other directions.

In the vicinity of the Monastery, two primary low-angle fault surfaces can be observed:

- An upper low-angle fault surface (No 3, Figure 1, Figure 2 & Figure 3, left), located at the main foundation level of the Monastery, which is the minor of the two.

- A lower and larger low-angle fault surface (No 4, Figure 1, Figure 2 & Figure 3, right), situated at lower elevation than the main foundation level of the Monastery.
-

Figure 2. UAV image showing the synthetic depiction of the tectonic contacts at the Holy Monastery of Kleiston. 1: Upper thrust which places the carbonate rocks above the volcanosedimentary rocks. 2: Lower thrust which positions the volcanosedimentary formation upon the carbonate rocks. 3: Upper low-angle fault surface located at the main foundation level of the Monastery. 4: Lower low-angle fault surface situated at lower elevation than the main foundation level of the Monastery. 5: Carbonate fragment.

Figure 3. View of the upper low-angle fault surface (No 3, Figure 1 & Figure 2) which forms the roof of the Catholicon (left). View of the lower low-angle fault surface (No 4, Figure 1 & Figure 2), situated at lower elevation than the main foundation level of the Monastery, where minor caves and undermining have formed (right).

The measurements conducted on the discontinuities at the Holy Monastery of Kleiston revealed two principal systems, with average strike of north-northwest to south-southeast and northeast to southwest, inclined primarily towards the northeast and southeast, respectively. Other secondary systems of discontinuities include northeast-southwest and northwest-southeast, which dip towards the north to north-northwest and southwest, respectively.
Overall, the discontinuities are represented by planar, curved, and open joints, as well as fractures or faults. When classified as open, the gaps range from 1 to 2 centimeters up to 0.30 m. They are frequently infilled with reddish soil and carbonate breccias. Along the open joints, root systems from trees and shrubs that have flourished in the area have penetrated. The depth of this penetration is not easily discoverable but exceeds 2 to 3 m, and in certain instances, it has been found to surpass 5 to 7 m. This phenomenon is evidenced by the presence of roots extending all the way to the Catholicon and the storage rooms.

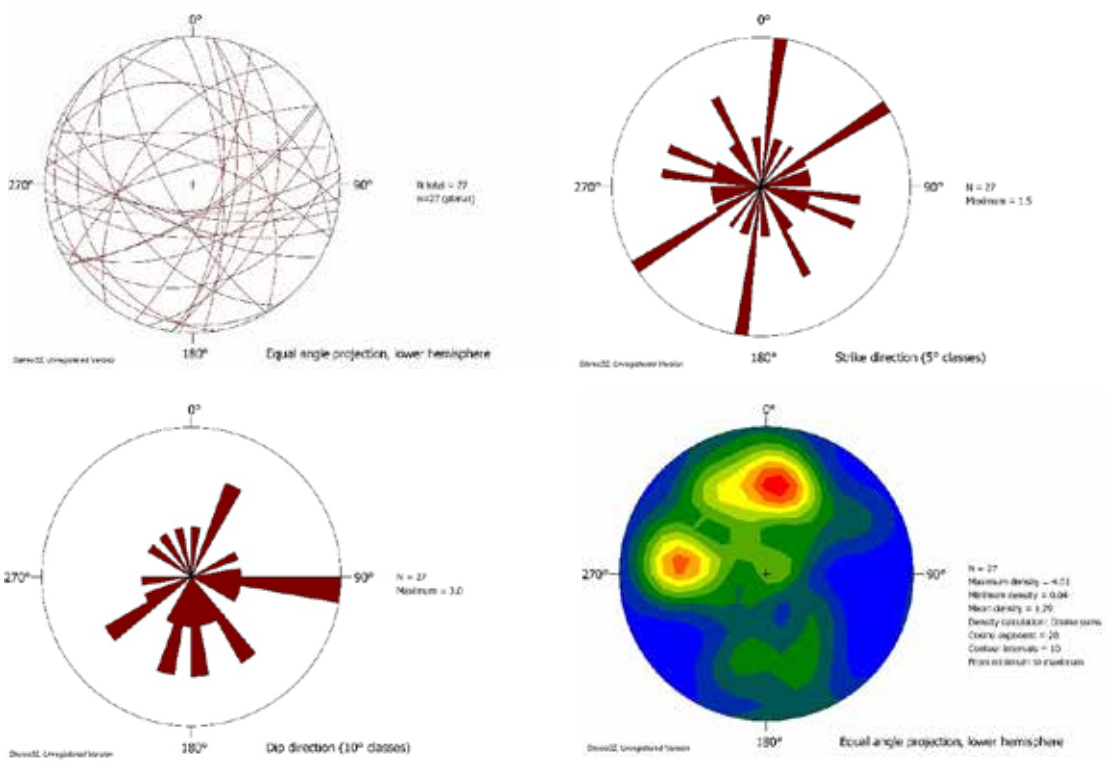

Figure 4. Stereographic projection (up, left), rose diagrams of direction (up, right) and dip direction (down, left) of maximum inclination, and pole density chart (down, right) for all measured discontinuities in the vicinity of the Holy Monastery of Kleiston.

Hydrogeological Conditions

The geological formations within the Holy Monastery of Kleiston fall into the following categories, according to the standards of the International Association of Hydrogeologists (Struckmeier & Margat, 1995; Nikas et al., 2010):

- Debris and scree (H.cs,sc): They develop local and thin aquifers with high yield or extensive aquifers with moderate yield (Subclass 1b).
- Carbonate formation of the Lower Triassic to Lower Jurassic (Ti-Ji.k,d): This formation generates extensive aquifers with high yield (Subclass 2a).
- Volcanosedimentary formation of the Upper Paleozoic to Lower Triassic (P-Ti.tf): This formation develops aquifers of little practical significance or non-aquifer formations (Subclass 3b).

The Holy Monastery of Kleiston is supplied by a spring located 150 m to its north. Improvement work has been performed in the spring, which operates year-round. This spring discharges from the weathered mantle of the volcanosedimentary formation, which is likely fed upstream by the overlying carbonate formations.

In the underlying carbonate formation, a deep karst aquifer of significant capacity has developed. This carbonate formation appears to be highly fragmented and fissured, displaying two primary systems of joints, alongside additional secondary systems that exhibit pronounced karstification.

Epikarst zone

The surface layer of the lower carbonates is characterized by the development of an extensive epikarst zone of high permeability, resulting from significant secondary porosity, with thickness exceeding 10 m in certain locations. The epikarst zone forms a locally saturated zone or an aquifer near the surface, occurring almost exclusively during the winter months when precipitation levels are elevated.

The recharge of the epikarst zone, upstream from the Holy Monastery of Kleiston, occurs through:

- Direct inputs from precipitation.
- Contribution from the overlying granular aquifer developed in the debris and scree, due to hydraulic communication. Notably, upstream there is localized lateral recharge to the granular aquifer from the upper karst aquifer, facilitated by the fractured volcanosedimentary formation at the base of the upper nappe.

The groundwater of the epikarst zone partially infiltrates the underlying rapid flow karst system developed within the

lower carbonates and partially discharges into fronts of epikarst springs that manifest at both the upper and lower fault surfaces of the lower carbonate rocks.
The front of the epikarst springs that emerges at the upper low-angle fault surface discharges in the area encompassing the Catholicon of the Holy Monastery as well as the adjacent buildings and functional spaces, including:

- The cell building located immediately prior to the entrance of the Catholicon (south of the Catholicon).
- The storage facility situated within a cave (north of the Catholicon).
- The small cave (north of the Catholicon).
- The building of the old cells of the Fathers and other common areas (east of the Catholicon).

1.

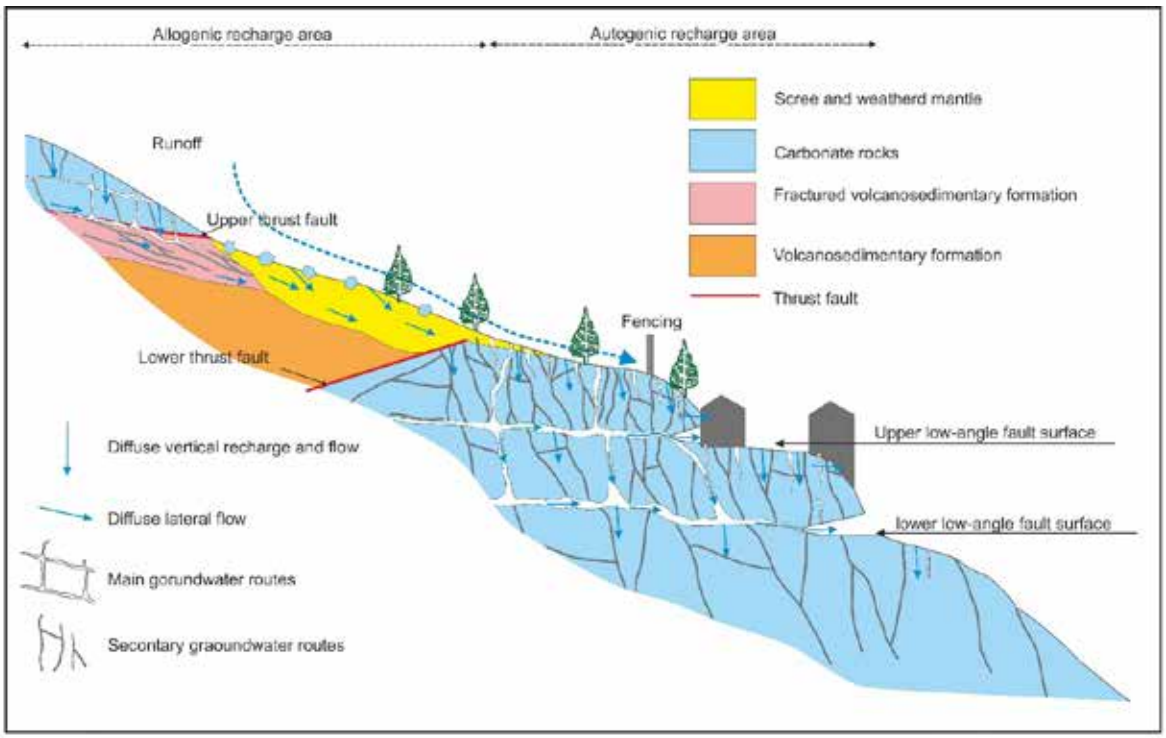

Figure 5. Sketch of the geological and hydrogeological conditions in the vicinity of the Holy Monastery of Kleiston. The various hydrogeological units and the main tectonic elements of the area, the main and secondary routes of the groundwater and the location of the main building infrastructure of the monastery are distinguished.

The front of the epikarst springs that appear at the lower low-angle fault surface discharges into minor caves beneath the foundation of several retaining walls along the northeastern and southeastern perimeter of the Monastery as well as the building containing the old cells of the Fathers and other communal spaces.
The building housing the old cells of the Fathers and other communal spaces is situated between the two discharge fronts of the epikarst springs, yet it is primarily influenced by the upper front and secondarily by the lower front, particularly following prolonged and continuous periods of intense rainfall and snowfall.
Given that the thickness of the overlying carbonate formation upstream of the Catholicon of the Monastery does not exceed 5-6 meters, this facilitates the direct infiltration of rainwater. This is further exacerbated by the significantly fractured and fissured nature of the rock mass, which is compounded by the presence of trees whose root systems have penetrated the rock's discontinuities, leading to further enlargement of these openings. Water intrusion thus extends into the interior of the Catholicon and the adjacent buildings and functional spaces.
In the vicinity of the Church of the Holy Cross, both the upper and lower carbonate series are observed in very close proximity, in places not exceeding 5 meters apart, resulting in highly deformed of the volcanosedimentary formation, which is entirely fissured.
The upper nappe of the carbonates upon the practically impermeable volcanosedimentary formation dips southeast, resulting in this carbonate formation discharging at a front of springs on the artificially constructed slope west of the Sanctuary of the Church. As water flows downstream, the path leading to Gkoura, which runs behind the Sanctuary, transforms into a small and ephemeral stream, with quantities of water infiltrating the interior of the Church through the foundation base (floor).

Discussion - Conclusions

The epikarst zone in the vicinity of the Holy Monastery of Kleiston constitutes a surface horizon of the lower carbonate formations, approximately 10 meters in thickness, characterized by high porosity and permeability. This significant porosity arises not only from the dissolution of carbonate rocks by CO_2-rich water but also from the presence of two main systems and at least two smaller groups of fractures and joints, as well as the existence of two low-angle fault surfaces. The lower of the two fault surfaces governs the base of the epikarst zone.

The epikarst is recharged by precipitation and laterally through the scree and the weathered mantle of the volcanosedimentary formation. These two formations, in turn, are fed by the upper carbonates. These conditions indicate that the recharge of the epikarst is dual in nature, both allogenic and autogenic.

During the wet season, rainwater and meltwater infiltrate the epikarst zone through discontinuities and percolate deeper into the horizons of the carbonate rocks. However, a portion of the infiltrating water remains within the voids and fractures of the epikarst zone, forming an epikarst aquifer where the presence of two low-angle fault surfaces enables the lateral flow of groundwater and the discharge of the epikarst aquifer into springs within caves observed along those two fault surfaces.

This discharge is the cause of water influx and the manifestation of moisture within many of the buildings of the Holy Monastery of Kleiston. The presence of vegetation cover in the epikarst zone helps retain soil moisture, minimizing evaporation and enhancing humidity in the areas surrounding the Monastery.

This study highlights the overall importance of the epikarst zone in the collection and flow of water infiltrating karst formations, particularly emphasizing its critical role in the hydrogeological conditions of the area surrounding the Holy Monastery of Kleiston. Its impact on water influx and the manifestation of humidity is complex and is influenced by morphological, lithostratigraphic, tectonic, and climatic factors.

Acknowledgements

The research team extends its most heartfelt gratitude to the Monks of the Holy Monastery of Kleiston, particularly to the Abbess Mariam, for the time they dedicated and their invaluable assistance during the fieldwork both within and beyond the Monastery. Additionally, we express our appreciation to Mayor Mr. Christos Pappous, the elected officials, and the staff of the Municipality of Fili for their collaboration and the generous provision of support.

Abstract
Mud samples from the Evros river deltaic sediments (ERDS) Thrace district (Northern Greece) were analyzed by several physicochemical techniques: grain size distribution, X-ray diffraction, optical microscopy, chemical composition (major and trace elements), cation exchange capacity (CEC) and plasticity index (PI), at an effort to evaluate their potential use in pelotherapy. Results showed that in terms of granulometry ERDS are characterized as loam-silts and silts, with silt-clay fractions varying from 69.8% to 97.72%. Non clay minerals include quartz, feldspars, amphiboles, calcite, sphene, rutile, magnetite, ilmenite, hematite, and pyrite. Main clay minerals present are illite (15-20 wt%), kaolinite (14-18 wt%), smectite (4-9 wt%), micas (6-8 wt%), and chlorite (5-7 wt%), and constituting 49 to 59 wt% of the mud samples. Among the analyzed potentially toxic elements (PTEs) average values of V, Cr, Ni, Cu, Zn, As and Pb exceed the Earth's crust content. Cation exchange capacity and PI range from 19.32 to 23.22 meq/100g and 18 to 32%, respectively. The measured properties of the studied Evros muds are comparable to those of peloids commonly used in SPA centers and, therefore, render them potentially suitable for pelotherapy. However, a sieving process of the muds is recommended to enhance the silt-clay size fraction particles and consequently to further improve the CEC and PI values, which are the more favorable properties for peloids in pelotherapy.
Key words: Clay minerals, physicochemical properties, pelotherapy, Evros river muds, Greece.

Introduction
Mud therapy or pelotherapy is the topical application of thermal muds (peloids) on the human body for medical or cosmetic purposes, and it is known since ancient times (Veniale et al., 2007). These applications are carried out either at natural sites or in thermal centers (SPAs) for the treatment of muscle, bone, skin pathologies, or for beauty therapy (Rebelo et al., 2010, Barthoumi et al., 2018). Peloids are defined as "matured muds composed of a complex mixture of fine-grained geological materials, mineral water or sea/lake water and very often organic compounds from biological metabolic activity" (Gomes et al., 2013, Maraver et al., 2021).
The growing interest in human health and welfare has increased the scientific investigation on the selection of potentially suitable materials for the formulation of thermal muds to be used in pelotherapy. To this direction a five years research project (2018-2023) has been performed by the Hellenic Survey of Geology and Mineral Exploration (HSGME) on many areas of Greece to localize natural occurrences of suitable muds for pelotherapy (Sofianska et al., 2019, 2022). Natural occurrences of thermal muds, which are empirically used for therapeutic, aesthetic, and pharmaceutical purposes exist in Greece (Kamitsou et al., 2017, Sofianska et al., 2019).
The suitability of a geologic material for pelotherapy can be defined on the basis of its mineralogy and chemistry, along with some physical and technological properties like granulometry, CEC, pH, organic matter content, adsorption capacity, plasticity, rheological and thermal behavior (Carretero et al., 2014).
With regard to chemical composition of muds in pelotherapy it is important to know the concentration of elements either beneficial (Ca, Mg, Na, K, Fe among others) or PTEs (Hg, As, Cu, Cr, Pb, Zn, Co, Sb, Ba, V, U) since both pass through the skin of the patient during treatment (Veniale et al., 2007, Carretero et al., 2014).
In the present investigation the texture, mineralogy, chemistry and some physicochemical characteristics of representative mud samples from the Evros river deltaic sediments (Thrace district, Northern Greece) were studied, at an effort to evaluate their potential use as raw material for peloids in pelotherapy.

Materials and methods
Mud samples collected in June of 2020 from the Evros river delta shore were used in this investigation. Four samples were collected from the sea bottom offshore and one from a river lagoon (AL-DE-05). The sampling points were randomly distributed, and their spatial site was recorded using a handhold positioning system (GPS). Collection of mud samples was carried out using a plastic pipe (3 m long and 2.5" ⌀) pressed on the bottom deposits. The raw material was collected in plastic boxes. Besides, depth, temperature and pH of water column were measured in each

sampling point. Mud samples collected were dried for 7 days and stored in polyethylene bags for further analytical work. Portions of the samples were used for grain size, mineralogical and geochemical analyses, as well as for the evaluation of physicochemical properties. Grain size distribution was performed in two stage processes. Firstly, the samples were wet sieved to separate the coarser particles (>74μm) in accordance with the ASTM D422-63. The fractions <74 μm were measured by means of a Laser granulometer Microtrac S 3500.

Optical microscopy and X-ray powder diffraction (XRD) analysis were used for the study of the mineralogical composition of the samples. Bulk samples and the separated clay fraction (<2 μm) in oriented, glycolized and heated to 550°C were X-rayed using a X'Pert PRO X-ray diffractometer equipped with graphite-filtered CuKα radiation.

Semiquantitative mineralogical composition of ERDS was found by analysis of the XRD patterns using the X'Pert PRO program.

The chemical composition of the samples (major and minor elements) was determined by X-ray fluorescence analysis (XRF), using the S4 PIONEER equipment of the BRUKER AXS. The concentration of PTEs were found by Inductively coupled plasma mass spectrometry (ICP-MS) using the PE SCIEX ELAN 6100 equipment.

Cation exchange capacity (CEC) was estimated by using the barium chloride solution method (ISO 11260:1994).

Plasticity index was calculated using Atteberg limit in the Casagrande test.

Chemical results were compared with the composition of the Earth's upper crust (Rudnick and Gao, 2003) and with peloids applied in pelotherapy in Spain (Carretero et al., 2014), Turkey (Karakaya et al., 2010) and Slovenia (Glavas et al., 2017).

All the analytical work was conducted at the Laboratories of the Hellenic Survey of Geology and Mineral Exploration (HSGME).

Results and discussion

In Table 1 the coordinates of the mud samples sites, along with some physicochemical parameters of sea water column are given.

Table 1. Coordinates of mud sampling sites and physicochemical parameters of water column.

Sample	X	Y	Depth of sea water	T °C of sea water	pH of sea water

AL-DE-05 lagoon	670731,06	4518477,55	0.1	34.1	8.4

Textural analyses showed that the ERDS are composed of 17.61 (2.28-30.19%) sand, 76.86% (64.92-92.86%) silt and 5.54% (4.89-5.92%) clay, with the silt and clay average fractions exceeding 82.49% (Table 2) and they are plotted in the silt and silt loam fields (Curtis, 2005) of the ternary discrimination diagram (Fig. 1).

In terms of granulometry best peloids should contain a high percentage of the clay fraction or a high silt and clay fraction as stated for the Spanish peloids (Carretero et al., 2014) and the Turkish thermal muds (Karakaya et al., 2010). Large clay fraction content creates a pleasant sensation, when applied to the skin and enhances ion exchange capacity through mud/skin interface (Veniale et al. 2004, 2007, Rebelo et al., 2010). Therefore, a sieving process to remove sand fraction is needed to improve the granulometry of the studied samples and their quality as raw material for peloid formulation.

Optical microscope study showed a polymineralic composition of the samples, including mainly detrital grains of quartz, feldspars, amphiboles, calcite, chlorite, mica, epidote, with minor amounts of sphene and rutile. Opaque minerals include magnetite, ilmenite, hematite and pyrite (single microcrystals and framboids). Calcite is present in the form of detrital grains, as well as biogenic in fossil shells. Non clay minerals match to 41-51wt%.

X-ray diffraction analyses showed that the clay minerals present are mainly illite (17.6 wt%), kaolinite (16.2 wt%), smectite (6.8 wt%), mica (7.4), chlorite (5.8%), and in one sample interstratified chlorite-smectite (3 wt%) (Table 2). The clay mineral content (mainly smectite) is relevant to therapy and of great importance, determining properties like high water absorption, CEC and specific heat (Cara et al., 2000).

Regarding the chemical composition of the studied muds, only TiO_2, MnO, MgO and F_2O_3 were found increased compared to the Earth's crust (Table 3, Fig. 2). Among the analyzed PTEs (values in mg/kg) (Table 3) V (98-125),

Cr (100-180), Ni (55-93), Cu (38-59), Zn (84-160), Pb (38-92) and As (6-13) were found to exceed significantly the composition of the Earth's upper crust (Rudnick and Gao, 2003). However, many examples of peloids applied in pelotherapy are referred to contain similar or even higher levels of these elements (Quintela et al., 2012, Carretero et al., 2014). Clayey materials selected for peloid applications must be safe. Therefore, elements like Cd, Pb and As known to be toxic to human and environmentally hazardous must be absent. European directives and USA regulations state that heavy metal concentrations in cosmetic products must be avoided if they exceed 10 mg/kg in case of Pb, 3 mg/kg for Cd and As (Rebelo et al., 2010). Besides, Mo, Ni, V, Cr and Cu, been reported to have less toxicity than previously mentioned elements must be limited in pharmaceutical formulations (Berthoumi et al., 2019). It is worth noting that the bioavailability and the potential enter of the PTEs in to the patient's body is more important than their concentration in the peloid constituents (Carreretero et al., 2014).

The analyzed SO_3 content of the Evros area muds was found varying between 1.04% and 2.01 wt% and comes most probably from pyrite. Sulfur content could influence therapeutic action as sulfur shows a keratolytic effect, analgetic influence on the pain receptors and inhibition of the immune response and has a bactericidal and antifungal effect (Baricz et al., 2021).

The CEC is controlled by the clay size fraction content, the kind of clay minerals, and the presence of organic matter (Baricz et al.,2021). The CEC of the muds studied are relatively low, ranging from 19.32 to 23.33meq/100g (average 21.54), and reflecting the clay minerals contents. Enhance CEC values in the studied muds are most probably related to both higher content of smectite and organic matter (Table 2).

UCC Upper Continental Crust (Rudnick and Gao 2003) 1* Average composition of Sečovlje healing saline mud (Glavas et al., 2017).

Similar CEC values are, however, referred for Spanish peloids (Pozo et al., 2013). As stated by Matike et al. (2011) at high CEC values (>15 meq/100g) ions exchange from the skin to the clay minerals mixture and release of ions to the skin can occur during application of peloid, facilitating skin cleansing and providing a refreshing sensation. CEC of clay mineral particles is significantly affecting ion exchange between peloid and the skin of the patient and thus contributes to a cleansing process (Tateo et al., 2009).

The liquid limit measured values and the plasticity indices found are varying between 43 and 63 (average 53) and 18 to 32% (average 25), respectively (Table 2), classifying the muds into the high plasticity clays in the Casagrande chart (Fig. 3) (except the AL-DE-02 sample). The liquid limit values >50% reflect the relative smectite content of the studied muds.

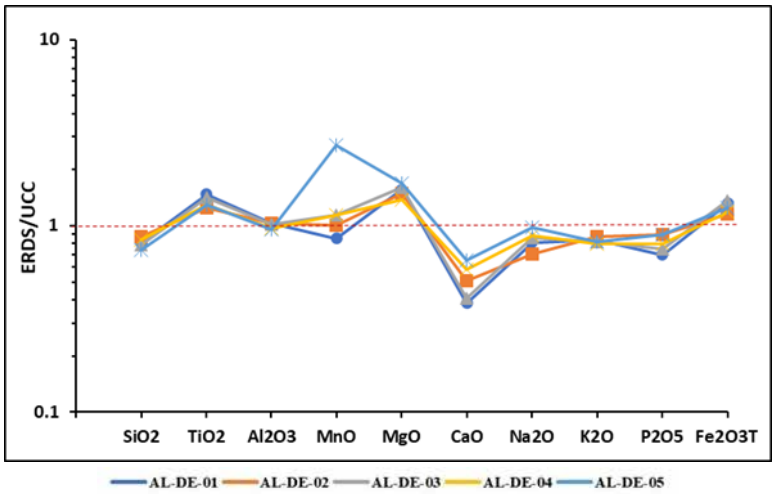

Figure 2. Earth's upper crust normalized composition of the Evros area muds.

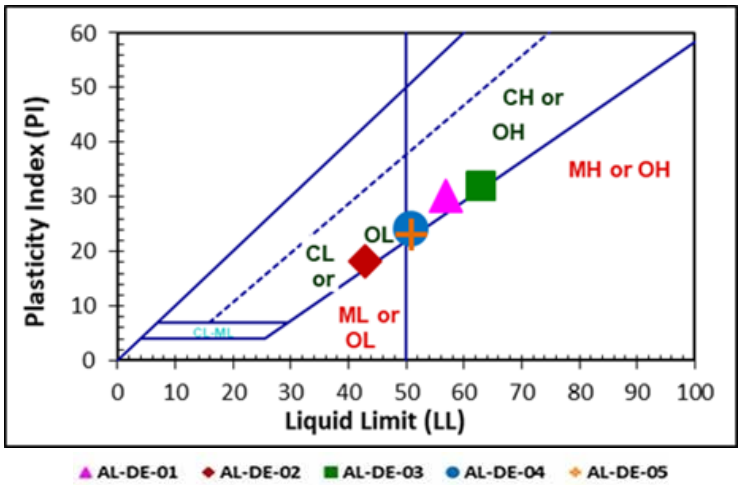

Figure 3. Projection of plasticity indices (PI) and liquid limits (LL)%values of the Evros delta muds in the Casagrande chart (C-clay, M-silt, O- organic, L- Low plasticity, H-High plasticity).

Conclusions

Mud samples from the Evros delta area were characterized in terms of different physicochemical (granulometry, mineralogy geochemistry, CEC and plasticity) properties.

Particle size, clay mineral content, CEC and PI found render the investigated mud samples from the Evros river delta potentially suitable for use as peloids in pelotherapy. Potentially toxic elements (PTEs) concentrations, although were found exceeding the Earth's crust composition, are considered acceptable because their concentrations are within the ranges referred for peloids applied in pelotherapy.

A sieving process is recommended to enhance the clay-size fraction particles of them and consequently improve their CEC and plasticity. Moreover, a further investigation is needed to study the technical properties of a derivative peloid formed from the mixture of the Evros muds with a medical mineralized water or sea water, after a maturation process.

REE distribution in the b1 bauxite strata of the Parnassos–Giona Unit, Greece

Sofis N.[1], Ntouros E.[1], Kalaitzidis S.[1*]
(1) Laboratory of Economic Geology, Department of Geology, University of Patras, Rio, Greece, skalait@upatras.gr

Research Highlights

The REE distribution in b1 bauxite strata of the Parnassos-Giona Unit points to variable forming conditions
The content of REE is moderate and strongly depended on the lithologies
REE bearing minerals were identified for the first time in b1 bauxite strata

Introduction

The Mesozoic carbonate sequence of Parnassos-Giona Unit extends over the mountainous areas of Oiti, Giona, Parnassos and Helicon. The neritic carbonate sedimentation began at the Upper Triassic and ceased at the beginning of Paleocene. The Unit hosts three major karstic-type bauxite strata namely b1, b2, b3, which were deposited between Middle Jurassic and Upper Cretaceous times (Papastamatiou, 1960; Celet 1962). The allochthonous karst-type bauxite deposits of the Parnassos-Giona Unit are part of the Mediterranean bauxite zone, and have been the subject of research by numerous researchers (e.g. Valeton 1972; Bárdossy 1982; Valeton *et al*. 1987).
The lower bauxite strata (b1) hasn't been studied extensively in the past decades, as it occurs sporadically (mainly in the east and northeast parts of the Parnassos-Giona Unit), with limited quantities and low grade in terms of Al.
In this study, seven sampling sites were examined in order to assess their main mineralogical, geochemical and mineral-chemical characteristics, with emphasis on the REE distribution. The aim of this study is to investigate the REE mode of occurrence in the bauxite samples in the lower bauxite strata of the Parnassos-Giona Unit (Fig. 1).

Figure 1: The PL2 section, in which the overlying Upper Jurassic limestones and the b1 bauxite strata are outcropping.

Methods

The main objective of this study is the assessment of the geochemical distribution of rare earth elements in the studied geological sites. In order to achieve this, geochemical analysis was applied on representative bauxite samples and transitional lithologies (in total 39 samples), including X-Ray Fluorescence (XRF) and Inductively Coupled Plasma Mass Spectrometry (ICP-MS), as well as Scanning Electron Microscopy to determine mineralogical chemistry. Furthermore, X-Ray Diffraction was applied to the total amount of samples to determine the mineralogical assemblage of each sample (Fig. 2A). Optical observation was performed using optical microscope of polarized white light for describing the petrographic characteristics and main morphological features.

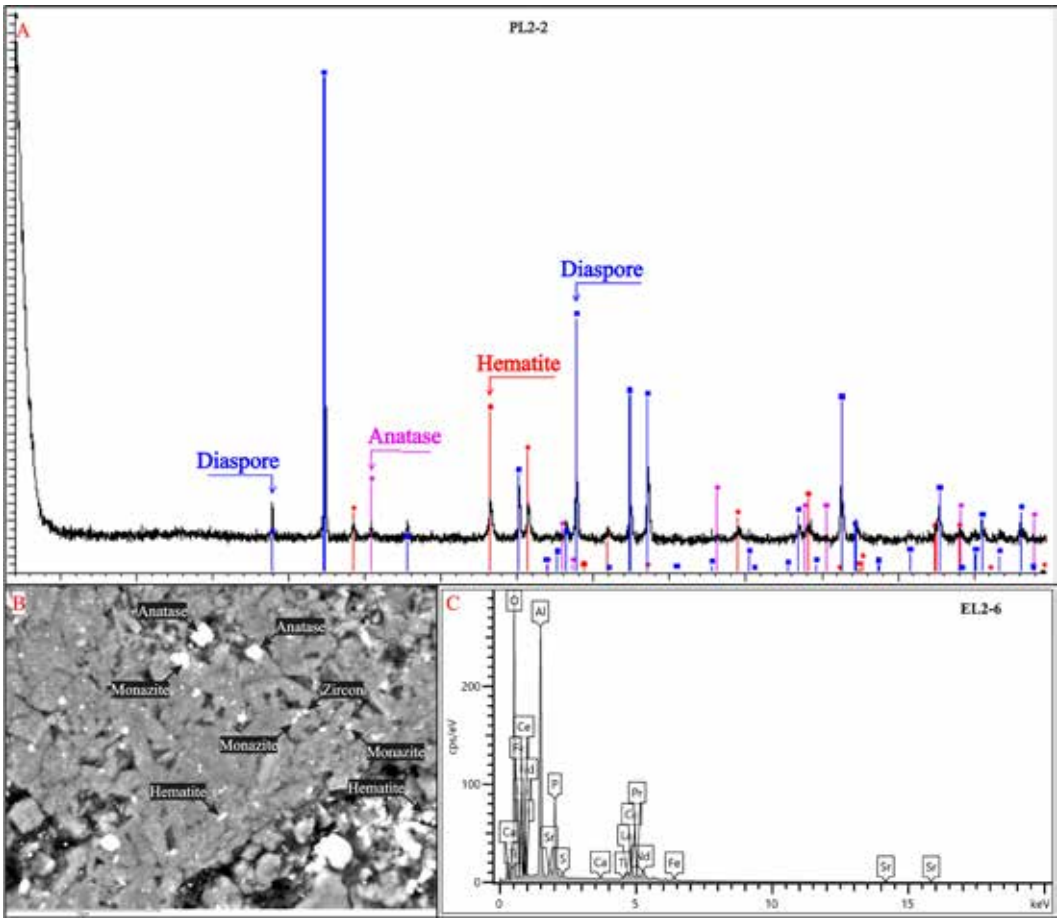

Figure 2: A) Evaluated PL2-2 X ray diffractogram, B) Back Scattered Electron image of the EL2-6 bauxite sample showing the presence of REE bearing mineral monazite, C) scanning electron microscopy (SEM) spectrum of monazite in sample EL2-6 bauxite sample.

Results

The geochemical data reveal an average Al_2O_3 content of 42.73 wt.-% in the bauxite samples, 58.08 wt.-% of CaO in the limestone samples, and 35.86 wt.-% of Fe_2O_3 in the bauxite samples and transitional lithologies. The SiO_2 and TiO_2 average value the studied lithologies are 6.77 and 2.24 wt.-%, respectively. The mean value of the ΣREE in bauxite samples is 565.4 mg/kg, while the ΣLREE and the ΣHREE are 433.06 mg/kg and 132.33 mg/kg respectively. The SEM analysis provided the mineral chemistry of the representative bauxite samples, as well as the presence of REE-bearing and REE minerals, e.g. cerianite and monazite (Fig. 2B and 2C).

Discussion

According to REE/Chondrite normalized patterns of the studied bauxite samples per sampling site, a positive anomaly is observed for Ce, Er, and Tm, while Eu, Dy and Ho show a negative one. Furthermore, the ratio Eu/Eu* ranges from 0.56 to 0.69, whereas the Ce/Ce* fluctuates from 0.41 to 7.43.

Variations on the total content of the REE depending on the lithological facies were observed. Generally, the bauxite samples seem to be more enriched (ΣREE = 565.4 mg/kg) than the transitional lithologies (ΣREE = 404.97 mg/kg). The Eu/Eu* fluctuates from 0.56 to 0.69, which based on published data regarding the parental rocks of the bauxites of the Parnassos-Giona region (Mameli et al., 2007; Mongelli et al., 2014; Mondillo et al., 2022) indicates that igneous rocks with intermediate to basic affinity were the parental rocks of the b1 bauxite.

According to Ellahi et al. (2016), positive La/Y anomalies indicate alkaline conditions during bauxitization, whereas the negative ones acidic. At the PR1, PR2, PL2, EL2, EL3A and EL4 profiles alkaline conditions prevailed, whereas at EL3 acidic ones. The positive Ce/Ce* anomaly indicates oxic conditions during bauxitization, whereas the negative ones show reduced conditions. At PR1, PR2, EL2, EL3A and EL4 bauxite profiles, most probably oxic conditions prevailed, while at PL2 and EL3 reduced ones.

Conclusions

The lower bauxitic strata b1 at Parnassos-Giona Unit shows a relative enrichment in rare earth elements, which seem to concentrate at the pure bauxite samples in comparison to the transitional lithologies. In most sampling sites alkaline and oxic conditions prevailed during the bauxitic mud deposition. Most probably, igneous rocks with intermediate to basic affinity were the parental rocks of the b1 lenses confirming previous studies in the area.

Plio-Quaternary tectonics and evolution of Southeastern Lesvos Island and Lesvos Basin, Greece: Transtensional deformation and relationship with the July 2017 earthquake activity

Sotiropoulou S.[1,2], Kalaitzis M.[1,2], Skourtsos E.[1], Sakellariou D.[2], Kranis H.[1]

1 Department of Geology & Geoenvironment, National and Kapodistrian University of Athens, 15784, Zografou, Greece

2 Institute of Oceanography, Hellenic Centre for Marine Research, 19013, Anavyssos, Greece

Introduction

The Aegean domain is regarded as a distinct, deforming microplate situated between the converging Eurasian (to the north) and African (to the south) tectonic plates, alongside the westward advancing Anatolian block (to the east) and Apulia (to the west) (Le Pichon & Angelier, 1979, 1981; Dewey & Şengör, 1979; Mascle & Martin, 1990; Armijo et al. 1996, 1999;). It is delineated to the north by the dextral, NE-SW strike-slip North Anatolian Fault (NAF), to the west by the NNE-SSW striking dextral strike-slip Kefallonia Fault, and to the southeast by the sinistral strike-slip fault zones of Strabo and Pliny. The region is characterized by a south-southwest directional extension, with a velocity of 40-50 mm per year relative to Eurasia, and experiences intricate extensional and strike-slip deformation influenced by the retreat of the Hellenic Subduction and the pressure exerted by the movement of the Anatolian Block along the NAF and its southern branches.

The present study concentrates on the northeastern margin of the North Aegean Sea, specifically on the southern part of Lesvos Island, encompassing the area that stretches from the eastern edge of the Gulf of Kalloni to the region further east of Vatera. The objective of this research is to provide insights into how the fault patterns of the study area are connected to the Lesvos Basin through geological mapping, conducting geological and structural observations, and integrating these findings with recent onshore data, particularly elucidating their significance in relation to the seismicity of the larger region.

Methodology

The present study employed a multifaceted approach to interpret the tectonic regime and fault network of the study area. A thorough examination of existing literature and research findings served as a foundational element in the development of this study's methodologies and framework. Between 2019 and 2021, a series of extensive field campaigns were conducted to comprehensively map the fault network governing the region. These expeditions enabled the possession of crucial geometric and kinematic data necessary for decoding the tectonic characteristics of the area. To supplement the field data, high-resolution topographic maps were utilized to establish the hydrographic network and identify potential fault zones of significance. The integration of geospatial techniques facilitated a more nuanced understanding of the tectonic landscape.

Tectonic Setting of NE Aegean and Lesvos Island

Most of the research conducted in the broader region predominantly relies on geological and geophysical data, focusing on earthquake mechanisms (e.g. Koukouvelas et al., 2002; Kiratzi et al., 2018, Papadimitriou et al., 2018). Seismic activity dates back to ancient time highlighted by a significant seismic event of magnitude 7.0 in 1867 along the Agia Paraskevi – Kalloni dextral strike – slip fault zone (Poumelioti and Kiratzi 2010; Chatzipetros et al., 2013). This activity persists today (Papazachos et al. 1997; Papazachos and Papazachou 2003; Taymaz et al. 1991, 2007), with a notable seismic event occurring in June 2017 featuring a mainshock of magnitude 6.3, characterized by a WNW-ESE normal fault, dipping 45º to the SSE. It was followed by two main aftershocks of magnitudes 5.2 and 5.0 on two NW-SE sub – vertical faults showing strike – slip motion (Nomikou et al., 2021; Papadimitriou et al., 2017; Kiratzi 2018).

The main fault structures in Lesvos can be categorized into three groups based on their strike. These consist of (i) NNE-SSW striking faults, which are mainly characterized as clockwise strike – slip faults, such as the Agia Paraskevi Fault Zone (APFZ), (ii) WNW-ESE striking faults which are represented mostly of normal faults with significant counterclockwise strike – slip component., (iii) E-W striking which is usually represented by normal faults, which act as "relay ramps" connecting the aforementioned strike-slip faults (Chatzipetros et al., 2013; Papadimitriou et al., 2018).

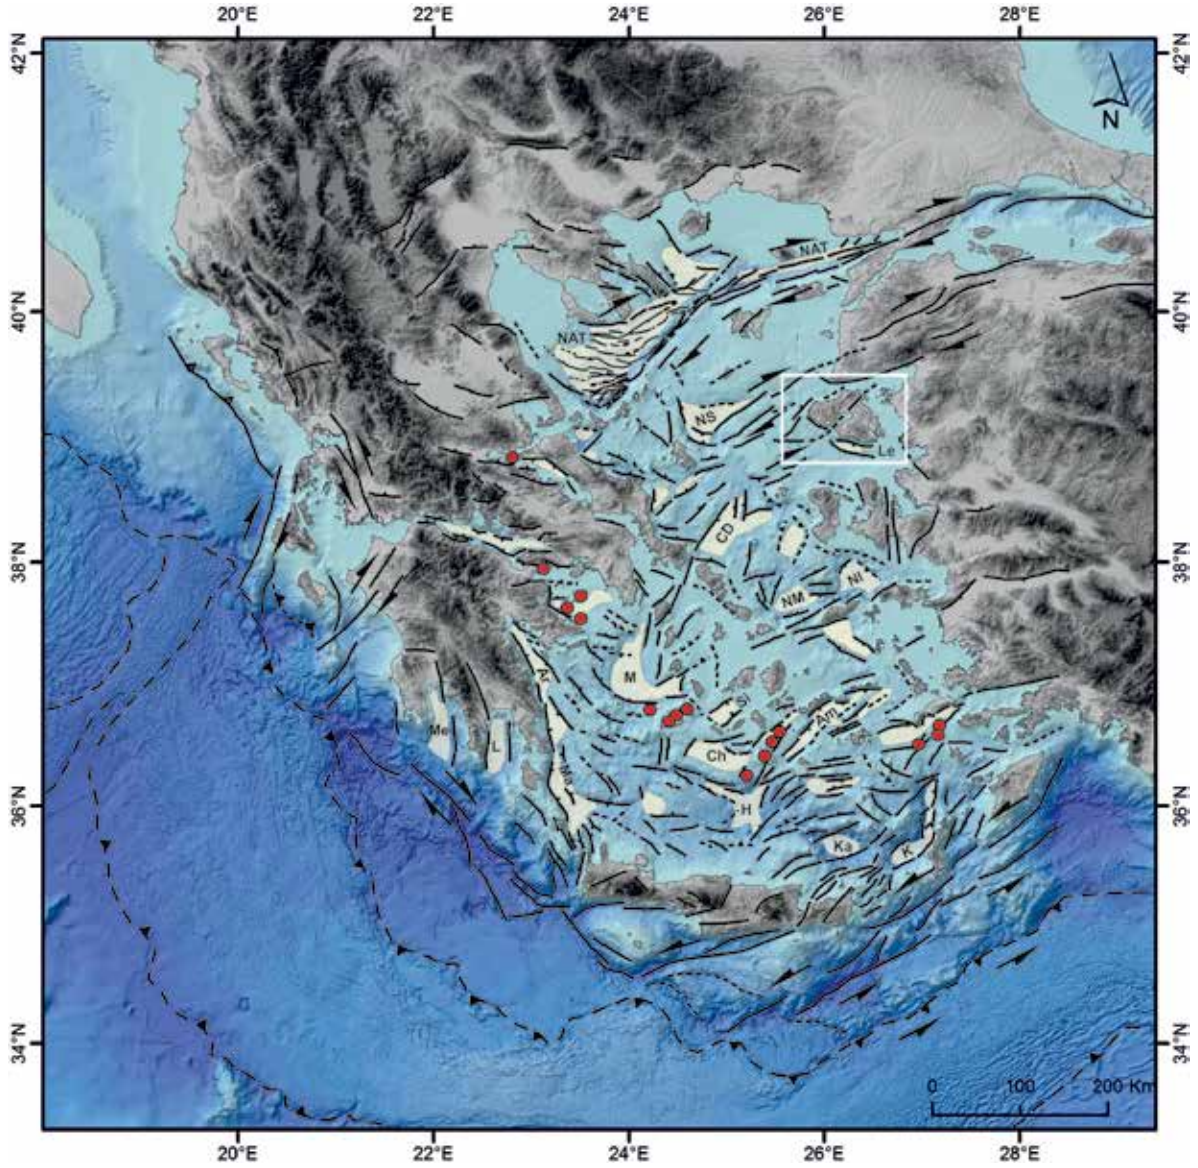

Figure 1. Active fault network and distribution of Plio-Quaternary basins in the Aegean. Red dots show the main volcanoes of the Volcanic Arc. Yellow areas indicate Plio-Quaternary basins with sediment thickness >500 m. Black lines show active faults, dashed black lines indicate possible/inferred faults. Ticks on the faults mark the hangingwall. Half arrows show the sense of strike-slip motion. The white box marks the island of Lesvos and the broader study area.

Geology and fault geometry of the SE Lesvos

The principal geological structure within the study area is the asymmetrical Vatera Basin, characterized by its triangular shape, bordered to the north by a series of hills that rise to altitudes of up to 350 meters, and to the south by the coastline. At the base of the southern slopes of this hill range lies the Vrisa Fault (VFZ), extending approximately 13 km from the Gulf of Kalloni to the west, passing south of the village of Polichnitos, north of the settlement of Vrisa, and reaching eastward to the settlement of Drota, while its trace terminates at the coastline, with a likely offshore extension further eastward. Vacchi et al. (2012) refer to this fault as the Vatera Fault, while Chatzipetros et al. (2013) and Papadimitriou et al. (2018) identify it as the Plomari-Polichnitos Fault. The fault exhibits a WNW-ESE strike with high-angle dips to the NNW. Kinematically, it displays counterclockwise strike-slip motion with a notable normal slip component, although normal characteristics were also observed through slickensides identified in its central segment. The thickness of the damage zone exceeds 1 m.

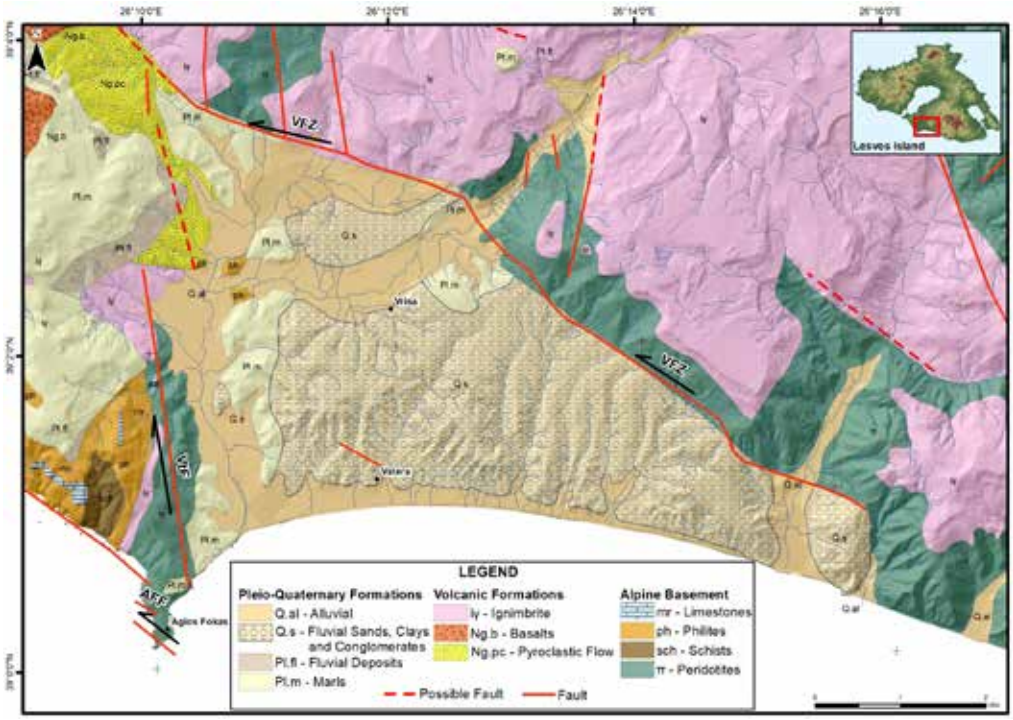

Figure 2. Geological and tectonic map of the study area, based on IGME maps (POLYCHNITOS and PLOMARI Sheets), showing the major fault zones described in this study. AFF: Agios Fokas Fault, VtF: Vatera Fault, VFZ: Vrisa Fault Zone.

The hill range constitutes the footwall of the fault and is composed of ophiolitic rocks, upon which beds of ignimbrites have been deposited. Above the fault block lies a thick sequence of Pleistocene fluvial conglomerates that comprises the central and eastern parts of the basin; beneath this, a Pliocene sequence primarily consisting of alternating marls and conglomerates, is distinguished in the western part. The size of the gravels in the upper sequence decreases from east to west, indicating a source of sediments from the northeast. The lower marly sequence exhibits eastern dips, while the overlying conglomeratic sequence dips southwest, although near the fault, it tends to tilt towards it.
During the June 2017 earthquake, surface ruptures were observed along the fault on the dirt roadway intersecting it. These ruptures measured 50 m in length and 1 cm in width without accompanying displacements. Additionally, large fragments of the fractured ophiolitic rock detached from the fault scarp and tumbled downward, while pre-existing ruptures within the fault's damage zone were widened (Mavroulis et al., 2018).

Figure 3. Fault scarps with the striations of the AFF (left image) and VFZ (right image). The geometry of the slickensides in AFF is 01º/122º and for VFZ is 112º/30º in a fault which dips towards SW.

Agios Fokas Fault Zone (AFFZ) is situated in the central south-southwestern region of the study area and predominantly extends parallel to the coastline, with its most notable onshore manifestation found at the eponymous cape. The AFFZ follows a NW-SE orientation, almost parallel to the VFZ, is a steep fault and consists of numerous

fault segments arranged in an en-échelon pattern. The footwall of the fault is built by old alpine formations, such as phyllites, crystalline limestones, green schists and metabasalts, on which Miocene volcanic rocks and finally Pliocene marls of the lower series of the Vatera basin have been deposited. Kinematical this fault zone is mainly characterized by strike-slip motion as indicated by the slickenlines observed on its fault surfaces. However, the presence of beachrocks above sea level on its footwall may suggest uplift attributable to this fault zone, potentially implying the coexistence of a normal component of shear. These kinematic features match those on the VFZ.
The faults situated in the NNW-SSE/N-S strike tend to play a subordinate role in the main fault zones outlined above (VFZ and AFFZ), serving as the structural connections between them. Notably, the steep Vatera Fault Zone (VtFZ), located in the central portion of the study area, is characterized by an almost N-S to NNW-SSE orientation, with a primary dip to the ENE. This fault zone extends from the VFZ to the north, terminating at the cape of Agios Fokas to the south. The existence of VtFZ is corroborated by the presence of distinct successive fault scarps arranged in an en échelon pattern, as well as geomorphological observations. In kinematic terms, VtFZ predominantly exhibits a clockwise component of slip, although its normal component holds substantial importance, as it significantly influences the hydrographic network of the region, causing it to shift towards the southwest and forming an asymmetry in its drainage basin. This asymmetry arises from the pronounced elevation of the western footwall of VtFZ relative to the eastern hanging wall. This relative vertical motion is further substantiated by the presence of Pleistocene conglomerates exclusively in the eastern part of the Vatera Basin.

Levos Basin

South of the study area, geomorphological analysis of the offshore morphology south of the Lesvos Island and seismic analysis results, highlight the existence of a depression, which is called the Lesvos Basin (LB) formed in Pliocene (Mascle & Martin, 1990). It is an asymmetric depression of about 700 m deep and of NW-SE strike which is characterized by a thick sedimentation (Sakellariou & Tsampouraki – Kraounaki, 2019). The results from a series of transverse Parasound profiles in the N-S direction, showed that the eastern part of LB is WNW-ESE basin, running parallel to the southeastern Lesvos coastline, with a length of more than 30km, maximum depth of 703m and its axis located at 5-6 km from the coast. Its northern margin is controlled by a WNW-ESE marginal fault of the Lesvos Basin with steep slopes forming a steep submarine escarpment more than 600 m height (Mascle & Martin, 1990; Sakellariou & Tsampouraki – Kraounaki, 2019; Nomikou et al., 2021). The eastern segment of the fault, located south of the town of Plomari, exhibits a WNW-ESE strike and is situated in the southeastern extension of the VFZ. Further west, south of the Vatera coastline, the marginal fault shifts slightly in strike, transitioning to a nearly E-W orientation. The earthquake of June 2017, along with its seismic aftershocks, aligns in a WNW-ESE direction within the LB, and it has been proposed that it resulted from the activation of the marginal fault associated with the basin, which corresponds to its eastern segment (Papadimitriou et al., 2018).
South of Agios Fokas Cape an abrupt change of the bathymetry of the LB is observed with a shallow-water platform around 300–400 m depth formed westwards. The change from the main basin occurs along a N-S boundary zone (Nomikou et al., 2021). According to the authors, a similar structure is evident in the eastern margin of the basin, where it has been proposed by them that this zone corresponds to a sinistral strike-slip fault. The western zone is in the submarine extension of the VtFZ. Thus, it can be suggested that this zone is also tectonically shaped by a strike-slip fault.

Discussion and conclusions

Various studies, (e.g. Sakellariou & Tsampouraki-Kraounaki, 2019; Beniest et al.,2016), indicate that certain faults in NE Aegean form transtensional and transpressional structures, especially where faults change strike. The Plio-Quaternary basins formed in a transtensional regime—such as releasing bends and pull-apart basins, or at the junction of NE-SW dextral and NW-SE sinistral strike-slip faults—are entirely controlled by those faults.
We have established that the VFZ is a NW-SE to NNW-SSE, sinistral strike-slip fault zone that exhibits a notable normal component. The kinematic characteristics of this fault align with the proposed models for the Northern Aegean, which support for this type of slip across all faults of similar strike (Sakellariou & Tsampouraki-Kraounaki, 2019). The characteristics of the VFZ are also corroborated by the tilting of conglomerates in the eastern part of the VB, indicating local extension. Furthermore, the VFZ is regarded as the onshore extension of the offshore eastern segment of the marginal fault of the LB (Vacchi et al., 2012; Papadimitriou et al., 2018), as both faults share comparable strike and dip orientations, as well as analogous kinematic behaviors.
The data presented above indicates the following possible scenario of basin evolution in the study area.
In Pliocene, a large basin was formed in the area of Southern Lesvos Island and the present LB. It was characterized by the deposition of (lacustrine?) marls and was bounded to the north-northeast by the VFZ and to the west by the NE-SW striking prolongation of the dextral Agia Paraskevi – Kalloni FZ (APFZ).

In Early Quaternary, enhanced uplift and erosion of the footwall of VFZ led to deposition of massive fluvial conglomerate deposits in the hanging wall of the fault, on VFZ hanging wall and possibly further east and south. At the same time two new faults initiate: the WNW-ESE striking Lesvos Fault (LF) and the NNW-SSE striking Vatera Fault (VtF). The latter marks the new western margin of the basin while the former leads to enhanced subsidence of its hanging wall (Lesvos Basin). Initiation of the Agios Fokas Fault (AFF) may also have taken place in Early Quaternary.
In Late Quaternary, activity on Lesvos Fault leads to uplift of the area of Vatera (Vatera Basin, conglomerate deposits) and enhanced subsidence of Lesvos Basin. The latter is bounded to the west by the offshore possible prolongation of Vatera Fault (VtF).
From Late Quaternary until present day, the morphology of the study area has changed a lot. The most important change concerns the uplift of the study area, which is now exposed to the surface conditions on land. The main reason for this relative uplift was the intense activity of the now offshore, normal, LF, which causes uplift of the NNE onshore part of the LB, and further subsides its NW part.

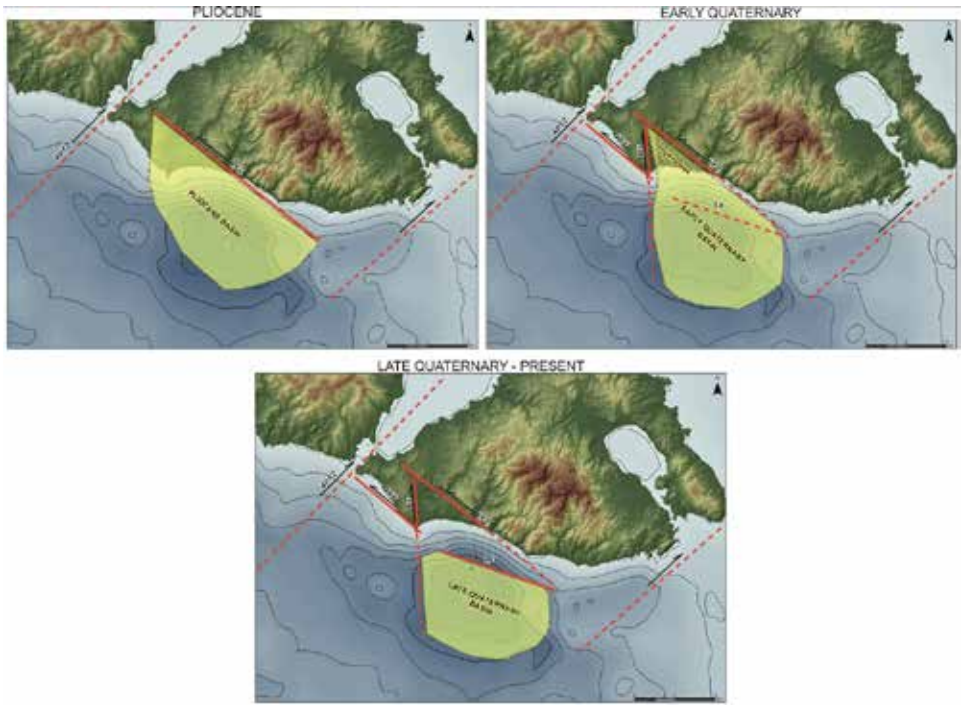

Figure 4. Proposed paleogeographic evolution of the basin in the study area. APFZ: Agia Paraskevi Fault Zone, VFZ: Vrisa Fault Zone, AFF: Agios Fokas Fault, VtF: Vatera Fault.

As regards the offshore LF, although the so far acquired data show a predominant normal slip character, it is considered quite possible for it to simulate the kinematic characteristics of almost all the fault zones mentioned in this study and act both as a normal and a strike – slip fault, which from the Pliocene until the present day, has greatly shifted the morphology of the study area.
The activity of the above structure is confirmed by the recent earthquake of June 2017 (Mw 6.3), with the seismic sequence taking place within the basin, in the hanging wall of the boundary fault (Kiratzi et al., 2018; Papadimitriou et al, 2018) and the focal mechanisms showing normal sense of shear (Kiratzi et al., 2018; Papadimitriou et al., 2018). According to the morphological data provided, this newly formed, offshore basin is probably delimited to the west by the offshore prolongation of the VtFZ, as the direction of both zones is similar.
In conclusion, it is noteworthy that both the VFZ and the AFFZ are regarded as segments or splays of the LF, collectively forming a comprehensive fault zone that governs the entire southern boundary of Lesvos Island and significantly contributes to the geological evolution of its southern region. It is evident that the strike orientations and kinematic characteristics of the mentioned fault zones, both onshore and offshore, align perfectly with the findings from prior research conducted in the North Aegean. Therefore, the kinematics of the fault network in the study area oscillates between strike-slip and extension, epitomizing a distinctly transtensional regime. This observation parallels the broader deformation occurring in the North Aegean region, attributable to the North Anatolian Fault and its extension into the Aegean Sea through its associated strands.

Discovering the geoheritage of Skiathos Island (Northern Sporades, Greece)

Soultanis K.[1], Soukis K.[1], Triantaphyllou M.V.[1]
(1) National and Kapodistrian University of Athens, Athens Greece, kimonasofficial@gmail.com

This paper attempts to probe and highlight the geoenvironmental attractions of Skiathos Island and to propose friendly geo-routes and accessible geo-locations that could appeal to visitors.

Skiathos Island belongs to the Northern Sporades located in north Aegean, Greece. It has an irregular, NE-SW elongated shape, stretching approximately 12 km in length and 6 km in width, with a hilly and undulating terrain. The highest peak, Mount Karafiltzanaka (433 m), and other smaller hills form a central spine running through the island, gradually sloping towards the coast. The island's northern part is steeper and more mountainous, with cliffs dropping sharply into the sea, while the southern part has gentler slopes and is more developed, with sandy beaches and natural harbors. The presence of weathered rock formations and thin soil layers supports dense pine forests and small seasonal streams that contribute to its lush, green environment. Skiathos features a well-developed coastal zone with numerous bays, peninsulas, small capes, and sandy shores formed by sediment transport and coastal processes.

Skiathos is situated in the back-arc area of the Hellenic Arc and comprises rocks belonging to the Pelagonian domain, a continental lithospheric block considered part of the Cimmerian ribbon continent, affected by the Late Jurassic - Early Cretaceous closure of the Vardar Ocean and the early Cenozoic Alpine deformation. The lower part includes late Paleozoic augen gneisses, para- and orthogneisses, amphibolites, and schists, occupying the central and western part, overlain by a Triassic-Jurassic marble and late Jurassic calc phyllites and slates, observed at the eastern and northern parts. The upper part is made of a transgressive late Cretaceous limestone observed at the central and northern parts of the island. (Ferentinos 1973; Jacobshagen and Wallbrecher 1986; Mountrakis 1986; Papanikolaou 2021)

We have identified and classified several key locations across the island, comprising distinct geosites that combine natural geoscientific monuments with aesthetic, naturalistic, cultural, historical, touristic and educational values (Figure 1). All included geosites have been assessed based on the criteria applied by Skentos (2012). The outcome of this assessment enabled the development of sustainable geo-routes (e.g., Spyrou et al., 2002; Triantaphyllou et al., 2023).

Figure 1. Geo-routes and geo-locations of Skiathos Island and the surrounding islets (Basemap: Esri Worldmap Imagery).

These sites exhibit significant geomorphological, mineralogical, tectonic, and historical interest. While primarily of local significance, they serve as an essential introduction for visitors and residents to engage with the island's diverse geoenvironment.

Beyond their scientific and educational value, these locations play a crucial role in advocating for the preservation of Skiathos' rich geological heritage. Some of these geosites form well-defined geo-routes, accessible by foot or vehicle, allowing visitors to immerse themselves in the island's breathtaking landscapes while exploring its geological diversity (Figure 2a-c). Others, more secluded and reachable only by sea, offer a unique opportunity to experience the island's untouched, rugged terrain, making them ideal destinations for daily excursions to remote and pristine coastal areas.

Cyclone Daniel's Impact: A Study of Geohazards in Meteora, Greece

Natalia Spanou[1]
(1) Hellenic Survey of Geology and Mineral Exploration (HSGME), Athens, Greece

Research Highlights

- Extreme weather events, such as Cyclone Daniel, significantly impact slope stability and increase the occurrence of geohazards, such as landslides, erosion, and flood-induced deposition of eroded materials.
- Understanding the mechanisms of geohazards can enhance risk mitigation strategies for affected communities.
- Evaluation of existing landslide susceptibility maps highlights the need for improved predictive tools in vulnerable regions.
-

Introduction/ Background

Cyclone Daniel, a severe weather event in September 2023, triggered extensive flooding, landslides, and associated phenomena across Central Greece. This event provides a unique case study for examining the link between extreme weather and the occurrence of geohazards. This analysis specifically focuses on the Meteora municipality, particularly the Municipal Units of Kleinovos, Kastania, and Aspropotamos, an area heavily impacted by landslide phenomena.

Detailed data on the geohazards that occurred in Meteora, meticulously collected through in-situ investigations, are analyzed. These data include the location, size, and characteristics of the geohazards. By examining these data, researchers aim to understand how the intensity of the cyclone and precipitation patterns affected slope stability in this region.

Existing landslide susceptibility maps for Greece are evaluated for the Meteora region. By comparing these maps with the actual landslide distribution, their effectiveness for the municipality is assessed, revealing areas that require adjustments.

Objectives

This study aims to achieve the following key objectives:

- Decipher Triggering Mechanisms: Identify specific meteorological factors associated with Cyclone Daniel that contributed to geohazards occurrences within the Meteora municipality.
- Inform Mitigation Strategies: Develop recommendations for improved geohazards risk mitigation strategies specific to Meteora, with potential applicability to other vulnerable municipalities.
- Validate Susceptibility Maps: Assess the accuracy of existing susceptibility maps in predicting landslide locations during the extreme weather event.
-

Methods

The detailed data on geohazard occurrences in Meteora, triggered by Cyclone Daniel, have been subjected to meticulous in-situ investigation and subsequent analysis. The dataset includes information on the location, dimensions, and characteristics of these phenomena. A total of 114 geohazard events were documented within the municipal boundaries of Meteora (Fig.1). These phenomena encompass a variety of processes, including rotational and translational slides, as well as soil and debris flows. Erosion in stream beds is also a common occurrence. Additionally, the accumulation of transported materials from the high sediment supply of the streams is another notable phenomenon (Spanou, 2024; Spanou, 2025a; Spanou 2025b).

The objective of this analysis is to assess the impact of the cyclone's intensity and precipitation patterns on slope stability within the region (Fig. 2). Additionally, recommendations for improved geohazard risk mitigation strategies specific to Meteora—with potential applicability to other vulnerable municipalities—are developed. Furthermore, the effectiveness of existing landslide susceptibility maps for the Meteora region has been evaluated. A comparison of these maps with the actual landslide distribution allows for an estimation of their accuracy for the municipality and identifies areas that may require adjustments (Apostolidis *et al.*, 2023).

Results

This study aimed to elucidate the mechanisms that precipitate geohazards in the Meteora municipality, which was significantly impacted by Cyclone Daniel. The specific meteorological factors triggering geohazard events within the municipality have been identified. Additionally, recommendations for enhanced geohazard risk mitigation strategies—tailored to Meteora and potentially applicable to other vulnerable municipalities—have been put forth. Finally, the accuracy of existing susceptibility maps in predicting landslide locations during extreme weather events was assessed (Spanou *et al.*, 2024).

Conclusions

Following the study, the most effective protection and mitigation measures were identified as follows:

- Surface and Subsurface Water Management: Implementation of surface water settlement projects and underground water drainage systems.
- Landslide-Specific Approaches: Adopting a case-by-case approach for selecting appropriate support works for landslides.
- Risk Demarcation: Conducting detailed demarcation studies to accurately identify and delineate areas already affected or at risk.
- Infrastructure Maintenance: Ensuring ongoing maintenance and repair of infrastructure along the road network—encompassing technical components, bridges, and other structures—to guarantee continued functionality and safety.

These measures provide a comprehensive framework for mitigating geohazard risks and enhancing public safety in vulnerable regions.

1. ntroduction

Flash floods are among the most destructive natural hazards, causing loss of life, infrastructure damage, and environmental harm, impacts expected to worsen with climate change, especially in the Mediterranean. Their sudden and localized nature makes systematic assessment difficult, particularly in urban and large-scale events (Merz et al., 2010; Petersen, 2001; Diakakis et al., 2017). The variability of impacts across different areas hinders the development of a standardized evaluation method. Existing approaches often target specific sectors, limiting a holistic understanding. A simple, multi-criteria system is needed to assess flash flood severity across events. (Marchi et al. 2023; Gourley et al., 2013; Boudou et al., 2016; Sîli et al., 2020). Lack of systematic impact data limits flood risk identification, relying on history and local knowledge. This weakens future predictions and mitigation efforts due to poor understanding of flood impacts. Using the Flash Flood Impact Severity Scale (FFISS), the study compares 2009 and 2020 floods to analyze severity patterns and improve preparedness (Schroeder et al., 2026; Boudou, 2016; Calianno et al., 2013; Diakakis et al., 2020).

2. Study area and flood events

The Lilas River catchment covers 249 km² in Evia Island (Greece), within two municipalities (Figure 1). It includes Vassiliko and nearby settlements, with a total population of about 16,500 residents (Hellenic Statistical Authority, 2021). Most of the area is forested, while the mid and lower sections support significant agriculture. The fertile Lilas Plain near the outlet has held historic agricultural and strategic importance. The Lilas catchment collects water from the southern and southwestern slopes of Mount Dirfi (1,743 m a.s.l.) and the surrounding Messapios mountains. Initially, the terrain is steep and rugged, but as the elevation decreases, the slopes become more gradual. Covering an area of 259.19 km², the drainage network is denser in the upper reaches, while in the lower elevations, the floodplain and main river channel have experienced flooding in the past (Figure 2).

2.1. The 2009 Flood

The 2009 flood in central Evia was triggered by intense rainfall, with 376.8 mm recorded in 18 hours at Steni. It caused major damage to infrastructure, homes, and vegetation, including roof collapse and severe erosion. Sediment deposition altered the river's flow, uprooted vegetation worsened flooding, and vehicles were swept away. The event underscored the need for better flood management, infrastructure upgrades, and ecosystem restoration (Meteo, n.d.).

2.2. The 2020 Flood

On August 8, 2020, a persistent storm system brought extreme rainfall to central Evia, with 300 mm recorded at Steni. The flood devastated the Lilas catchment resulting in damage to homes, roads, bridges, and farms and five fatalities. Infrastructure failures disrupted emergency response, while erosion reshaped riverbanks and reduced water capacity. The event revealed the need for resilient infrastructure, ecological restoration, and better flood preparedness (Lekkas et al., 2020; Mavroulis et al., 2021).

Figure 1. Map of the Evia Island in the eastern part of Mainland Greece. The red frame indicates the study area affected by flash floods in 2009 and 2020.

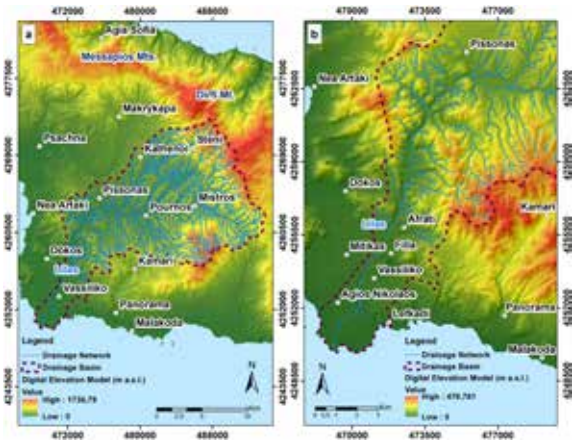

Figure 2. (a) Map showing the flood-affected Lilas catchment along with its drainage network and the elevation reaching over 1,730 m a.s.l. in the wider mountainous area comprising Messapios and Dirfi Mts located north of Lilas. (b) Map illustrating the lower part of the Lilas catchment, which was mainly affected by the 2009 and 2020 flash floods.

3. Methodology

3.1. Flash Flood Impact Data Collection

Flood impact data were gathered from official reports and media sources, alongside field surveys by the authors. These surveys used drones (DJI Mavic 2) and on-ground methods to capture high-resolution images and videos. UAS technology helped assess damage in areas too large or inaccessible for traditional methods. Geo-tagged data documented the location, type, and scale of damage with high spatial accuracy. Combining aerial and ground surveys ensured a complete picture of both widespread and localized impacts. Using the Unique Flood Impact Elements (UFIEs) enabled structured analysis, supporting better flood response and long-term planning (Spyrou et al., 2020; Spyrou et al., 2025; Andreadakis et al., 2020).

3.2. FFISS application

Flood impact data from both events were added in a GIS geo-database, with each entry (UFIE) mapped as a point and described by type, severity, and damage using FFISS (Diakakis et al. 2020). FFISS includes four impact categories:

(i) Built environment – damage to structures and infrastructure, from minor flooding to collapse or dam failure.

(ii) Mobile objects – displacement of items from lightweight to large vehicles.

(iii) Natural environment – effects on geomorphology, vegetation, agriculture, and pollution, from debris to severe contamination.

(iv) Population – from minor disruptions to fatalities. The scale consists of ten classes (Class I–X) to differentiate flood impact severity and avoid saturation seen in other models. It was developed through a global review of flash flood impacts, ensuring comprehensive coverage of diverse effects (Musson & Cecić, 2012; Diakakis et al., 2020).

3.3. Data processing and uncertainties

Only UFIEs with precise locations were used. Data lacking exact coordinates were excluded from analysis. Field data were GPS-logged with 3 m accuracy, while official records were mapped using building centroids or multiple points if needed. Visible pollution signs marked contamination, and with a 100 m grid, minor placement errors were acceptable unless exceeding cell size. (Diakakis et al., 2020; Spyrou et al., 2025).

4. Results

4.1. Application of the FFISS scale in the study area

According to the FFISS scale, the impacts of the 2009 Lilas River flood were systematically recorded and mapped across several affected areas, including Vassiliko, Afrati, and critical road networks. The transportation infrastructure experienced a range of damage severity, from road inundation and asphalt degradation to embankment erosion. Notably, partial and complete bridge failures led to the temporary isolation of entire communities during the peak of the flooding event (Figure 3). Varying levels of impact severity were recorded in the built environment, particularly at the level of individual buildings. In many inundated areas, flooding affected gardens, yards, pilotis, ground floors, and basements of both residential and commercial properties, significantly disrupting daily life. Structural damages ranged from collapsed fences to partial building failures, necessitating urgent search, rescue, and evacuation operations (Figure 4). The impact severity on mobile objects ranged from minor incidents, such as lightweight items and flower pots being displaced, to more significant cases like large waste bins carried by floodwaters. The severity escalated considerably with the displacement of vehicles, including cars and trucks swept into the sea, posing

serious risks to human life, particularly if occupants were present during the event (Figure 5). Finally, the observed impact severity in the natural environment included the uprooting and transport of low vegetation to riverbeds, roads, bridges, and residential areas, along with the flooding of higher ground plants. Severity increased with the uprooting of trees over 3 meters and significant geomorphological changes, such as soil erosion and deposition exceeding 3 meters in depth, which altered the morphology of the riverbed and delta (Figure 6).

Figure 3. Different flash flood impact severity classes on transportation. (a, b) Inundation of road surface in Vassiliko village (a) and Afrati settlement (b) (Class I). (c, d) Damages to the asphalt surface and levees scoured on the road Afrati – Pissonas (c) and in the Afrati settlement (d) (Class V). (e, f, g) Bridges suffered from structural damages and partial collapses in Vassiliko (e), Filla (f) and Afrati (g) (Class VII). (h) Bridge suffered from complete collapse in the settlement of Mistros (Class VIII).

Figure 4. Different flash flood impact severity classes on buildings. (a, b) Garden and pilotis had flooded in Lefkadi beach (Class I). (c) Yard walls and fences suffered from structural damages including total collapse in Vassiliko (Class IV). (d) House suffered from structural damages including failure of supporting elements in Vassiliko (Class VI).

Figure 5. Different flash flood impact severity classes on mobile objects. (a) Very light and small objects were transported at the beach of Agios Nikolaos (Class I). (b) Flower pots transported by floodwaters at Agios Nikolaos beach (Class II). (c) Large trash bins were carried away by floodwaters at Agios Nikolaos beach (Class III). (d, e, f), Cars were carried away during the flood in Vassiliko (Class IV). (g, h) Large tracks were transported by floodwaters in Afrati (Class VIII).

Figure 6. Different impact severity classes on the natural environment including (a, b) low vegetation uprooted and transported in the riverbed in Vassiliko (a) and on the bridge of Afrati (b) (Class II), (c) higher ground plants are affected by the flood in Vassiliko village (Class III), (d) tree smaller than 3 meters uprooted and carried away in the riverbed in Vassiliko (Class V), (e) large tree over 3 meters uprooted and destroyed on the riverbank in the village of Vassiliko (Class VI), (f, g) deposited material with a thickness of less than 3 meters in the riverbed downstream of Vassiliko village (f) and upstream of Afrati settlement (g) (Class VI), (h, i) eroded material with a thickness of more than 3 meters on the riverbank along the street of Afrati - Pissonas (h) and in Afrati (i) (Class VII).

Overall, 886 unique flood impact elements (UFIEs) were identified. We identified 187 and 699 UFIEs for the 2009 and the 2020 events, respectively. The frequency distribution across severity classes, highlighting key trends in the built and natural environments for the years 2009 and 2020. In the built environment, 2020 exhibited the highest frequency in Class III, with 104 events, indicating a notable concentration of lower-impact occurrences, while 2009 showed a peak in Class V with 15 events, reflecting more severe impacts. In the natural environment, both years recorded the highest frequency in Class IV. However, 2020 had a significantly higher count (116 events) compared to 2009 (57 events). This consistent dominance of Class IV, despite differing magnitudes, reveals a recurring vulnerability in the natural environment over time. Also, the highest frequency of severity for mobile objects was observed in Class IV, with 27 recorded events, indicating a notable concentration of impacts within this

class. Similarly, the human population sector showed the highest frequency in Class III, with 48 events, reflecting a moderate level of impact during the 2020 flood. No impact data were recorded for either sector in 2009, likely due to the absence of precise georeferenced information during that period.

4.2. Comparison of flood impact severity between 2009 and 2020

A comparison of impact severity between the two events shows both similarities and differences, influenced by environmental factors, land use changes, and discharge magnitude. In the built environment near the Lilas delta, the 2020 event showed lower severity than the 2009 one, largely due to post-2009 riverbed widening and the removal of damaged structures. However, in areas like Vassiliko, Filla, and Afrati, 2020 recorded higher severity, driven by greater discharge, erosion, and resulting structural damage to bridges. These findings underline the role of river morphology and infrastructure changes in shaping flood impact severity (Figures 7, 8).

Figure 7. Depiction of the morphological changes and the riverbed widening from the 2020 flood.

Figure 8. Illustration of the riverbed and estuary morphology of the Lilas River before the 2009 flood (above), as well as the destroyed buildings during the 2009 flood due to the widening of the riverbed (below).

The 2020 flood event resulted in a marked increase in impact severity in the area extending from Agios Nikolaos to Afrati and along the Afrati-Pissonas road. Elevated water levels and increased discharge significantly affected the river's geomorphology, leading to substantial sediment deposition within the riverbed and pronounced erosion along the riverbanks, phenomena not observed during the 2009 flood, which was characterized by lower discharge levels. This contrast in hydrological intensity and geomorphological outcomes is illustrated in Figure 9. Furthermore, no impact data concerning mobile objects or the human population were recorded during the 2009 event, although the absence of fatalities implies a lower severity level. Consequently, all relevant data and observations pertain exclusively to the 2020 flood. Notably, near the Afrati Bridge, high severity was recorded due to the floodwaters sweeping away heavy trucks and bulldozers from a nearby business (Figure 10).

Figure 9. A downstream view of the Vassiliko bridge, illustrating the estimated maximum water levels during the 2009 and 2020 flood events (indicated by white and yellow lines), based on high-water marks identified during post-flood surveys. The blue arrow indicates the river flow direction.

Figure 10. Illustration of the Afrati Bridge featuring bulldozers and large trucks that were carried away by the floodwaters. The yellow arrow indicates the river flow direction.

Across the entire impacted region and within all sectors of flood impact, the 2020 flood event was characterized by high-severity classifications in areas upstream of Agios Nikolaos, extending toward the settlement of Pissonas. In contrast, the 2009 flood exhibited lower-intensity classifications overall, with the notable exception of the Lilas River delta. This variation is primarily attributed to the fact that, in 2009, the built environment in the delta area suffered extensive damage, as several structures that

existed at the time were destroyed, thereby elevating the severity levels. By 2020, these structures had been removed, leading to a notable reduction in impact severity.

In addition, elevated severity classes (Classes V to VIII) were recorded in 2020 along the stretch from Agios Nikolaos to Afrati, due to extensive geomorphological alterations, significant damage to the built environment, particularly bridges, and the displacement of large mobile objects. Conversely, in 2009, no impact severity was documented in the areas of Agios Nikolaos and Lefkandi. Downstream of Pissonas, higher severity classifications (Class VIII) were also recorded in 2020 compared to 2009, mainly due to pronounced geomorphological changes and widespread vegetation disturbance caused by increased surface runoff. As for the Lilas River delta, severity classifications in 2020 were generally lower (Classes II–V) than those recorded in 2009 (Classes V–VIII) (Figure 11).

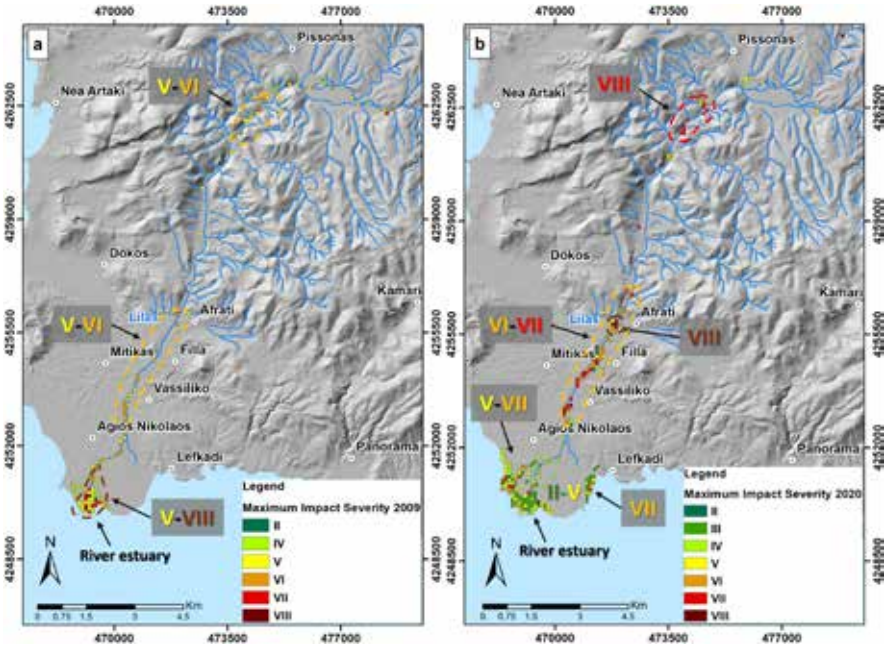

Figure 11. Comparison of maximum flash flood impact severity in the affected area of 2009 (a) and 2020 (b). The zones of impact concentration are divided as follows: at the estuary of the Lilas River, upstream of the Vassiliko bridge and downstream of Filla, in Afrati, and along the road Afrati-Pissonas.

5. Conclusions

This study applied the FFISS scale with four categories (built environment, natural environment, mobile objects, and population) and ten severity classes to assess two flood events in 2009 and 2020. Advanced technologies, including drones and ground-based observations, were used to capture high-resolution imagery and data across the affected areas. The FFISS scale allowed for a detailed comparison of both events, revealing a range of severity from classes II to VIII. While the 2009 flood had higher severity near the Lilas River delta, the 2020 flood impacted a wider area, including regions near the Vassiliko bridge and Pissonas. The 2020 flood was more intense, with increased discharge, higher flow velocities, and severe impacts such as sediment deposition, bank erosion, and bridge collapse. In 2009, riverbed widening near the delta affected the built environment, increasing the severity, but the absence of these structures in 2020 reduced impacts. The study demonstrated that the FFISS scale is useful even without geo-referenced data, as seen in the 2009 flood's movable objects and population sectors. The 2020 flood, however, involved significant displacement of large vehicles and fatalities, highlighting increased risks. The findings suggest that riverbed widening and flood mitigation measures, including hydraulic structures and retention measures upstream, are essential to reduce future flood risks.

Abstract

Understanding and monitoring shoreline changes is critical for effective coastal zone management, particularly in regions experiencing dynamic erosion and accretion. This study evaluates the effectiveness of airborne LiDAR and RGB imagery acquired via Unmanned Aerial Systems (UAS) for accurate shoreline detection, focusing on Gavathas Beach, Lesvos Island, Greece. Both technologies were utilized to generate high-resolution Digital Elevation Models (DEMs) and orthophotographs, enabling precise delineation of the shoreline. The LiDAR data, collected using the YellowScan VX-15 system mounted on a DJI Matrice 600 Pro, provided dense 3D point clouds with centimeter-level accuracy. Simultaneously, RGB imagery was captured using a Sony Alpha 6000 camera synchronized with the LiDAR system. The RGB-derived orthophotographs facilitated visual interpretation and supported the identification of shoreline features under varying environmental conditions.

Digital Shoreline Analysis System (DSAS) was employed to quantify shoreline changes by comparing the extracted shorelines with reference data collected using a Differential GPS (DGPS) system. The results demonstrated that LiDAR-derived shorelines exhibited superior accuracy, with mean deviations of less than 0.5 meters from the reference data. RGB-derived shorelines showed slightly higher deviations due to challenges in image contrast and environmental lighting conditions but remained within acceptable thresholds for practical applications. This comparative analysis highlights the potential of integrating airborne LiDAR and RGB imagery for efficient and reliable shoreline mapping. The findings emphasize the advantages of LiDAR for its high spatial resolution and robust performance in complex coastal environments, while RGB imagery offers a cost-effective and operationally flexible alternative for areas with clear land-water boundaries. These insights contribute to the optimization of coastal monitoring practices and inform future applications of remote sensing technologies in shoreline management.

Keywords: LiDAR, UAV, 3D point cloud, Erosion, Remote Sensing

Introduction

Coastline mapping is an essential practice for understanding and managing coastal dynamics. Coastal zones worldwide are subject to significant changes due to natural and anthropogenic factors, including sediment transport, sea-level rise, and human intervention (Boak and Turner 2005). Monitoring these changes is critical for mitigating the risks associated with coastal erosion, flooding, and habitat loss (Klemas 2011). Traditional methods of monitoring, such as aerial photography and satellite imagery, have provided valuable insights into large-scale patterns but often lack the spatial resolution required for detailed shoreline mapping (Ford 2013; Kaichang Di, Jue Wang, Ruijin Ma et al. 2003). Measurement sensors deployed along coastlines, such as geodetic instruments and soil pressure gauges, also offer systematic data but are constrained by limited coverage and resource-intensive operations (El-Raey et al. 1999).

Over recent decades, advancements in remote sensing technologies have transformed coastal monitoring practices. Unmanned Aerial Systems (UAS) equipped with LiDAR sensors and RGB cameras now enable high-resolution, cost-effective data collection in dynamic and inaccessible coastal environments. Airborne LiDAR, in particular, is recognized for its ability to produce detailed Digital Elevation Models (DEMs) with high vertical and horizontal accuracy, making it an indispensable tool for analyzing complex topographies (Fiedler et al. 2021; Wozencraft and Millar 2005). For example, Wozencraft and Millar (2005) emphasized the critical role of LiDAR in capturing high-resolution elevation data for developing accurate DEMs, which significantly enhance shoreline delineation and coastal management practices.

Complementary to LiDAR, RGB imagery offers a more affordable and operationally flexible approach to shoreline mapping, particularly in areas with clear visual contrast between land and water. Gómez-Gutiérrez et al. (2024) demonstrated the effectiveness of combining RGB photogrammetry with LiDAR to generate accurate 3D models, even in the absence of ground control points (GCPs) (Lin et al. 2019). This integration highlights the growing potential of combining LiDAR and RGB technologies for coastal applications, as it balances precision and cost-efficiency.

In this study, we leverage the capabilities of airborne LiDAR and RGB imagery to evaluate their performance in shoreline mapping at Gavathas Beach, Lesvos Island, Greece. This site, characterized by its diverse coastal features—including sandy beaches, rocky outcrops, and vegetated dunes—offers a robust testing ground for these technologies. By employing Differential GPS (DGPS) as ground-truth data, we assess the accuracy of LiDAR- and RGB-derived shorelines and provide a comparative analysis of their strengths and limitations. The findings aim to contribute to the optimization of remote sensing methods for coastal monitoring and to inform sustainable coastal management strategies.

Materials and Methods

Study Area

The study area is Gavathas Beach, situated on the northwest coast of Lesvos Island, Greece. This location was selected for its diverse coastal morphology, characterized by a gently sloping sandy shoreline bordered by rocky outcrops and vegetated dunes. Gavathas Beach experiences minimal tidal variation, with a microtidal range typically less than 0.5 meters, providing stable conditions for data collection. The wave energy is generally low to moderate, influenced by the northwest orientation of the beach, which shelters it from prevailing winds and swells. This relatively undisturbed environment, with limited human activity, was ideal for uninterrupted data collection and minimized interference with the deployed equipment. The study focused on a 200-meter segment of the eastern beach, where the combination of sandy and rocky sections offered a valuable testing ground for evaluating the performance of airborne LiDAR and RGB imagery in shoreline mapping. The data collection was conducted on June 8, 2023, under clear skies and light winds, ensuring optimal conditions for aerial surveys.

Field data

The data collection process involved the coordinated use of airborne LiDAR and RGB imagery systems. A DJI Matrice 600 Pro Unmanned Aerial System (UAS) was employed as the platform for both sensors. The YellowScan VX-15 LiDAR system was mounted on the UAS to capture high-resolution 3D point clouds, providing detailed elevation data with centimeter-level accuracy. This system integrates a LiDAR sensor with advanced GNSS and IMU systems, ensuring precise georeferencing of the collected data. The TopCON Hiper VR GNSS system was utilized to achieve precise georeferencing and real-time measurement capabilities. Supporting multiple GNSS constellations (GPS, GLONASS, Galileo, BeiDou), it provided exceptional accuracy, reaching up to 8 mm in horizontal and 15 mm in vertical measurements under optimal conditions. This system ensured the reliable alignment of the airborne LiDAR data. Ground control points (GCPs) were established using the Hiper VR rover, which also measured the reference coastline for subsequent shoreline change analysis. Simultaneously, a Sony Alpha 6000 camera was mounted and synchronized with the LiDAR system to capture high-resolution RGB imagery. The camera underwent professional calibration to ensure optimal alignment with the LiDAR system, enabling seamless integration of image and elevation data during post-processing. The RGB images were used to create orthophotographs, which provided additional context for shoreline delineation. The data acquisition was conducted early in the morning to ensure stable environmental conditions and minimize potential disturbances. Ground control points (GCPs) were established using a Differential GPS (DGPS) system to provide accurate georeferencing for both LiDAR and RGB datasets. The UAV followed a pre-programmed flight path, capturing overlapping data to ensure complete coverage of the study area. This coordinated approach ensured the collection of high-quality datasets for subsequent analysis of shoreline changes.

Methodological framework

The methodological framework for this study integrates data acquisition, processing, and analysis to evaluate the accuracy of shoreline delineation using airborne LiDAR and RGB imagery, as shown in **figure 1**. The workflow began with field data collection, as described above, followed by pre-processing of the datasets. LiDAR data were first georeferenced and processed using Applanix's POSPac Mobile Mapping Suite to correct trajectory data and align the LiDAR point clouds accurately. The refined point clouds were imported into YellowScan's CloudStation software for visualization, noise filtering, and delineation of the study area. Key processes included the removal of redundant points, outliers, and the selection of the region of interest for analysis. The data were then exported in LAS format for compatibility with GIS software and further processing. The RGB imagery underwent a structured photogrammetric workflow using Agisoft Metashape. The process started with image alignment, where overlapping images were analyzed to generate a sparse point cloud. This was followed by the creation of a dense point cloud, which provided high-resolution 3D spatial data. An orthophotograph was subsequently generated, ensuring accurate representation of the study area. Ground control points were used to enhance the spatial accuracy of the outputs, and the resulting orthophotographs were exported in GeoTIFF format for integration into GIS platforms.

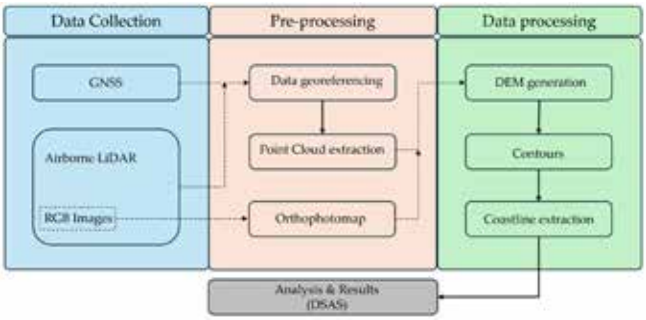

Figure 1. Methodology flowchart.

The data processing workflow involved generating high-resolution Digital Elevation Models (DEMs), extracting elevation contours, and analyzing shoreline changes using the Digital Shoreline Analysis System (DSAS). Initially, LAS files derived from LiDAR pre-processing were imported into ArcGIS Pro for further analysis. These georeferenced point clouds were visualized using the LAS Dataset Layer tool, enabling a detailed overlay of elevation data on basemaps of the study area. The creation of DEMs utilized the LAS Dataset to Raster tool in ArcGIS Pro, which transformed the elevation points into a continuous raster format. The interpolation method was configured to Binning (Natural Neighbor), and a cell size of 0.5 meters was selected to balance high resolution with computational efficiency. The Z-values from the LAS files represented elevation data, and the resulting raster was exported as a GeoTIFF file, capturing the intricate topography of the coastal zone. From these DEMs, elevation contours were extracted using the Contour tool in ArcGIS Pro. Contours provided a vectorized representation of elevation data, simplifying the interpretation of topographic variations. The contour interval was set to 0.5 meters, reflecting fine-scale changes in coastal morphology, and the base contour value was aligned with the minimum elevation within the DEM. The resulting contours were saved in ESRI Shapefile format, ensuring compatibility with spatial analysis tools. These contours served as a critical reference for shoreline delineation by identifying the contour line closest to the mean sea level (MSL). The integration of DEMs and contours enabled a comprehensive examination of the coastal environment, providing precise inputs for shoreline extraction and subsequent DSAS analysis. This systematic approach ensured that the spatial data maintained high accuracy and reliability, supporting detailed assessments of coastal dynamics and morphological changes.

The Digital Shoreline Analysis System (DSAS) was utilized within ArcGIS to quantify shoreline changes and assess accuracy. Baselines were manually digitized landward of the shorelines to serve as references. Transects were generated perpendicular to the baselines at regular intervals to measure deviations between LiDAR, RGB-derived shorelines, and the DGPS reference data. Metrics such as Net Shoreline Movement (NSM) and End Point Rate (EPR) were computed to evaluate temporal and spatial changes. Visual outputs, including charts and maps, were created to illustrate deviations and shoreline dynamics.

Results

For the evaluation of different mapping technologies, this study utilized data from airborne LiDAR and RGB imagery, which were processed to generate high-resolution Digital Elevation Models (DEMs) and elevation contours. These data were georeferenced using a GNSS base station, a GPS rover, and ground control points strategically placed within the study area to ensure accuracy. Additionally, on the day of data acquisition, the shoreline was recorded using DGPS as a reference line, serving as the benchmark for validating results from the airborne sensors. Table 1 summarizes the detected shorelines from DGPS, RGB imagery, and airborne LiDAR, focusing on their ability to delineate features such as the Instantaneous Shoreline, Intermediate Shoreline, and Wave Runup.

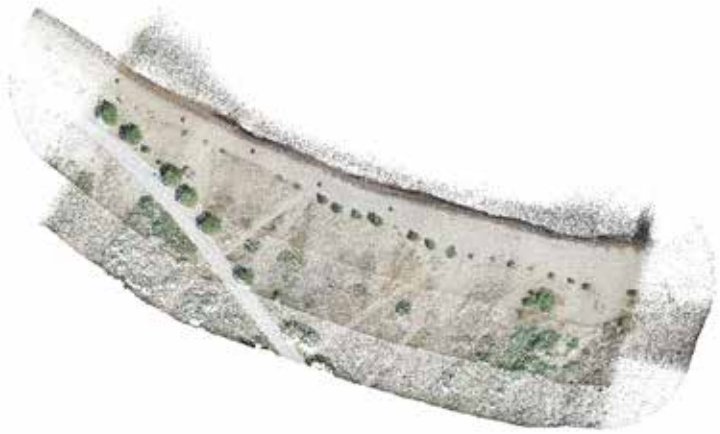

Figure 2. Results of airborne LiDAR: Colorized point cloud.

Airborne LiDAR showcased outstanding capability in shoreline mapping, delivering high spatial resolution and accuracy across extensive coastal areas. The method excelled in identifying key shoreline features, including the instantaneous shoreline, wave runup, and intermediate shoreline, with minimal deviations. Its deployment on a UAV platform enabled rapid data acquisition with consistent coverage, even in complex and dynamic coastal environments. The coastline derived from LiDAR data demonstrated

a mean deviation of just 0.5 meters when compared to the DGPS reference, emphasizing its precision. Moreover, the wave runup and intermediate shoreline were accurately captured, reflecting the system's ability to resolve fine-scale topographic variations. **Figure 2** highlights the outcomes of LiDAR data processing, showcasing the raw point cloud colored with aerial RGB imagery and **figure 3** shows the corresponding Digital Elevation Model (DEM) with extracted contours on the right, which were used to delineate the final shoreline.

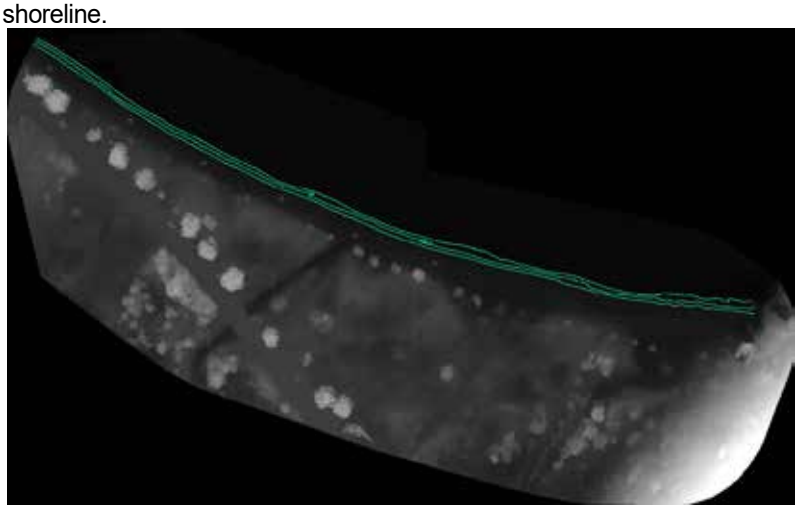

Figure 3. Results of airborne LiDAR: Digital Elevation Model (DEM) and elevation contours.

The RGB imagery captured by the mounted Sony Alpha 6000 camera on the UAV proved effective in generating a high-resolution orthophotomap, providing a visual reference for shoreline extraction, as shown in **figure 4**. However, this method was more prone to errors influenced by lighting conditions and image contrast. The approach performed best in areas with distinct land-water boundaries, where photogrammetric techniques delivered accurate results. Nevertheless, the shoreline derived from the RGB orthophotomap exhibited a larger deviation from the DGPS reference, with a mean offset of approximately 1.5 meters. This discrepancy was primarily attributed to difficulties in identifying clear shoreline boundaries in regions with low contrast. **Figure 5** presents the Digital Elevation Model (DEM) and the extracted elevation contours are shown, which were employed for precise coastline delineation.

Figure 4. RGB imagery results: Orthophotomap.

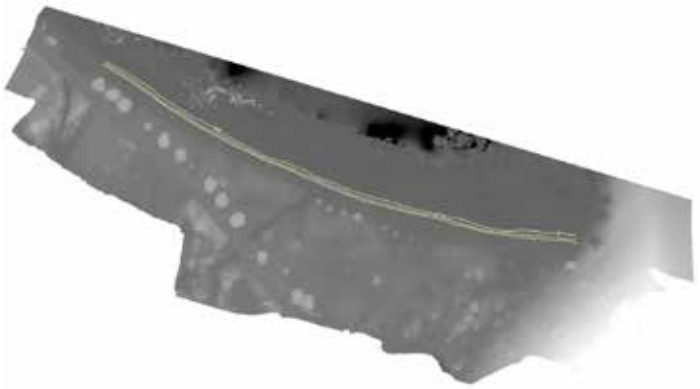

Figure 5. RGB imagery results: Digital Elevation Model (DEM) and elevation contours.

The analysis results demonstrate that airborne LiDAR provides superior accuracy and precision in delineating coastal features compared to the RGB imagery. LiDAR data achieved a mean deviation of only 0.5 meters from the DGPS reference coastline, showcasing its exceptional capability in capturing fine-scale topographic details. This accuracy is particularly evident in the identification of critical shoreline features, such as the instantaneous shoreline, wave runup, and intermediate shoreline. The ability of the LiDAR system to generate high-resolution Digital Elevation Models (DEMs) and extract detailed elevation contours further highlights its effectiveness in coastal monitoring. In contrast, the RGB-derived orthophotomap, while offering valuable visual context, exhibited a larger deviation from the DGPS reference. The mean offset of approximately 1.5 meters was primarily attributed to limitations in photogrammetric processing, especially in areas with low contrast or ambiguous land-water boundaries.

These challenges were particularly evident in vegetated or shadowed regions, where the RGB imagery struggled to distinguish the shoreline accurately. Despite these limitations, the RGB orthophotomap proved to be a cost-effective and operationally flexible alternative for areas with well-defined shoreline features. In **figure 6**, we can observe the coastlines detected using the RGB sensor (on the left) and airborne LiDAR (on the right).

Figure 6. Results of coastline detection: (Left) Coastlines from Orthophotomap; (Right) Coastlines from airborne LiDAR.

The DSAS analysis revealed consistent trends between the LiDAR and RGB-derived shorelines, with LiDAR consistently outperforming RGB in terms of accuracy. The transects generated across the study area showed that the maximum deviation between the LiDAR and RGB-derived shorelines reached up to 2.1 meters in areas with complex coastal features, such as rocky outcrops or densely vegetated dunes. However, in regions with clear visual contrast between land and water, the RGB orthophotomap aligned closely with the LiDAR data, demonstrating its potential for efficient shoreline mapping in less challenging environments. **Figure 7** illustrates the results of the DSAS analysis. The baseline and transects used for measuring deviations between the LiDAR- and RGB-derived shorelines are displayed, providing an overview of the study area. **Figure 8** demonstrates a close-up section that highlights the alignment of the shorelines, clearly showing the areas where deviations are most pronounced. The LiDAR data precision in capturing subtle elevation changes is evident in its ability to detect features such as the wave runup and intermediate shoreline, which are less distinct in the RGB-derived data.

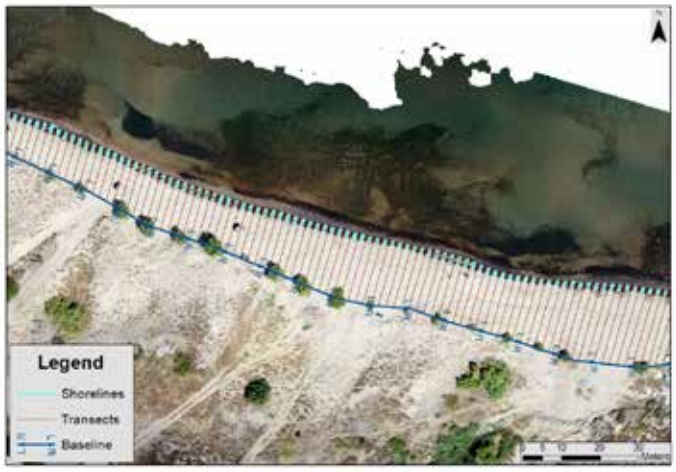

Figure 7. Results of the DSAS analysis: The entire study area, showing the baseline, transects, and shorelines.

In addition to accuracy, the efficiency of data collection and processing was another significant advantage of the airborne LiDAR system. The LiDAR system required only 7 minutes of flight time and approximately 30 minutes of preparation to complete the survey, compared to the longer photogrammetric processing time required for the RGB data. Moreover, LiDAR's elevated perspective and dense point cloud generation minimized the influence of environmental factors, such as lighting conditions or vegetation movement, which significantly impacted the RGB results.

Figure 8. Results of the DSAS analysis: A portion of the study area, highlighting the difference between the shorelines.

While both methods have their strengths, the comparative analysis underscores the superior performance of airborne LiDAR in terms of accuracy, efficiency, and versatility. However, the RGB orthophotomap remains a valuable tool for providing supplementary visual information and serves as a practical alternative for mapping in areas where LiDAR deployment may be constrained by budget or logistical challenges. These findings contribute to the ongoing development of integrated approaches for coastal monitoring, combining the strengths of both technologies to optimize shoreline detection and analysis.

Conclusions

The outcomes of this study confirm the efficacy and unique characteristics of airborne LiDAR and RGB imaging in coastal mapping applications. Airborne LiDAR demonstrated unparalleled accuracy and spatial coverage, closely aligning with the reference coastline captured via DGPS. Its ability to precisely capture dynamic shoreline features, such as the instantaneous shoreline, wave runup, and intermediate shoreline, highlights its suitability for complex coastal environments. The dense 3D point clouds generated by the LiDAR system enabled the creation of high-resolution Digital Elevation Models (DEMs) and detailed elevation contours, which are essential for understanding subtle topographic variations and monitoring morphological changes over time.

In contrast, RGB imaging, while a cost-effective and flexible alternative, exhibited greater sensitivity to environmental factors, including lighting conditions and surface contrast. These challenges resulted in slightly lower precision, with deviations from the reference coastline averaging 1.5 meters. Nevertheless, RGB orthophotomaps provided valuable visual context, particularly in areas with distinct land-water boundaries, and offered an operationally efficient method for shoreline delineation in less dynamic environments.

This comparative analysis underscores the importance of selecting the appropriate technology based on specific project needs. Airborne LiDAR excels in applications requiring high accuracy, extensive spatial coverage, and the ability to capture fine-scale details in dynamic coastal settings. Meanwhile, RGB imaging serves as a practical alternative for budget-constrained projects or areas where logistical challenges limit the deployment of LiDAR systems.

The integration of Differential GPS (DGPS) data as ground truth further validated the performance of both methods, providing a reliable benchmark for assessing their accuracy. Additionally, the use of the Digital Shoreline Analysis System (DSAS) enabled a comprehensive evaluation of shoreline changes, quantifying spatial discrepancies and providing insights into the dynamic processes shaping coastal environments. The ability to combine LiDAR and RGB data into an integrated analysis framework enhances our understanding of shoreline dynamics and supports the development of more robust coastal monitoring practices.

The broader implications of this research highlight the growing need for innovative and hybrid approaches to coastal management. As demonstrated, the complementary strengths of airborne LiDAR and RGB imaging can significantly improve the precision and reliability of coastal assessments. By leveraging these technologies in tandem, researchers and policymakers can better address the challenges posed by coastal erosion, sea-level rise, and other environmental changes.

This study contributes to the advancement of coastal monitoring methodologies by offering a detailed comparative framework for evaluating remote sensing technologies. The findings emphasize the importance of tailoring the choice of technology to the specific requirements of each project, ensuring the optimal balance between accuracy, cost, and operational feasibility. As environmental changes accelerate, integrating cutting-edge remote sensing tools will be crucial for sustainable coastal development and the implementation of effective erosion mitigation strategies.

Acknowledgments: We would like to express our gratitude to Professor Christos-Nikolaos Anagnostopoulos from the Department of Cultural Technology and Communication at the University of the Aegean for providing the Terrestrial Laser Scanner (TLS) used in this study. We also extend our thanks to the team from the Cartography & Geoinformatics Laboratory at the Department of Geography, University of the Aegean,

for their valuable assistance in the TLS data collection process. Special thanks go to Argyris Moustakas and Apostolos Papakonstantinou for their significant contributions during the fieldwork operations.

Domestic Rainwater Harvesting Tanks´ Sizing under Climate Change Conditions in Nisyros Island

Stavropoulos T., Feloni E.

Department of Surveying and Geoinformatics Engineering, University of West Attica, 28 Ag. Spiridonos, 12243 Egaleo, Athens, Greece; tstavropoulos@uniwa.gr; efeloni@uniwa.gr

Introduction

The Mediterranean region has long been recognized as a climate change hotspot by numerous studies and researchers (e.g., Giorgi, 2006; Zittis et al., 2022). Arid and semi-arid areas, such as the Greek islands (Pnevmatikos and Katsoulis, 2006), face heightened challenges due to their unique climatic conditions (Köppen, 1936), which make them particularly susceptible to extreme heat, droughts, and water scarcity. Additionally, the growing influx of tourists, even on smaller islands like those in the Aegean Sea, further strains local water resources. This evolving reality underscores the urgent need for stakeholders to implement cost-effective strategies to ensure water security. In this context, the present study examines the performance of a rainwater harvesting system (RWHS) on Nisyros, a small island in the southeastern Aegean Sea, Greece, with a population of 1,048. Nisyros is renowned for its unique geological history and volcanic origin and is currently a candidate for UNESCO Global Geopark designation (Nomikou et al., 2023).

Aligned with Sustainable Development Goals 9 and 11, enhancing resilience in local communities and ensuring sustainable water management solutions are critical for the years ahead (UNDESA, 2024). Rainwater harvesting (RWH) is explored as a viable domestic-scale approach to supplement water needs for non-potable uses, reducing reliance on conventional freshwater sources. RWH is an economically feasible and relatively simple method to implement (Farreny et al., 2011) and has been widely utilized for centuries, dating back to ancient civilizations (Valdez et al., 2016). Depending on the level of treatment, RWHS can provide both potable and non-potable water for household and agricultural applications (Londra et al., 2015).

Methodology

This study employs a daily water balance model to evaluate the efficiency of an urban RWHS (Figure 1) using rooftop collection. The model is designed to determine the optimal rainwater tank dimensions necessary to store the collected rainwater while meeting a targeted percentage of household water demand, excluding drinking water. In this study, the household water consumption was determined to be 150 liters per capita per day. This value represents the average prescribed limits according to Government Gazette Issue B 174/1991, which sets a minimum consumption of 100 liters per day per person and a maximum of 200 liters per day per person. Additionally, according to the official data from ELSTAT (2011), most households consist of 1 to 3 members (Ncap). Therefore, scenarios are applied for Ncap = 1, Ncap = 2, and Ncap = 3.

The simulation tracks the daily water balance in the tank, considering both inflow from rainfall and outflow for domestic use, providing insights into the system's overall efficiency.

Daily rainfall data from the National Meteorological Service station on Nisyros were used for the available period from 2017 to 2023, spanning six hydrological years. This timeframe aligns with the German standard DIN 1989-1 (2002), which recommends a minimum of 5 to 10 years of rainfall data for RWHS dimensioning. The rainfall station was selected based on data availability, completeness, and geographic relevance, ensuring accuracy in tank sizing calculations.

The water balance equation applied in this study is:

$$S_t = S_{t-1} + R_t - D_t, 0 \leq S_{t-1} \leq V_{tank}$$

where: St is the stored volume at the end of t day (m^3); St-1 is the stored volume at the beginning of t day (m^3); Rt is the daily harvested (added) rainwater volume at the end of t day (m^3); Dt is the daily water demand at the end of t day (m^3); and Vtank the capacity of the rainwater harvesting tank (m^3).

To enhance the accuracy of the system's spatial assessment, mapping tools such as ArcGIS and Google Earth Pro were utilized to calculate the available rooftop catchment area of buildings (Durgasrilakshmi et al., 2018). This approach ensures that the estimated collection areas reflect real-world conditions.

Additionally, future climate projections were incorporated to assess RWHS performance under climate change conditions. Two Representative Concentration Pathways (RCPs) were examined: RCP 4.5 (moderate emissions scenario) and RCP 8.5 (high emissions scenario). Future rainfall data for the period 2026–2060 were obtained from the DEAR Clima database (DEAR-Clima-2024).

Three main scenarios were investigated, varying in household size and catchment area:

- A single-person household with a rainwater collection area of 20–120 m².
- A two-person household with a rainwater collection area of 20–120 m².
- A three-person household with a rainwater collection area of 20–120 m².

These scenarios provide a comprehensive evaluation of RWHS effectiveness under different household and climate conditions, offering valuable insights for sustainable water management on Nisyros.

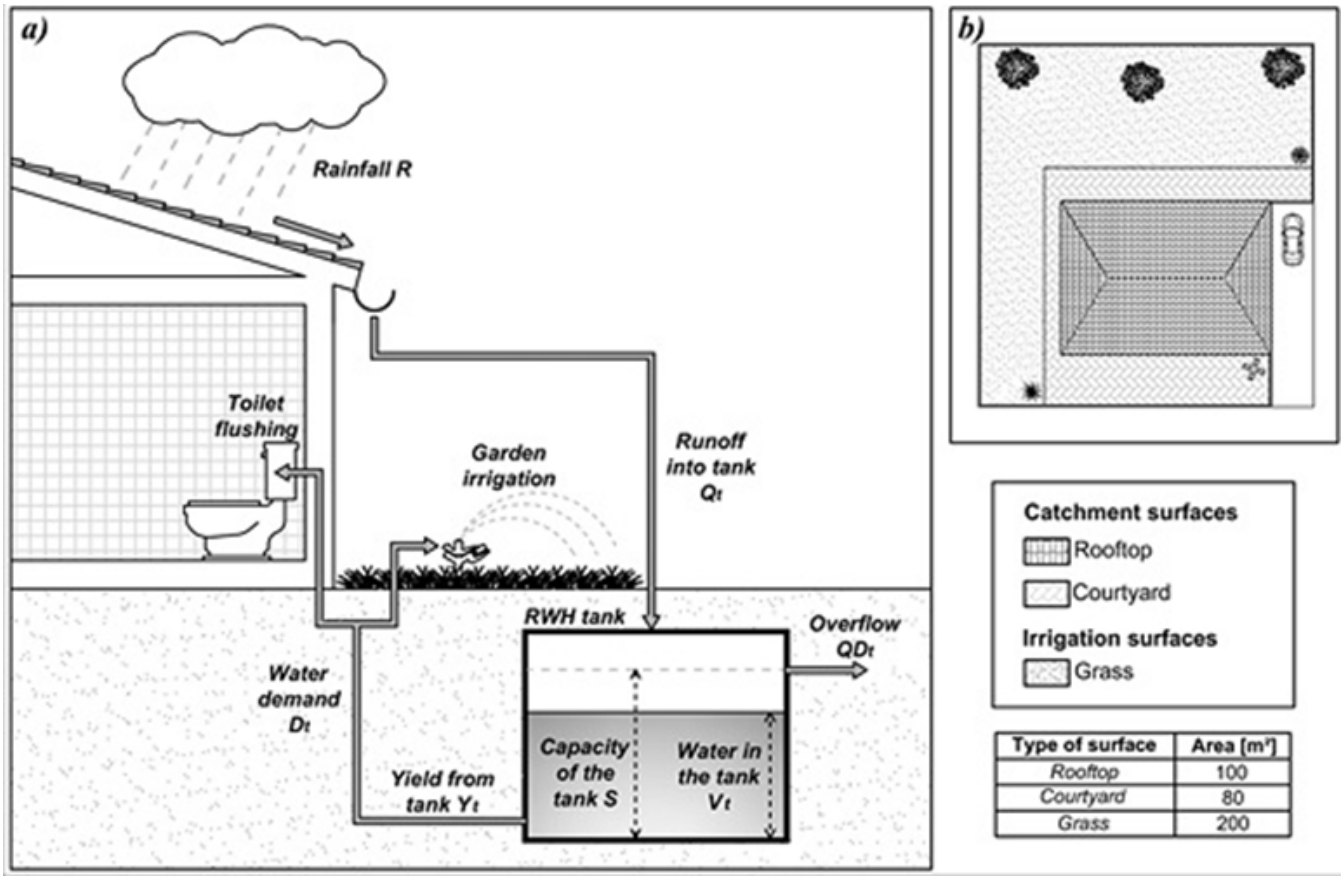

Figure 1: RWHS scheme (Source: Liuzzo et al., 2016)

Results

A. Results for historical timeseries

Figure 2 illustrates the results for the first scenario (single-person household), showing that system reliability ranges from 38% to 100%. The smallest rainwater collection area that ensures 100% reliability is 40m², with a tank capacity of 30m³. Additionally, the smallest tank volume that achieves full reliability is 5m³ when paired with a 60m² collection area. In general, for collection areas between 60 and 120m², the system consistently reaches 100% reliability for a single-person household, with tank volumes (Vtank) varying from 5 to 30m³. Notably, a significant shift in system performance is observed for collection areas between 20 and 40m², while at 20m², full reliability is not attained.

For the second scenario (Figure 3), which considers a two-person household, system reliability ranges from 14% to 100%. Compared to the first scenario, minimum efficiency is notably reduced due to the increased water demand. A sharp transition in system efficiency occurs for collection areas between 20 and 100m². Full reliability is achieved for households with collection areas of 100m² and 120m², with tank capacities between 10 and 30m³. The table below details the combinations of tank volume and collection area that ensure full reliability.

In the third scenario (Figure 4), representing a household with three members, reliability values range from 6% to 82%. Unlike the previous cases, full reliability is not achieved under any configuration. Additionally, a pronounced shift in system reliability is observed across collection areas ranging from 20 to 120m².

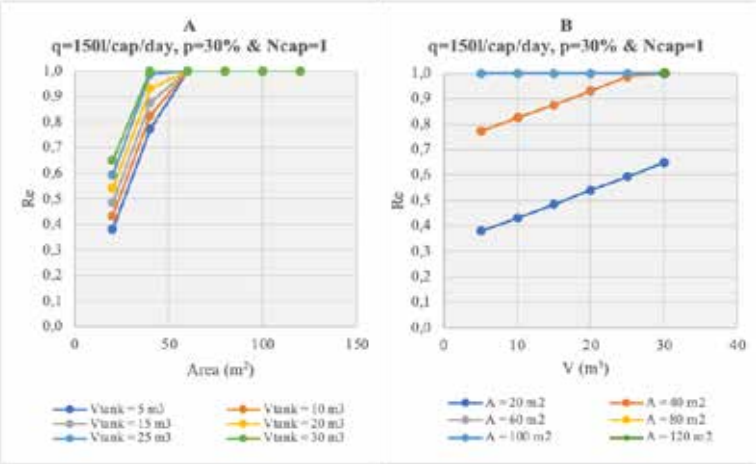

Figure 2. Reliability of demand coverage by the studied rainwater harvesting system for an average daily demand of q=150 l/cap/day, a demand coverage percentage of p=30%, and Ncap=1, with water collection areas ranging from 20 to 120 m². A: Reliability as a function of collection area range. B: Reliability as a function of tank volume.

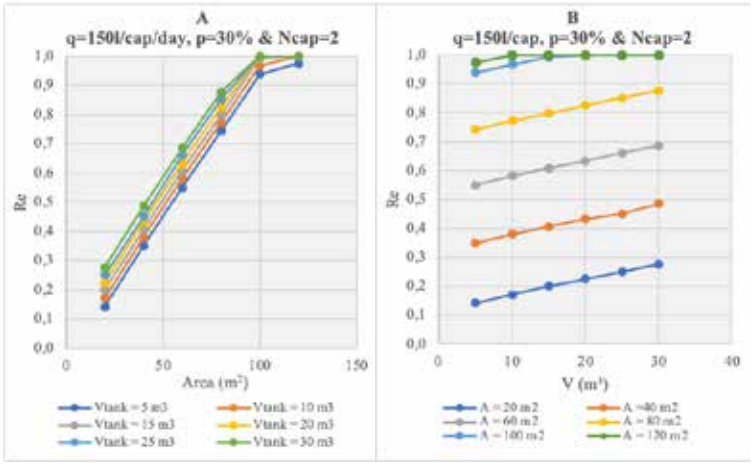

Figure 3. Reliability of demand coverage by the studied rainwater harvesting system for an average daily demand of q=150 l/cap/day, a demand coverage percentage of p=30%, and Ncap=2, with water collection areas ranging from 20 to 120 m². A: Reliability as a function of collection area range. B: Reliability as a function of tank volume.

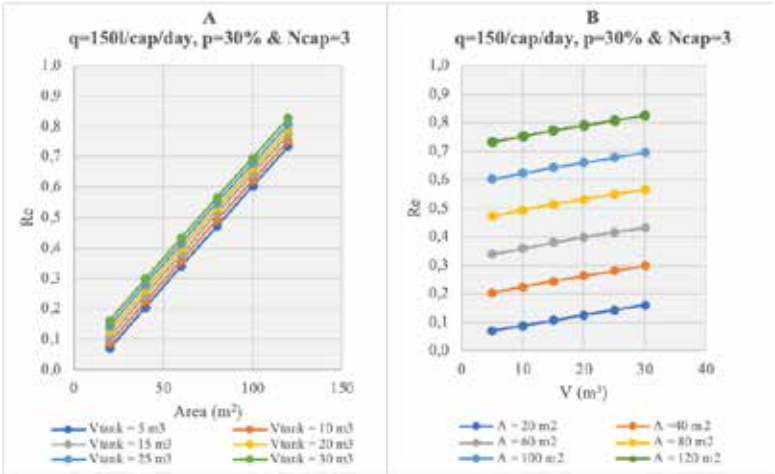

Figure 4. Reliability of demand coverage by the studied rainwater harvesting system for an average daily demand of q=150 l/cap/day, a demand coverage percentage of p=30%, and Ncap=3, with water collection areas ranging from 20 to 120 m². A: Reliability as a function of collection area range. B: Reliability as a function of tank volume.

B. Results for future climatic scenarios

In most scenarios involving a two-person household, the system successfully meets the target of supplying 30% of the total water demand. The water collection area (A) is identified as a critical factor, with smaller collection areas leading to lower reliability. Regarding the rainwater tank volume (Vtank), increasing the storage capacity results in only a marginal improvement in system reliability.

For households with three members, full reliability is achieved in certain cases under the RCP 4.5 climate scenario. However, under the RCP 8.5 scenario, a slight decline in reliability is observed compared to RCP 4.5, which is in accordance with the negative trends of rainfall patterns, indicating a potential impact of future climate conditions on system performance.

Table 1: Combinations of minimum rainwater collection areas and rainwater tank volumes for full system efficiency under the scenario Ncap=2.

	A (m^2)	Vtank (m^3)
Historic Time Series	100	20
RCP 4.5	60	5
RCP 8.5	60	5

Table 2: Combinations of minimum rainwater collection areas and rainwater tank volumes for full system efficiency under the scenario Ncap=3.

	A (m^2)	Vtank (m^3)
Historic Time Series	-	-
RCP 4.5	80	5
RCP 8.5	80	10

Conclusions

The study demonstrated that the reliability of the rainwater harvesting system is highly sensitive to both the collection surface area and tank volume. For the historical rainfall time series (2017–2023), reliability increased with larger collection areas and storage capacities. A single-person household achieved full reliability with a 40m² collection surface and a 30m³ tank, while the smallest volume ensuring 100% reliability was 5m³ with a 60m² surface. In the two-person household scenario, full reliability was reached at 100m² with a 20m³ tank, with the minimum tank volume ensuring complete reliability being 10m³ for a 120m² surface. However, for three-member households, full reliability was not achieved due to higher water demands. Regarding future climate projections (2026–2060), the system generally showed improved reliability under the RCP 4.5 and RCP 8.5 scenarios compared to historical data, except for the SMHI-RCA4_IPSL-IPSL-CM5A-MR dataset, which exhibited lower reliability. The system's reliability appears to improve, likely due to an increase in daily rainfall values within the upper 20% of the distribution, as observed in future scenarios compared to historical data. Most projections also indicate a reduction in wet days, though the duration of the longest drought periods does not appear to be significantly affected. Although RCP 8.5 led to a slight decline in system performance compared to RCP 4.5, it still outperformed the historical series. However, due to the limited timespan of the available historical data, the reliability of these estimates remains uncertain. For two-member households, full reliability was first achieved with a 60m² collection surface and a 5m³ tank in both RCP scenarios, while in the three-person household scenario, full reliability was obtained at 80m² with a 5m³ tank under RCP 4.5 and at 80m² with a 10m³ tank under RCP 8.5. Further research could provide valuable insights by assessing the system's performance under a broader range of climate projections and exploring the relationship between reliability and changing water consumption.

Research Highlights

The structure and evolution of the Santorini-Amogos basin can be reproduced by applying a plane-strain numerical model.

The Santorini-Amorgos basin (SE Cycladic plateau) is the stage of a complex interaction between active faulting and magmatism, causing the January- March 2025 swarm-type earthquake sequence.

Introduction

The Aegean Sea (Greece), in its present configuration, was formed as a response to the retreat of the Hellenic subduction zone, a retreat that was accelerated since the Middle Miocene, leading to the exhumation of lower and middle crustal rocks that were previously subducted to great depths (Jolivet and Brun, 2010; Ring et al., 2010). Active faulting is restricted along narrow zones with strike-slip and oblique-normal sense of motion, where shallow-intermediate depth seismicity also manifests (Kokkalas et al., 2006).

The Attic Cycladic Crystalline Complex (ACCC, Figure 1) is one such area where the central part is generally aseismic, and major active faults and earthquake activity are located along the north and especially the southern margin, where the modern volcanic arc has been established since the Pliocene (Pe-Piper and Piper 2002 and references therein; Papanikolaou 2021). At the southeastern margin, the Santorini – Amorgos basin is characterized by NE-SW faults creating a complex horst and graben pattern with sediments exceeding 1000m thickness (Figure 2a-b, Nomikou et al., 2016, 2018; Sakellariou and Tsampouraki 2019; Tsampouraki et al., 2021). From January to March 2025, swarm-type earthquakes of magnitudes in the range 1≤M≤5.2 were recorded, having epicenters at depths mainly from 15 km up to 4 km concentrated along a narrow zone extending offshore Santorini near the Columbo volcanic center towards NE, south of Amorgos island (Figure 2c, seismicity catalog of the National Observatory of Athens available in http://www.gein.noa.gr). Whether this sequence could result just from tectonic forces or the combined effect of tectonic forces and magmatic activity is debated.

In this paper, we investigate the structural evolution of the region by virtue of a numerical model, starting from a pure continuum brittle crust due to combined tectonic forces and magmatism. Given that the studied region of the south Cyclades plateau is a major volcanic center and driven from knowledge of hydraulic fracturing processes in deep reservoirs, we examine the hypothesis that the swarm-type of earthquakes is that of magma injections in chambers or dykes lying along this narrow zone.

Geological Framework

The Hellenides represent a segment of the Alpine-Himalayan orogeny, characterized by the convergence between the Eurasian and African plates since the Jurassic (Jolivet and Brun, 2010; Papanikolaou 2021). The Attic-Cycladic Crystalline Complex (ACCC) in the central Aegean comprises scattered relics of the Upper Cycladic Nappe (UCN), which overlies the Cycladic Blueschist unit (CBU), the Cycladic Basement (CB), and the Basal Unit. The lower units experienced Eocene-Oligocene high-pressure metamorphism and then were exhumed to the surface first synorogenically within the subduction zone and then post-orogenically during the Neogene through low-angle crustal-scale detachment systems (Figure 1), rooting in the brittle-ductile transition, as a result of subduction zone retreat (Jolivet and Brun 2010; Jolivet et al., 2010; Ring et al., 2010; Grasemann et al., 2012). The southeastern part of the Cycladic plateau was exhumed from the top-to-SE Santorini Detachment system (Schneider et al., 2018; Grasemann et al., 2022; Laskari et al., 2024; Roche et al., 2024). High-angle faults that succeeded the low-angle faulting further contributed to the exhumation of the metamorphic rocks since the Pliocene and facilitated the ascent of melts that formed, among others, the Santorini volcanic center with the adjacent Christiana and Columbo volcanoes (Kokkalas et al., 2006; Kokkalas and Aydin 2013). The Santorini – Amorgos Fault Zone comprises NE-SW faults with NW-SE direction of extension and a significant dextral sense of motion in the same area where the 1956 Amorgos >7Mw earthquake took place (Nomikou et al., 2018; Sakellariou and Tsampouraki 2019; Tsampouraki et al., 2021).

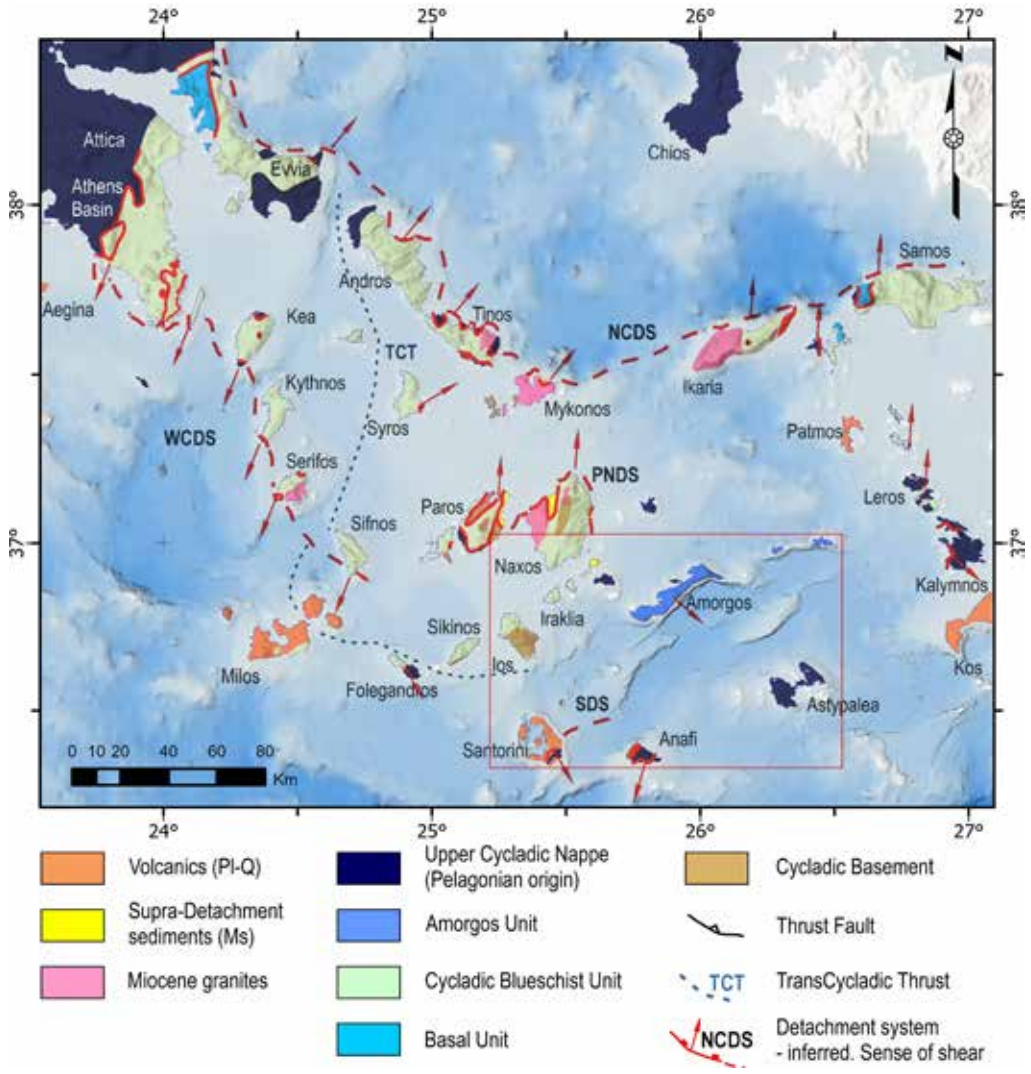

Figure 1. Geotectonic map of the Attic-Cycladic Crystalline Complex (modified after Laskari et al., 2024 and references therein). (Rectangle indicates the study area shown in detail in Figure 2a).

Model Parameters

As mentioned, the first objective is to reproduce the structural features of the Santorini-Amorgos basin associated with the NW-SE extension direction, and the second is to introduce magmatic activity. The sedimentation in the basin is ignored for simplification reasons. To this purpose, a plane strain numerical model corresponding to the NW-SE section of Figure 2a-b was constructed (Figure 3). The model comprises two regions above and below a mechanical decoupling zone 1-2-3 dipping SE (detachment zone) between the upper and the lower crust, corresponding to the brittle-ductile transition for silicate-dominated rocks. The upper region (A) corresponds to the upper crust and is occupied by brittle material, whereas the lower (K) corresponds to the lower crust and is occupied by ductile material. The rock material of the upper crust (A) is modeled as an elastoplastic (e-p) Mohr-Coulomb material, whereas the material of the lower crust (K) is considered a rigid body (r-b).

Simulations were performed with FLAC, a large-strain finite difference software, and an explicit time-marching solution of the full equations of motion (including inertia terms). The finite difference grid is shown in Figure 3. The top surface is stress-free, whereas we assume H_M=10km; thus, the depth of the upper crust at the right end of the model is approximately $2H_M$. Each simulation was conducted in two stages: an initial stage to establish initial equilibrium under the influence of gravitational body forces and boundary restraints, followed by a stage during which the kinematic or static boundary conditions were applied. The extensional loading of the continuum model was simulated by imposing a constant displacement velocity *v* along the right-vertical boundary and the segment 2-3 of the detachment zone.

In the sequel, we assume the formation of a magmatic chamber due to the injection of magma in the weakest region between the two half-grabens between points 1 and 2 of the model. We assume a hemispherical shape of the chamber with the center at the detachment zone and its apex at a depth of 5 km, given that the dip angle of the detachment zone is δ_M=12°. To obtain new shear bands after a few simulation steps, we have applied constant pressure *p/E=1/1000* where E denotes Young's modulus of the upper crust. We do not consider infiltration of magma in the crust; hence, all new cracks are not propagating due to hydraulic fracturing but due to stresses created by the constant applied pressure. This is a reasonable assumption, provided that the viscosity of the fluids is large, and the cracks are tortuous.

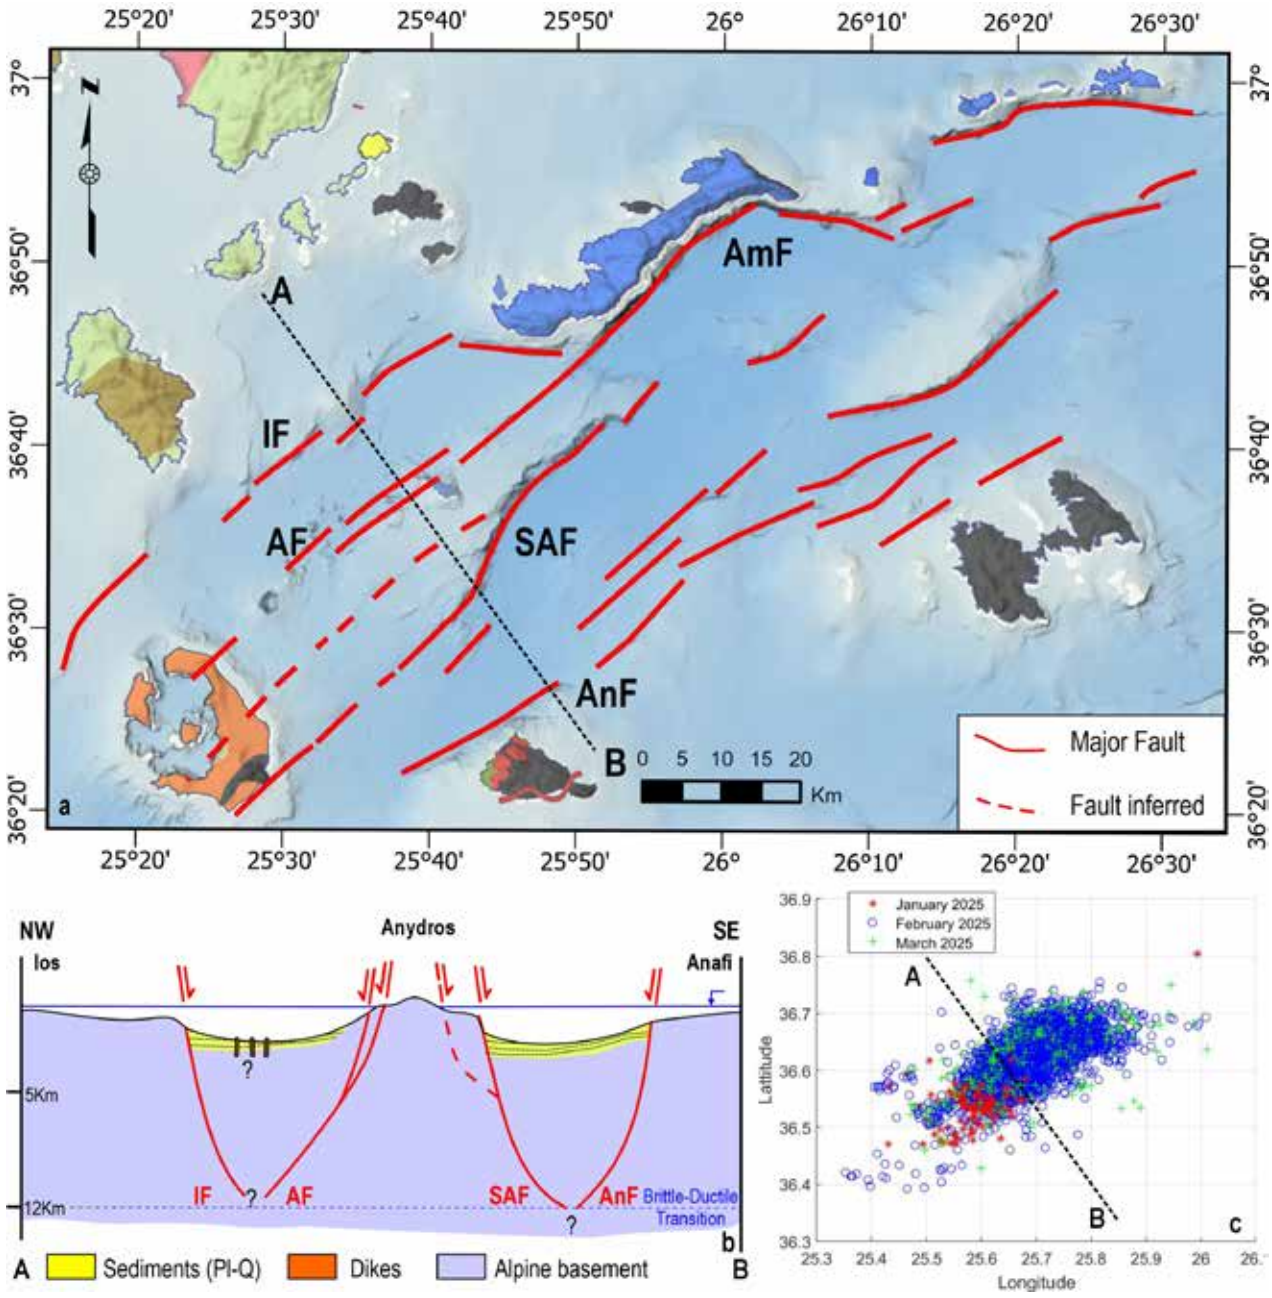

Figure 2a-c. a) Detail of Figure 1 showing the Santorini-Amorgos basin and the main faults (compiled after Nomikou et al., 2018; Sakellariou and Tsampouraki 2019; Tsampouraki et al., 2021), IF: Ios Fault, AF: Anydros Fault, SAF: South Anydros Fault, AnF: Anafi Fault b) Schematic NW-SE cross-section AB (not to scale) c) Projection of the swarm-type earthquake sequence of January-March 2025 (Seismic catalog. of the National Observatory of Athens http://www.gein.noa.gr)

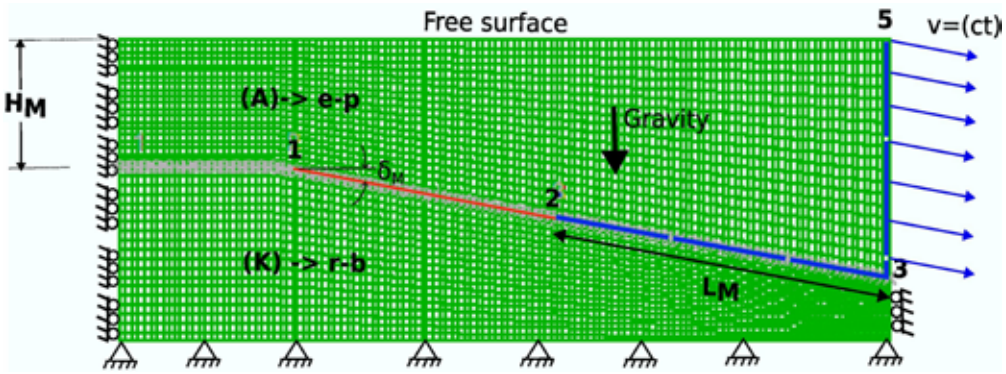

Figure 3. Vertical section of the discretized model and boundary conditions, along the AB cross-section of Figure 2a.

Results

The first stage of the simulation depicts the obtained structural configuration without the interference of magmatic activity. In this first stage, a decoupling zone is assumed at a depth of ~10-12 kilometers. Seismic reflection surveys in the Cycladic plateau estimate the upper and lower crust boundary at ~15 Km (Sachpazi et al., 1997). Since the area is adjacent to the Santorini volcanic center, e.g., within the volcanic arc domain, the geothermal gradient is probably elevated, and it is reasonable to assume that it is close to ~25-30°C/Km. Accordingly, at 10-12 Km depth, the temperature is ~300°C, roughly corresponding to the brittle-ductile transition zone. This zone corresponds to the level of the crust where deformation is localized.

Figure 4a depicts the contours of the maximum shear strain rate after a certain amount of sliding along the detachment zone. These contours indicate strain localization in shear bands (faults). Inside the band, the stress is lower than immediately outside. This stress drop at a newly formed shear band (fault) segment during the upward propagation of the normal fault creates an earthquake. Four sets of contours are formed in the final configuration, e.g., four fault zones, creating alternating horst and graben structures. Our model predicts that the southeast-dipping faults are the main faults and the northwest dipping are antithetic. The dip of the main fault (South Anydros Fault, SAF) of the right half-graben is greater (~70°) compared to the dip values of the rest of the normal faults (Ios Fault IF →60°, Anydros Fault AF →50°, Anafi Fault AnF→50°). It is also evident from the subsidence profile of the surface that the antithetic fault AnF has reached the surface like the rest of the faults.

Figure 4b shows the results of the second stage, where the effect of magmatic activity on the structural configuration obtained in the first stage is depicted. The application of pressure causes the creation of new faults starting at the chamber wall and propagating upwards. These could correspond to earthquakes clustering at 4-6Km depth. Some shallow faults are created due to the bending of the surface. New radially propagating faults are confined in the ridge between Anydros Fault (AF) and the main fault of South Anydros Fault (SAF). Shear strain also accumulates at the base of the fault zones, along the detachment zone, which could correspond to the second group of earthquakes clustering around 12Km depth.

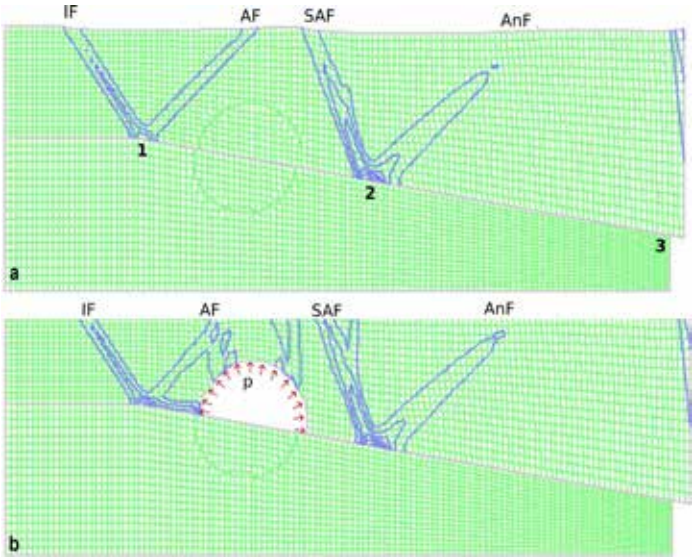

Figure 4a-b. a) Final graben structure of the modeled region at the end of the first simulation phase b) Second simulation phase: applied constant pressure at the wall of the magmatic chamber leads to initiation and propagation of shear bands in the ridge between AF and SAF faults.

Conclusions

- The application of a plane strain numerical model can simulate the structural configuration of the Santorini Amorgos basin and the January-March 2025 swarm-type earthquakes.
- The proposed model is based on the localization of deformation and differential sliding along a decoupling zone at a depth of 10-12Km, corresponding to the brittle-ductile transition.
- The complex geometry of the basin with alternating horst and graben segments results from successive NE-SW faults perpendicular to the local direction of extension.
- The shallow part of the structural configuration obtained from the first step of the simulation is at least in accordance with shallow seismic reflection data in the region.
- The injection of magma strike increases shear strain and creates new faults starting at the magma chamber wall and propagating upwards. The occurrences of new faults are confined in the Anydros ridge, between the AF and SAF.
- The Santorini-Amorgos basin is in the stage of a complex interaction between active faulting and magmatism, causing the January- March 2025 swarm-type earthquake sequence.

Research Highlights

Laboratory and field investigations held for a rock and mineral exhibition of the Vikos-Aoos UNESCO Global Geopark revealed new intersections between geoheritage and cultural heritage, indicating significant links between specific rocks, minerals and cultural features.

Introduction

Geodiversity forms the basis of geoheritage and geoconservation, representing the variety of geological, geomorphological, pedological, and hydrological features of Earth. Geoheritage refers to geodiversity elements deemed significant for conservation due to their cultural, scientific, and educational value (Wolniewicz, 2021). It supports the preservation of unique geological sites and provides essential resources like raw materials, water, and energy. Rocks, minerals, and fossils are key components, revealing the dynamic history of the Earth (Pereira, 2023). The growing connection between geoheritage and cultural heritage enhances the value of geoheritage sites by linking them to social identity, history, and art (Pijet-Migón & Migón, 2022). In Greece, this extraordinary geodiversity is exemplified by the Vikos-Aoos UNESCO Global Geopark, where ophiolites, igneous and metamorphic rocks, and fossil-rich sedimentary formations narrate the story of the evolving landscapes of the Earth. UNESCO Global Geoparks like Vikos-Aoos play a vital role in fostering education, conservation, and sustainable tourism, offering a platform to explore the deep connections between geology, culture, and society.

In this context, the Development Agency of Epirus S.A. (EPIRUS S.A.), the managing organization of the Vikos-Aoos UNESCO Global Geopark, organized the exhibition "The Rocks of the Vikos-Aoos UNESCO Global Geopark Under the Microscope: Aspects of Their Microcosm" to highlight the geoheritage of the region. The exhibition was curated by members of the School of Geology, Aristotle University of Thessaloniki, and was first presented in Ioannina from 7th to 10th June 2023, and later traveled to Konitsa and Aristi village in Zagori. The exhibition welcomed hundreds of visitors, which had the opportunity to explore the geology of the geopark and the intricate world hidden within its rocks, through large-scale photomicrographs taken under a petrographic microscope. The exhibition featured hands-on rock and mineral samples, and a microscope allowed attendees, especially younger visitors, to examine thin sections of rocks. Informational material and volunteers helped explain the mineral microcosm, complemented by maps and field photographs, encouraging further exploration of the geopark.

The research conducted for the preparation of the exhibition further expanded the existing knowledge on the mineralogy, petrology, and micropaleontology of the geopark, while also exploring new aspects where geoheritage and cultural heritage intersect. This has led to the development of new research fields and geoeducational potential. In this publication, we briefly present the exhibition and highlight two major findings from the ongoing research that link specific rock types and minerals to cultural aspects and processes and are related to the large spherical concretions of Gamila peak and the Oxya ophiolites.

Geology of the Vikos-Aoos Geopark

The Vikos-Aoos UNESCO Global Geopark, located in the Pindos mountain range in NW Greece, spans 1200 sq. km and presents a geological history that exceeds 200 million years. Rock units belonging to the Ionian Unit, the Pindos Unit and the ophiolitic nappe of Pindos Unit build up the geopark. The Ionian Zone encompasses extensive formations of carbonate rocks and flysch (Figure 1). Upper Jurassic-Lower Cretaceous dolomites and limestones of Vigla Formation, "Senonian limestones" with rudist fossils, and Paleocene-Eocene limestones rich in planktonic microfossils constitute a continuous, collectively over 2200 m thick, calcareous marine stratigraphy, deeply exposed within the Vikos and Aoos Gorges through karstification (Perrier *et al.,* 1968). Overlying the Paleocene-Eocene limestones the Oligocene to Lower Miocene flysch formation is found, including an 1,800 m thick, turbiditic sequence of sandstones and marlstones, which dominates the eastern Zagori region and parts of Konitsa (Perrier *et al.,* 1968, Figure 1).

Pindos Unit underpins almost half of the regional geology covering the eastern part of the geopark (Figure 1). It is represented by Upper Cretaceous limestones and the overlying Paleocene to Eocene flysch formation (Mavridis & Manakos, 1987). The flysch, over 1250 m thick, consists of silty marlstones, fine-grained sandstones, limestones and conglomerates with ophiolitic clasts. Ophiolitic rocks are found obducted on the Pindos flysch and constitute fragments of the old Tethyan oceanic sediments,

crust and upper mantle that were obducted on Pindos Unit forming a now appearing fragmented ophiolitic nappe. The ophiolite components date back to the Lower Jurassic, and consist of ultramafic to mafic igneous rocks that have undergone extensive serpentinization. These include harzburgite, dunite, pyroxenite, gabbro, and diabase veins (i.e. igneous rocks), alongside large occurrences of serpentinite (i.e. metamorphic rocks, Mavridis & Manakos, 1987). The thickness of the ophiolitic thrust sheets reaches 1000 m at their most prominent and complex exposure found at Mount Smolikas (Figure 1). Locally, small outcrops of Jurassic schists, red cherts and limestones intercalated with cherts occur, representing Tethyan deep sea and hemipelagic sedimentation respectively (Mavridis & Manakos, 1987). These outcrops are typically less than 100 m thick and are often bounded by tectonic contacts (Figure 1). This complex geology combined with faulting and folding, documents the tectonic evolution of the region, which transitioned from passive margin sedimentation to compressional orogenesis during the Alpine orogeny.

The Pleistocene-Quaternary deposits include glacial moraines, prominent in the Tymfi and Smolikas mountains, and Holocene alluvial sediments along the Voidomatis, Aoos, and Sarantaporos rivers (Perrier *et al.,* 1968, Figure 1). Glacial deposits often loosely cemented and landslide-prone, contrast with the sands, clays, cobbles, and angular fragments of alluvial terraces elevated above current river flows (Perrier *et al.,* 1968, Figure 1).

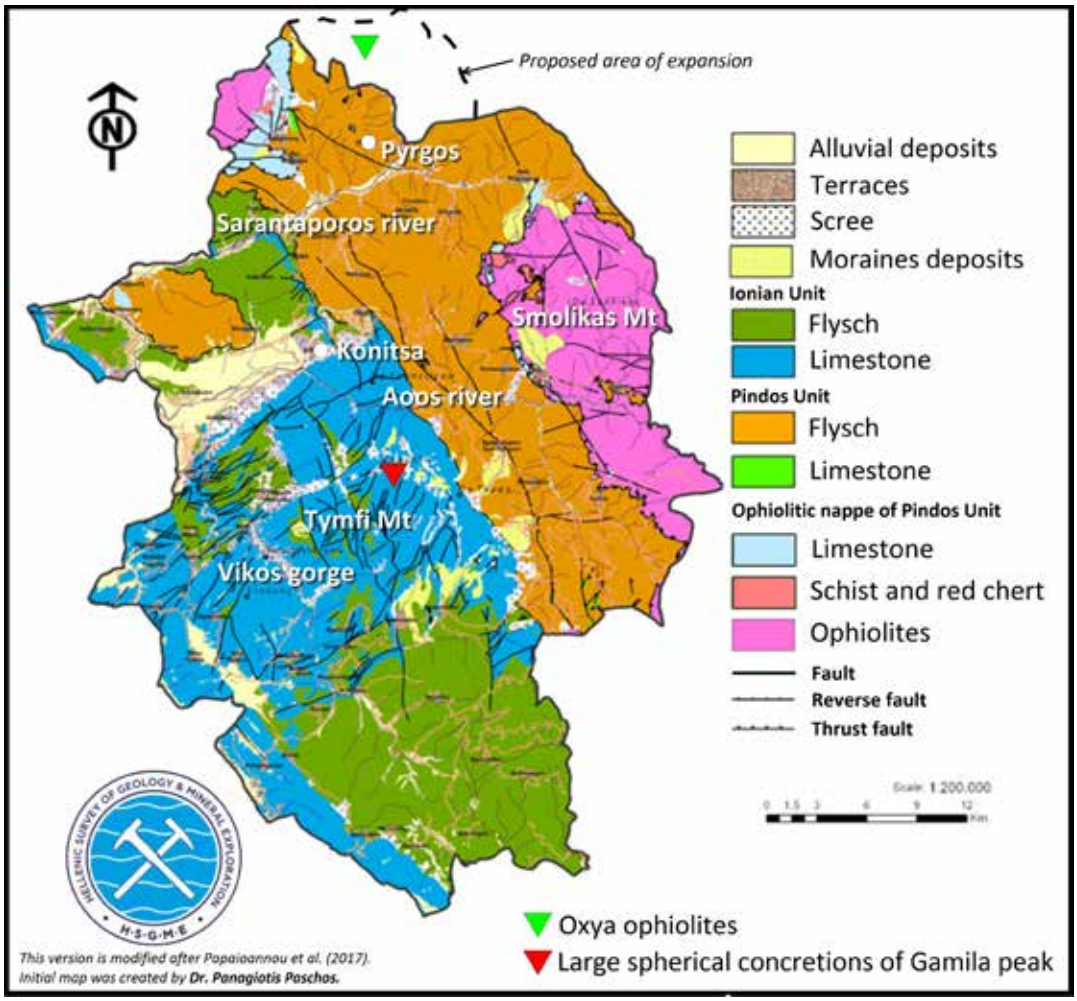

Figure 1. Simplified geological map of the Vikos-Aoos UNESCO Global Geopark. Main rock units and faults are shown. The Ionian limestone sequence is presented unified for clarity (modified after Papaioannou *et al.* (2017), initial map was created by Dr. Panagiotis Paschos).

Methods

Forty one samples were collected from primary outcrops and secondary sources, such as alluvial deposits, representing all the rock units of Vikos-Aoos Geopark, as well as special geological features (e.g. concretions, ore minerals, calcite masses). Rock samples were collected from outcrops close to the 51 recognized geosites and to the additional 30 sites of special

geological interest, which represent the geodiversity and geoheritage of the geopark. The collection sites were documented photographically using appropriate scales, and GPS data were collected for future reference. Thirty one of these samples were selected to be studied under the microscope. Thus, twenty six thin sections and 5 polished sections were produced and studied under a ZEISS Axioskop 40 dual reflected-transmitted light polarizing microscope coupled with a Canon Powershot A640 digital camera at the Department of Mineralogy-Petrology-Economic Geology, School of Geology, Faculty of Sciences, Aristotle University of Thessaloniki. The acquired micro-photographs were saved and logged. The digital enhancement of the micro-photographs and the preparation of the exhibition materials were carried out using the software Adobe Photoshop and Adobe Illustrator. For the exhibition needs twenty one micro-photographs were printed on 70 cm X 50 cm foam boards to cover the needs of the photographic exhibition. Following the exhibition, EPIRUS S.A. decided to publish a special volume dedicated to the mineral microcosm of the Vikos-Aoos UGGp in an effort to extend the impact of the exhibition and to ensure that the educative content and the aesthetics captured in the photographs will continue to inspire and engage audiences and forward the education on geoheritage and cultural heritage intersections (see Figure 4 below).

The Oxya ophiolites

The ophiolitic occurrence (N40.243086°, E20.804622°) at Oxya village, Konitsa, lies just outside the northern periphery of the geopark in a proposed area of expansion, and is one of the 30 designated sites of special geological interest (Figures 1, 2a). It is part of the ophiolitic cover of Pindos Unit, which appears thrusted on the flysch of Pindos Unit. These outcrops were first studied and reported back in the 1950s by Marinos *et al.* (1957) during the post-World War II efforts to support the economic development for Epirus. The ophiolitic assemblage includes gabbros and diabases intruding into basalts and pillow lavas, surrounded by serpentinites and scattered serpentinized dunites. Within the diabases, disseminations and minor stockworks of metallic mineralization occur, comprising pyrite, magnetite, and minor pyrrhotite, chalcopyrite, galena and ilmenite. In contrast, the pillow lavas host mainly pyrite and minor magnetite (Figure 2b,c), which, in surface samples, is heavily oxidized to form yellowish brown to red encrustations of goethite and hematite (Figure 2b).

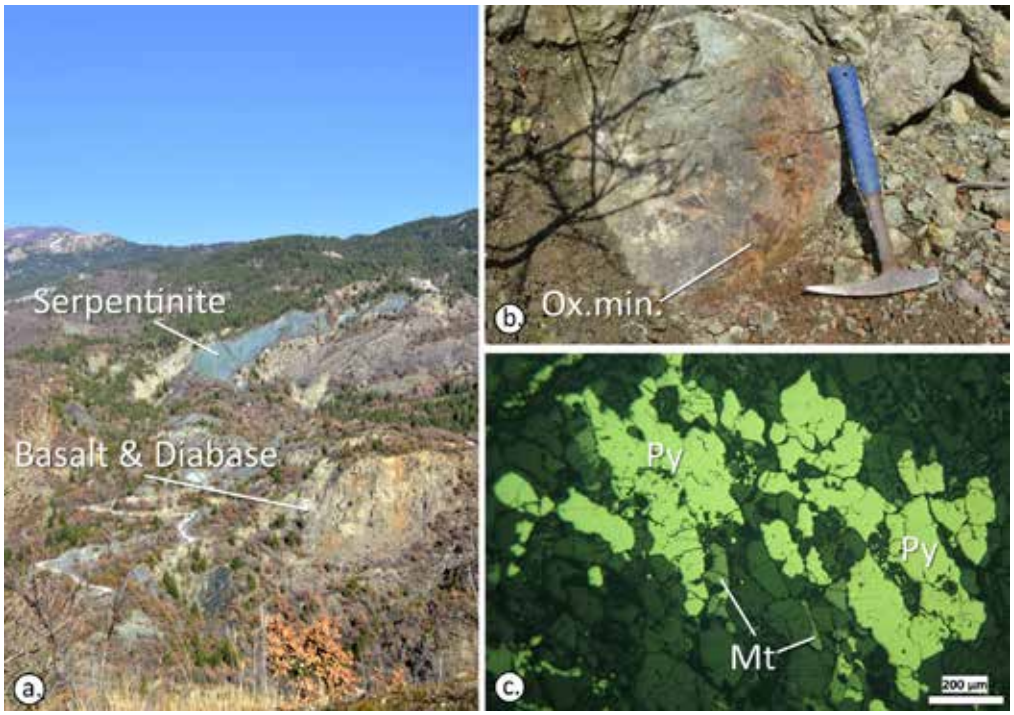

Figure 2. a. Field photograph of the Oxya ophiolites, characteristic outcrops of serpentinite, basalt and diabase are highlighted. Rocky cliffs appear yellowish brown due to the extent encrustations of goethite and hematite. b. Oxidized mineralization (Ox.min.) in diabase. c. Photomicrograph under plane reflected light (Nichols //) of the pyrite (Py) and magnetite (Mt) mineralization hosted in basalt.

Local reports support that pieces of the oxidized pyrite mineralization collected as ochre have historically been utilized as pigments for coloring by the famous Chioniadites painters, demonstrating an intersection of geological and cultural significance. Chioniades village is located NW of the Oxya ophiolites at 1150 m on the eastern slopes of Mount Grammos, and is where the Chioniadites School of painters had thrived between 18th and 20th centuries. Religious and popular creations of this school of painters are found from Albania and Epirus to Macedonia and Thessaly (Tsiodoulos, 2009). The artistic tradition of the village dates back to 1747 as is documented by the signed depiction of Saint George in the church of Koimisi Theotokou at Vourbiani

village, attributed to Konstas of Chionades (Tsiodoulos, 2009). The Chioniadites School of painters does not exhibit any characteristic painting style but follows the aesthetic standards of each time period (Stergiou 2024). Anastasios Papakostas-Marinas (1856) and his sons Christodoulos (1857-1932) and Thomas (1864-1930), are among the last and most famous painters of the Chioniadites School of painters (Stergiou 2024).

South of the Chioniades and Oxya villages, near Pyrgos village, another smaller ophiolitic outcrop (N40.164892°, E20.785197°) is found thrusted on the flysch of Pindos Unit (Figure 1). There, the local tradition narrates the extraction of a hard stone, locally called "gretzia," derived from the local term "grentzos" (meaning rough, coarse, uneven on the surface), which in turn comes from the Italian greggio/grezzo (meaning raw, unprocessed, unshaped) for the production of millstones. Hard, fine grained volcanic rocks like diabase or basalt have been traditionally used across Greece for the production of millstones (Melfos *et al.,* 2014), and this could also be the case at Pyrgos village.

The Large Spherical Concretions of Gamila Peak

The Gamila Peak spherical concretions (N39.97753°, E20.79079°), is another remarkable geological feature of the Vikos-Aoos Geopark, first described by Telbisz *et al.* (2019). Found at approximately 2,100 m a.s.l. along the trail to Gamila Peak (2,497 m a.s.l., Figure 1), these formations are observed in limestone boulders or as individual concretions within collapsed rocky scraps. The Paleocene-Eocene limestone formation of the Ionian Zone is the host rock of the concretions. The concretions exhibit spherical to elongated elliptical shapes, ranging usually from 0.1 to 1 m in diameter, and exhibit distinctive concentric layering (Figure 3a). Locally, large concretions form discontinuous layers reaching or exceeding 20 m in length (Figure 3b). The concentric layers that build up the concretions, alternate between fine-grained carbonate material and varying amounts of siliceous and carbonate cement, and contain abundant bioclastic material (Figure 4). The mixed cement suggests a diagenetic process involving early, incomplete carbonate cementation coupled with substantial SiO_2 precipitation in the intergranular spaces. The silicification likely resulted from the dissolution of siliceous bioclasts, though contributions from external SiO_2-enriched fluids cannot be excluded. The microscopic study revealed that the concretions retain embedded microfossils of *Nummulites*, *Alveolina* and orthophragmines. The size of the microfossils in some cases exceeds 3 mm in length (Figure 4). These microorganisms, part of the Large Benthic Foraminifera group, lived in shallow marine environments during the Middle Eocene (47 to 41 My ago), in depths up to 40 m according to the total recorded assemblage. Their presence, along with the intricate mineralogical composition of the concretions, underscores the complex diagenetic and paleoenvironmental history preserved within this extraordinary natural feature. A smaller outcrop of spherical concretions is found at the northern foundation (N39.862341°, E20.775298°) of the Noutsos (or Kokkoris) arch-stone bridge near Kipoi village, Zagori. Mapping and documentation of all outcrops with such concretions on Mount Tymfi is essential for reconstructing the paleoenvironment and understanding its geological history.

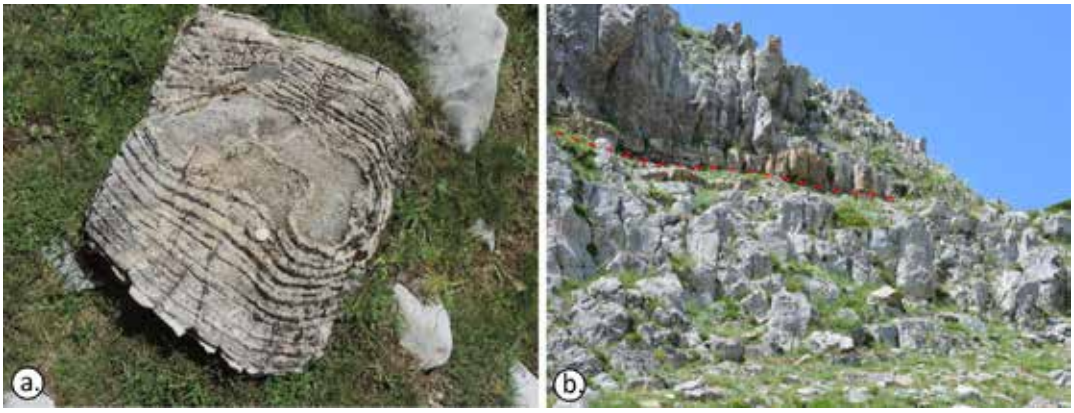

Figure 3. Field photographs of the large spherical concretions appearing as a fragmented boulder (a) and a discontinuous layer (red dashed line) of such large spherical concretions at a cliff close to Gamila peak, Mount Tymfi.

Recent field research at the villages of Megalo Papigo, Zagori, held by Christos L. Stergiou and Haritakis Papaioannou, documented another case of intersection between the geoheritage and cultural heritage of the Vikos-Aoos Geopark. Concentric concretions, texturally identically to those found near the Gamila peak but of smaller size (<40 cm in width) have been documented being embedded as stone carvings on traditional house facades that were mainly built along the 19th century (Figure 5a,b). These stone carvings are called hologlyphs and typically depict relief representations of anthropomorphic or dragon-like heads and were often embedded in churches, houses, fountains, and bridges in the Epirus region. They served a protective and apotropaic role, supported by three main characteristics: their grotesque appearance, the expression of the eyes, and the locations where they were placed (Tsoupi, 2006).

Figure 4. Sample layout from the upcoming special volume of the Vikos-Aoos UNESCO Global Geopark, showcasing rocks and minerals under the microscope alongside stories highlighting the intersection of geoheritage and cultural heritage. This example presents the geological significance and mineralogical composition of spherical concretions through macro-photographs and photomicrographs.

Figure 5. Photographs of the apotropaic hologlyphs installed on the facade of a traditional house at Megalo Papigo village build at 1876. Both are made of small spherical concretions. a. A roaring dragon-like. b. An anthropomorphic figure with a critical and stern gaze.

Conclusions

The Vikos-Aoos UNESCO Global Geopark, nestled in the geologically diverse terrain of the Pindos Mountains, exemplifies the intricate interplay between geology, culture, and nature. This research has highlighted key geological features within the geopark, such as the ophiolitic occurrences in Oxya and Pyrgos, the Gamila Peak

spherical concretions, and their connections to cultural heritage. The Oxya ophiolitic outcrops, part of Pindos Unit, host metallic mineralization, which were historically used by the Chioniadites painters as pigments. Similarly, the "gretzia" stone from Pyrgos village, likely derived from local diabases or basalts, showcases the traditional use of volcanic rocks for millstone production.

The spherical concretions at Gamila Peak, with their concentric layers and microfossil inclusions, offer insights into the Paleocene-Eocene shallow marine habitats and diagenetic processes that shaped the region. These concretions not only reveal vital biostratigraphic and paleoenvironmental data but also intersect with cultural heritage through their use as decorative carvings in traditional architecture. The hologlyphs embedded in house facades and other structures across the region serve as powerful symbols of the protective and artistic traditions of Zagori and Epirus. By uncovering these connections between geoheritage and cultural heritage, this ongoing research deepens our understanding of the geological and cultural history and enhances the geotourism and educational potential of the Vikos-Aoos Geopark.

Acknowledgements

Eleni Tsirigoti is acknowledged for handling the graphic production of the exhibition and the handbook under development. Region of Epirus, Municipality of Konitsa and the Ioannis Saralis Foundation are thanked for supporting the exhibitions held at Ioannina, Konitsa and Aristi, Zagori, respectively. The Development Agency of Epirus S.A. (EPIRUS S.A.) funded the thin and polished sections preparation of the collected rock samples, and covered the printing costs for the photographs and the informative material of the exhibition. Furthermore, EPIRUS S.A. is acknowledged for undertaking the publication of the album on the minerals and rocks of the geopark.

Research Highlights

Preliminary results on the mineralogy and chemistry of Sb-mineralization at Philadelphio emphasize the mineral intergrowths and inclusions within stibnite, as observed through SEM-EDS analysis. Discussed with data from Rizana and Gerakario, these findings provide insights into the mineralization processes, with ongoing EPMA and LA-ICP-MS analyses focused on refining the genetic model and investigating key metal compositions.

Introduction

Antimony (Sb), a critical metalloid, has a long history of use, from early cosmetics to modern applications in flame retardants, aerospace, and defense. Primarily occurring in stibnite (Sb_2S_3), it is associated with over 100 minerals, including sulfosalts like tetrahedrite. Major Sb deposits are found in diverse geological settings, such as orogenic, Carlin-type, volcanogenic seafloor, and epithermal environments (Kanellopoulos et al., 2024). Stibnite often contains micro- to nano-scale inclusions of minerals that contain critical metals, underscoring its economic and geochemical significance.

The Serbo-Macedonian Metallogenic Belt (SMMB), spanning from Serbia to northern Greece, is a Pb–Zn–Ag district with notable Au resources and polymetallic Sb deposits. In northern Greece, the SMMB includes the Kilkis ore district within the Vertiskos Unit, hosting porphyry, epithermal, and carbonate-replacement deposits formed during Oligocene-Miocene magmatic-hydrothermal processes (Melfos and Voudouris, 2017; Stergiou *et al.,* 2018; Voudouris *et al.,* 2019). Mineralized veins along shear zones in metamorphic rocks contain Cu-As-Pb-Bi-Au-Te polymetallic and Sb-rich varieties (Stergiou et al., 2023). These mineralizations are linked to concealed magmatic intrusions and magmatic-hydrothermal processes along shear zones under retrograde greenschist facies conditions (Stergiou et al., 2023).

Major Sb mineralizations in the Vertiskos Unit include Rizana and Philadelphio, and minor Sb mineralization at Gerakario (Stergiou et al., 2023, Kanellopoulos et al., 2024). This study presents preliminary findings on the mineralogy and chemistry of Sb-mineralization at Philadelphio, based on optical microscopy and scanning electron microscopy and energy dispersive X-ray spectroscopy (SEM-EDS) analysis. The results, combined with data from Rizana and Gerakario, enable a comparison of the three mineralizations. As part of ongoing research, electron probe microanalysis (EPMA) and laser ablation inductively-coupled plasma mass spectrometry (LA-ICP-MS) analyses are being used to refine the genetic model, examine critical metal compositions, and compare with similar studies in the region.

Geological setting

The Vertiskos Unit is a northwest-trending geotectonic zone with a complex polytectonic and polymetamorphic history, extending from the Greek-North Macedonian border to the Chalkidiki peninsula (Brun & Sokoutis, 2018). It consists primarily of gneisses, schists, amphibolites, Paleozoic to Triassic metagabbros, metadiabases, and A-type granites, alongside Cenozoic I-type plutonic, sub-volcanic, and volcanic rocks from four magmatic episodes (Late Paleocene to Pliocene) with calc-alkaline, high-K calc-alkaline, and shoshonitic affinities (Stergiou et al., 2023, Figure 1).

Mineralized intrusions from the Oligocene-Miocene are prominent in the Kilkis and northeastern Chalkidiki ore districts, linked to structural controls from the Eocene-Oligocene Kerdylion and Miocene Strymon detachment faults. These faults, part of an extensional regime active from the Late Cretaceous to the Miocene, facilitated the south-southwest-directed collapse of the Vertiskos Unit, with shear zones, normal to oblique faults, and strike-slip faults influencing the region's magmatic activity and mineralization (Stergiou et al., 2023).

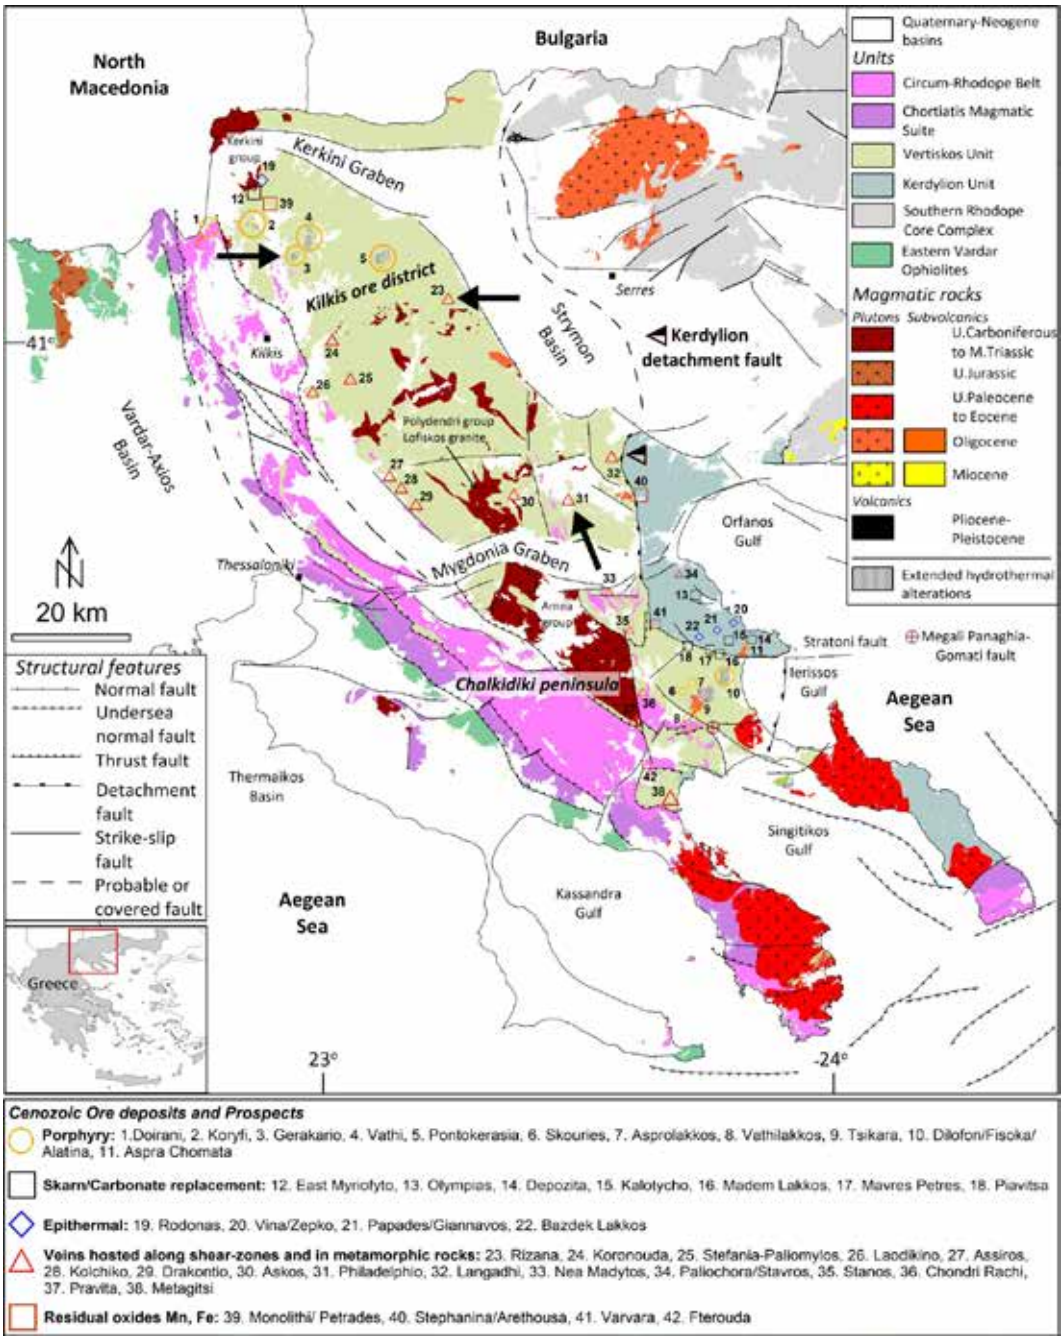

Figure 1. Geological map of Cenozoic magmatism and Oligocene-Miocene mineralization in the Vertiskos and Kerdylion Units (modified from Stergiou *et al.,* 2023), with black arrows marking ore deposits at Philadelphio, Rizana, and Gerakario.

Antimony occurrences at Philadephio, Rizana and Gerakario

The Philadelphio (or Philadelpia) Sb-mineralization has experienced historical mining during the early 20th century. Indicative resources are estimated at 10.08 Mt of ore, with an average grade of 3.36 wt.% Sb (Kanellopoulos *et al.,* 2024; Figures 1 & 2a-c). The mineralization is hosted in a shear zone cutting amphibolite, gneiss and schist of the Vertiskos Unit. Cenozoic magmatic rocks are absent from the region, but geothermal manifestations are found (Kanellopoulos *et al.,* 2024). The ore texture includes massive and discordant quartz veins, set along faults (<1 m wide). The main hydrothermal alteration is silicification and chloritization (Figure 2c). Ore related faults strike in average N30°W and dip 80°NE. Mineralization occurred in two stages: an early Zn-Fe-As-Cu-Au-enriched phase, and a later Sb-dominated. Metallic, gangue and alteration minerals are presented in Table 1.

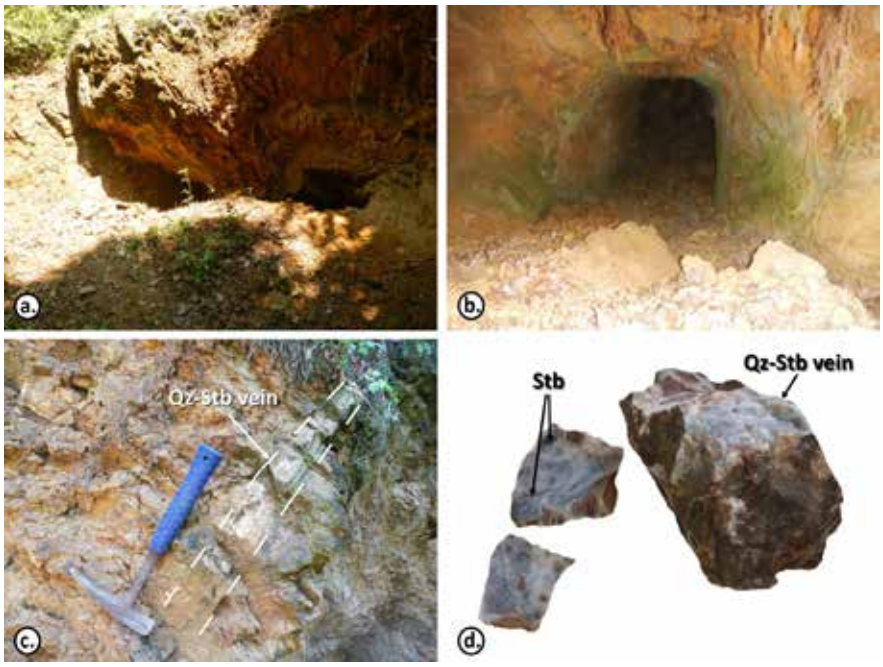

Figure 2. Field photographs (a-c) and macroscopic photograph (d) of the sampled ore from Philadelphio. a. Entrances to the underground workings. b. The interior of a gallery. c. A quartz (Qz)-stibnite (Stb) vein cutting the gneiss. d. Cuttings of a quartz (Qz)-stibnite (Stb) vein indicative of the ore texture in these veins.

The Rizana (or Lachanas) mineralization hosts the most significant Sb-ore deposits in Greece, with historical mining efforts dating back to pre-1930. Between the 1930s and 1950s, approximately 9000 metric tons of stibnite ore were extracted; averaging 40% Sb content (Stergiou *et al.,* 2023 and references there in; Figure 1). At "Tas-Kapou" location, the mineralization occurs within NE–SW-oriented brittle shear zones intersecting two-mica and augen gneiss of the Vertiskos Unit (Stergiou *et al.,* 2023). The Rizana rhyodacite is found close to the mineralization; it is hydrothermally altered (sericitic alteration) and contains pyrite disseminations (Stergiou *et al.,* 2023). The mineralized fault zones strike in average N30°E and dips 80°NW. Ore bodies are found as veins and discordant lodes with brecciated and massive textures, surrounded by hydrothermal halos marked by sericitization and silicification, predominantly affecting the two-mica gneiss (Stergiou *et al.,* 2023; Table 1). The metallic assemblage includes mainly stibnite, berthierite, pyrite, sphalerite, and chalcopyrite, (Dimou, 1989, Stergiou *et al.,* 2023; Table 1). In close proximity to the Sb-mineralization at Rizana a wolframite mineralization also occurs. At "Pilaf-Tepe," 1 km southeast of the Rizana rhyodacite, W-mineralization occurs in a silicified fault zone, featuring Fe-wolframite and stibnite with supergene oxidation products like tungstite, cervantite, and stibiconite, while minor Pb-Zn veins are found at the margins of the W-Sb mineralization and near the rhyodacite (Vasilatos et al., 2001). According to Stergiou *et al.,* (2023), the Rizana Sb-mineralization shows enrichments mainly in As, as well as Mn, Cu, Zn, Ni, Pb, Mo, Au and Ag.

The Sb-mineralization at Gerakario constitutes a minor prospect that has experienced random historical exploration and possibly exploitation probably between the 19th and early 20th century (Figure 1). Resources estimates are not available. It is found at the periphery of the Gerakario Cu-Au porphyry deposit (Stergiou *et al.,* 2022), which is related to Cenozoic plutonic and subvolcanic rocks, including silica-saturated granodiorite (34 ± 0.5 Ma) and syenite (22 ± 0.8 Ma) with calc-alkaline to slightly alkaline affinities (Stergiou *et al.,* 2022). Potassic, propylitic, and sericitic hydrothermal assemblages are superimposed on both magmatic and surrounding metamorphic rocks. The porphyry-style mineralization, associated with syenite, is characterized by pyrite-chalcopyrite disseminations, A- and D-type veins, and extensive oxidation near the surface (Stergiou *et al.,* 2022). The structurally controlled (N45°E/75°NW in average) epithermal quartz-stibnite veins, intersect the hydrothermally altered two-mica gneiss, and accommodate mainly stibnite, berthierite, native antimony, pyrite, arsenopyrite (Stergiou *et al.,* 2022, Table 1). The geochemistry of the mineralization reveals poor enrichments in trace elements, mainly including Co, Ag, Ga and Au (Stergiou *et al.,* 2022).

The formation of these Sb-mineralizations is associated with the Cenozoic (Neogene-Quaternary) structural framework and magmatic-hydrothermal activity of the Vertiskos Unit. At Rizana the mineralization occurred in two stages: tungsten-rich fluids forming wolframite and arsenopyrite, followed by antimony-rich fluids forming stibnite under low salinities

(6.6–8.1 wt.% NaCl) and moderate temperatures (217–254°C) (Stergiou et al., 2023). At Gerakario, fluid boiling in A-type veins generated high-salinity fluids (35.7–45.6 wt.% NaCl equiv.) at 380–460°C and pressures of 100–580 bar, later mixing with meteoric water to form lower salinity fluids (8–10 wt.% NaCl equiv.) associated with epithermal mineralization at 280–320°C (Stergiou et al., 2022). Although microthermometric data are unavailable for Philadelpeio, the comparable structural controls and regional geothermal activity strongly suggest analogous formation conditions (Kanellopoulos et al., 2022).

Table 1. Summary table of the metallic, gangue, alteration and oxidation assemblages of the Sb-mineralizations at Philadelphio, Rizana, and Gerakario (Dimou, 1989, Stergiou et al., 2022, 2023, Kanellopoulos *et al.,* 2024, this study).

Locality	Alteration style	Metallic assemblage	Gangue and alteration assemblage	Oxidation assemblage
Philadelphio	Silicification + chloritization	1st stage: Sph + Py + Apy + Cpy + Au, 2nd stage: Stb + Sb + Sph + Py + Ccsb + Ttr + Mln + Wf + Zkn ± Bth ± Mrc ± Po ± Bou	Qtz + Ser + Chl + Rt	Kem ± Sbc ± Cpm ± Sfz ± Cov ± See
Rizana	Silicification + Sericitization	Stb + Bth + Sph + Py + Cpy + Sb ± Wf ± Gn ± Ttr ± Mrc ± Po ± Apy ± Rlg ± As ± Au	Qtz + Brt + Ank + Ser	Vln ± Gth ± Cld

Abbreviations: Apy = arsenopyrite, As = native arsenic, Au = native gold, Bou = boulangerite, Bth = berthierite, Ccsb = chalcostibite, Cov = covellite, Cld = claudetite, Cpm = chapmanite, Cpy = chalcopyrite, Gth = goethite, Kem = kermesite, Lo = löllingite, Mln = melnikovite, Mrc = marcasite, Po = pyrrhotite, Pn = pentlandite, Py = pyrite, Rlg = realgar, Sb = native antimony, Sbc = stibiconite, See = seelite, Sfz = schafarzikite, Stb = stibnite, Sph = sphalerite, Ttr = tetrahedrite, Rt = rutile, Vln = valentinite, Wf = wolframite, Zkn = zinkenite.

Methods

Optical microscopy and SEM-EDS analysis was focused on Sb-mineralized samples from Philadelphio. Six polished and thin-polished sections were studied under a ZEISS Axioskop 40 dual reflected-transmitted light polarizing microscope at the Faculty of Geology, AUTH. Scanning electron microscope (SEM) studies were conducted at the Faculty of Sciences, AUTH, using a JEOL JSM-6390LV SEM equipped with an OXFORD INCA 300 EDS (Oxford Instruments Ltd., Abingdon, UK). Set in the back-scattering electron (BSE) mode, the operating conditions were: 20 kV accelerating voltage, 0.4 mA probe current, 80 s analysis time, and a beam diameter of ≈1 μm. The SEM–EDS micro-analyses were targeted on mineral texture and chemistry of stibnite and sphalerite. The results were examined after univariate statistical analysis (minimum, maximum, standard deviation, and average) for comparison with previously shared SEM-EDS results for stibnite and related minerals from Rizana and Gerakario (Stergiou *et al.,* 2022, 2023).

Results & Discussion

The Sb-mineralization at Philadelphio, linked to the 2nd mineralizing stage, includes stibnite, native antimony, sphalerite, pyrite, chalcostibite, tetrahedrite, wolframite, zinkenite, berthierite, marcasite, pyrrhotite, and boulangerite (Table 1). Stibnite shows bireflectance, pressure lamellae, and forms massive or disseminated textures in quartz or cavity fillings. Sphalerite, berthierite, and pyrite (<700 μm) occur in massive stibnite or at stibnite-quartz boundaries, while euhedral pyrite (<200 μm) is also found in quartz (Figure 3a-d). Boulangerite and native antimony occur as inclusions in stibnite. Supergene oxidation resulted in the oxidation of stibnite to stibiconite ($Sb^{3+}Sb^{5+}{}_2O_6(OH)$), chapmanite ($Fe2^{3+}Sb^{3+}(Si_2O_5)O_3(OH)$), schafarzikite ($Fe^{2+}Sb^{3+}{}_2O_4$) and kermesite ($Sb_2S_2O$), with dimensions below 50 μm (Figure 3a-d).

Chemically, stibnite contains impurities of trace elements including Ag, As, Cu and Fe. The standard deviation values for impurities in stibnite indicate a consistent but slightly variable incorporation of elements. Silver shows a maximum concentration of 3.00 wt.% with a relatively low standard deviation (STDEV: 0.71 wt.%), suggesting a stable distribution across the samples (Table 2). Arsenic with a maximum content of 1.36 wt.% and a STDEV of 0.32 wt.%, also exhibits moderate stability. Cu and Fe show slightly higher variability, with STDEV of 0.33 wt.% and 0.35 wt.%, respectively, relative to their maximum values of 1.05 wt.% and 0.95 wt.%, respectively (Table 2). This suggests localized or irregular incorporation, possibly influenced by varying mineralization conditions. Overall, these trends indicate that trace metals incorporation in stibnite is not entirely random but influenced by geochemical and structural factors.

Sphalerite, identified through SEM-EDS analysis, is the predominant Zn phase in the studied samples. It occurs in

association with quartz, where it fills interstices (<400 μm in width) and occasionally contains stibnite inclusions (<40 μm in width). Sphalerite also forms intergrowths with stibnite, suggesting co-precipitation or later infiltration. Trace metals in sphalerite include As, Cd, Fe, Mn, Sb, Sn and Te displaying low averages (<0.2 wt.%) but relatively high standard deviations (<0.52 wt.%), suggesting heterogeneous incorporation, potentially due to variable fluid conditions during formation (Table 2). The standard deviation values of impurities in sphalerite suggest moderate variability in their incorporation during mineral formation. Iron (STDEV: 0.34 wt.%), Mn (STDEV: 0.23 wt.%), and Sn (STDEV: 0.49 wt.%) show relatively low but noticeable variations, indicating a consistent yet slightly heterogeneous inclusion process (Table 2). Conversely, elements like Sb (STDEV: 0.40 wt.%) and Te (STDEV: 0.52 wt.%) exhibit slightly higher standard deviation values despite their low average concentrations (<0.15 wt.%, Table 2). These observations highlight that the mineralization environment for sphalerite was relatively stable overall but subject to minor compositional variability, likely due to dynamic changes in fluid chemistry or temperature during its formation.

Quartz, the dominant gangue mineral associated with the mineralization, exhibits a range of textures from semi-transparent to polycrystalline. Quartz veins display features such as lamellar and brecciated textures, reflecting intense hydrothermal brecciation that caused significant fragmentation and grain size reduction. These veins often contain a mix of angular and rounded quartz fragments.

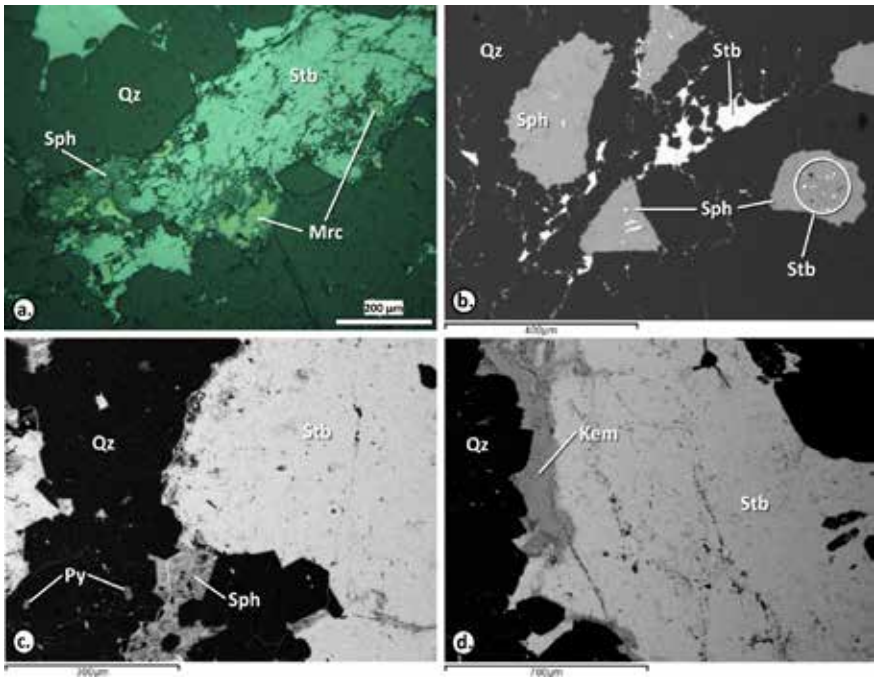

Figure 3. Micro-photograph (a) from Philadelphio under plane reflected light (Nichols //) and SEM back-scattered electron images (b-d): a. Stibnite (Stb), sphalerite (Sph) and marcasite (Mrc) cementing euhedral quartz (Qz). b. Stibnite (Stb) and sphalerite (Sph) with stibnite replacements (white cycle) filling cavities in quartz (Qz). c. Stibnite (Stb) and sphalerite (Sph) cementing quartz (Qz) including euhedral pyrite (Py). d. Stibnite (Stb) rimmed by kermesite (Kem) cementing quartz (Qz).

The stibnite from the Philadelphio mineralization after SEM-EDS analysis indicate a more complex and variable mineral chemistry compared to the stibnite from Rizana and Gerakario (Stergiou *et al.,* 2022, 2023). The trace impurities in Philadelphio stibnite, such as Ag, As, Cu, and Fe, display moderate to significant variability, while at Rizana trace impurities, are present at low levels and show minimal variability. At Rizana, Fe shows the highest variability (STDEV: 0.33 wt.%), with concentrations reaching up to 0.95 wt.%, which may suggest localized substitutions or inclusions (Stergiou *et al.,* 2023). Copper (Cu) also exhibits notable variability (STDEV: 0.21 wt.%), while Ag, As, and Zn display minimal influence on the overall composition, with low concentrations and STDEV values (Stergiou *et al.,* 2023). Trace element incorporation in Gerakario stibnite is more pronounced than in Rizana, with Ag concentrations reaching up to 1.33% and showing significant variability (STDEV: 0.57 wt.%). Other impurities, such as Cu, Zn, and As, occur at lower levels but exhibit moderate variability. Iron is present at up to 0.18 wt.% and shows limited variation, with a STDEV of 0.08 wt.% (Stergiou *et al.,* 2022).

Table 2. Mineral chemistry and formulas of stibnite and sphalerite from Philadelphio as calculated for MIN, MAX, and AVG values after SEM-EDS micro-analysis. Values are in weight percent (wt.%).

Abbreviations: AVG = average value, b.d.l. = below detection limit, MIN = minimum value, MAX = maximum value, Sph = sphalerite, Stb = stibnite, Stb imp. = stibnite with impurities, STDEV = standard deviation.

Conclusions

The stibnite from the Philadelphio mineralization displays specific mineralogical and geochemical characteristics. Microscopically, it exhibits strong bireflectance, pressure lamellae, and quartz intergrowths, indicating a complex crystallization history. Trace metals such as Ag, As, Cu, and Fe, along with minor phases like sphalerite, berthierite, and pyrite, highlight the heterogeneity of the mineralization. Compared to Rizana and Gerakario, the stibnite at Philadelphio shows greater trace element enrichment, suggesting more enriched mineralizing fluids and varied formation conditions.

EXTENDED ABSTRACT 302

Threshold Value Analysis in Geochemical Mapping for Gold-Only Vein-Type Mineralization

Strongylis S.[1], Sakellaris G.A.[1], Kantiranis N.[1], Chatzipetros A.[2]

(1)Department of Mineralogy-Petrology-Economic Geology, School of Geology, Aristotle University of Thessaloniki, 54124, Greece, email: Spyroslis.spyros@gmail.com, (2)Department of Structural, Historical and Applied Geology, School of Geology, Aristotle University of Thessaloniki, 54124, Greece

Introduction

Gold-only vein deposits such as these of the orogenic-gold type are among the most significant sources of gold worldwide, but their exploration has several challenges. Besides their weak physical properties and commonly deep burial depth, orogenic-gold deposits often exhibit weak geochemical signatures and/or subtle surface gold anomalies, especially in regions with thick overburden or significant weathering. In addition, gold concentrations within the quartz veins or soil cover, can deviate significantly from the statistical normal distribution, commonly showing extreme positive skewness and nugget effect, complicating anomaly detection.

The fundamental task when using surface geochemical data for mineral exploration is to identify and delineate geochemical anomalies within the various occurring lithologies. This is realized by calculating the threshold value (Garrett, 1991) above the background levels (Hawkes and Webb, 1962) and by applying interpolation to the anomaly (point) data to produce a continuous anomaly map. The latter can act as a single predictive layer or queried in a mineral prospectivity mapping technique, to indicate potential drilling locations.

Exploratory Data Analysis (EDA) is a robust technique that leverages both statistical and graphical methods in order to identify patterns, anomalies, and relationships in the exploration geochemical datasets (Tukey, 1977; Kürzl, 1988).

In this work, the accuracy and efficiency of four different threshold estimation techniques are tested, which can be applied in areas with unexposed bedrock and thick soil cover. High-resolution gold-concentration distributions in thick soil cover are investigated and visualized, collected during brownfields exploration campaign for orogenic-gold. Finally, through spatial analysis and zonal statistics the degree of element (gold) dispersion is evaluated.

The case study area is the southern segment of the Archaean Hattu orogenic-gold district in Eastern Finland (Hattu Schist Belt - HSB), which is part of the Ilomantsi greenstone belt and covers an area of 6 km in length with width 3 km. The main rock types of the belt consist of the Hattu supracrustal rocks, which include sedimentary-metasedimentary rocks (e.g., greywacke, schist, tuff), intruded by the plutonic rock units (tonalitic and granodioritic compositions). The belt has been progressively deformed, characterized by steeply dipping, upward-facing structures with transpressional N-NE trending dextral shear systems, and intensely hydrothermally altered due to large-scale fluids under greenschist to lower amphibolite-facies conditions peaking at 500-600°C at 4-6 kbars (O'Brien et al., 1993; Kojonen et al., 1993; Sorjonen-Ward et al., 2015). The Archean bedrock of the area is entirely covered by ~5-meter-thick glacial till, and the gold mineralization exact locations are depicted solely by drill core data.

Database and Software

The surface geochemical dataset contained gold concentrations from 936 basal till samples, collected and analysed by Endomines Oy. The company used Fire Assay for analysis of the gold content, which is measured in mg/kg, with a detection limit of 1 μg/kg. The classification of the soil samples, as well as their locations relative to the southern segment of the HSB, can be seen in Figure 1.

The lithological formations and their boundaries that occur in the area were first digitized and further classified according to the two main lithologies of the belt. After projecting drill core data (lithological and geochemical) the main mineralization zone is traced on the map (Figure 4).

For statistical analysis, IBM SPSS Statistics 27.0 was used, and for geochemical data processing and visualization, ArcMap 10.8.1 GIS software with the Spatial Analyst tool was utilized under academic license.

Methodology

The flowchart in Figure 1 illustrates the methodology used for threshold estimation and the generation of gold anomaly map for the HSB area. Briefly includes:

1) Descriptive statistics for measuring mean, median, skewness and kurtosis to understand the central tendency and spread of element concentrations. This phase also includes the examination of the dataset regarding censored and extreme values.

2) EDA graphical tools such as histograms and boxplots for visualization of data distribution, assessing the frequency of gold concentrations, and identifying outliers that may signify anomalies or errors in the dataset.

3) Logarithmic transformation (Miesch and Chapman, 1977) to manage the highly skewed data.
4) Geochemical anomaly detection to identify the threshold values for gold and delineate the anomalous zone. Four different threshold estimation techniques were applied, namely the:
i) Mean +2Standard Deviation (SD)
ii) Upper Whisker (UW)
iii) Median + 2Median Absolute Deviation (MAD)
iv) Percentiles
5) Application of the straightforward Inverse Distance Weighting (IDW) interpolation method (Shepard, 1968) to generate continuous geochemical anomaly surface maps and contribute to the comparison of the threshold techniques.
6) Validation of the results through the GIS-diagnostics (Mean Error - ME, Root Mean Square Error - RMSE), to assess whether geochemical anomaly mapping provided a reliable anomaly map with a rational threshold.
7) Interpretation and evaluation of the gold anomaly zones. Spatial and zonal statistics analysis to further correlate gold concentrations with other types of geological information.

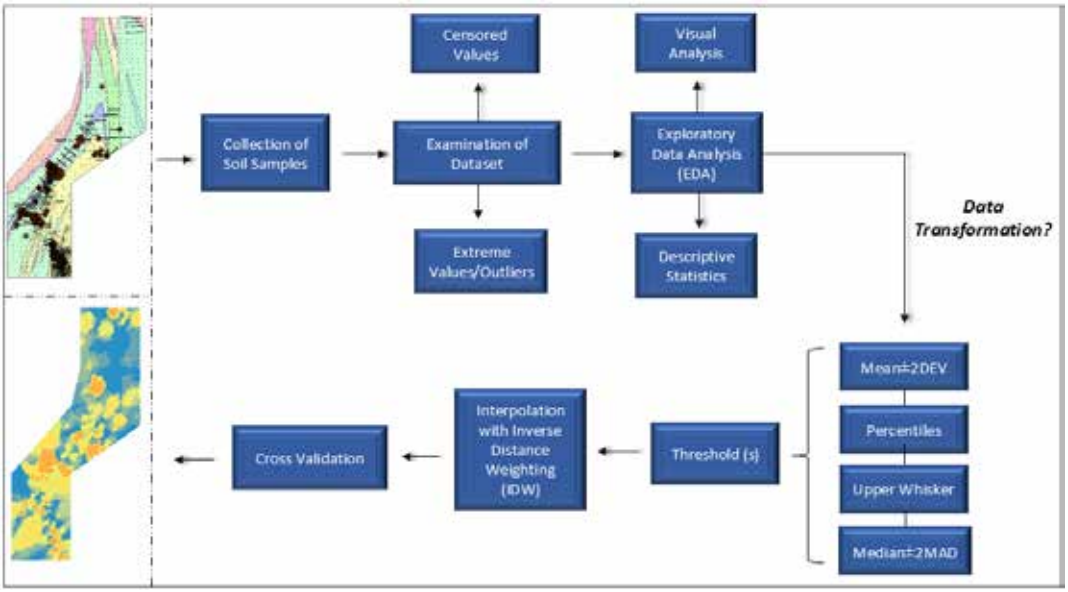

Figure 1. Overall methodology for threshold estimation and gold anomaly mapping for the southern segment of the HSB.

Results

Histograms and boxplots revealed positive extreme values and outliers. Since the number is too small and have minimal effect on the mean values, no top-cut was applied.

Table 1. Descriptive statistics of the datasets related to the threshold methods

Au in till (mg/kg)	Raw dataset	Transformed dataset
Mean	0.046	-3.88
Standard Deviation (SD)	0.13	0.96
Median	0.014	-4.26
Median Absolute Deviation (MAD)	0.04	0.34
Percentile90 (P90)	0.07	-2.55
Skewness	9.73	1.77
Kurtosis	136.86	3.28
Max	9.00	2.19

As shown in Figures. 2a and 2b the data are extremely positive-skewed and did not conform to normal or near-normal distribution model. The data were first logarithmically transformed and then an inverse transformation was applied to estimate reliable positive thresholds for each method and ensure that the final thresholds are meaningful to the original dataset. The transformed dataset demonstrated improved symmetry, reducing the impact of outliers (Figures 2c, 2d).

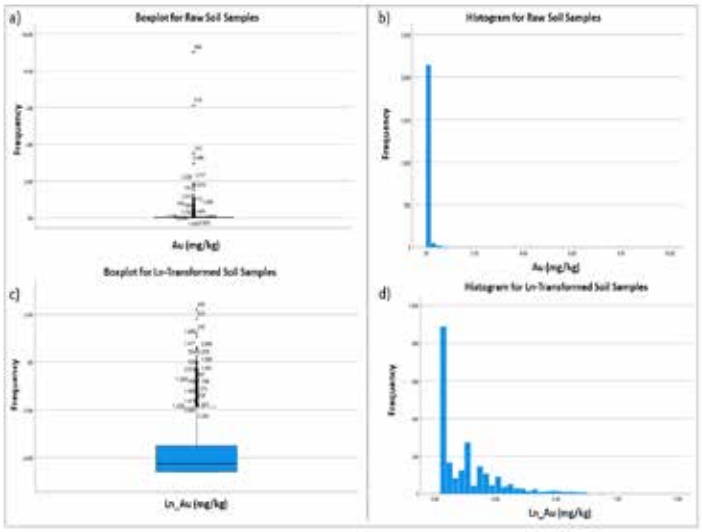

Figure 2. The figures (a, b) at the top present the boxplot and histogram for the raw soil dataset with their ID's, while figures (c, d) below display the boxplot and histogram after applying the natural logarithm transformation.

Table 2 shows the threshold values calculated using the four different methods. A comparison between them shows that the median +2MAD produces the lowest threshold for the soil samples, followed by the percentiles, the mean +2SD, and the upper whisker method.

Table 2. Overview of the threshold values

Au (mg/kg) in till	**Mean + 2 SD**	**Median + 2 MAD**	**Upper Whisker**	**Percentile (P90)**
Threshold	0.14	0.027	0.15	0.07

Figure 3 shows the geochemical gold-anomaly maps produced using the threshold values as calculated by each method. The parameters of IDW interpolation were carefully evaluated and tested to minimize the diagnostics of ME and RMSE and are summarized in Table 3.

Table 3. Parameters for IDW interpolation for soil samples

IDW Analysis	**Soil Parameters**
Neighbourhood Type	Standard
Power Parameter	1
Maximum Neighbours	5
Minimum Neighbours	2
Sector Type	One Sector
Angle	30°

Cross-validation (Table 4) of IDW indicated that the ME is close to zero, implying high accuracy in the prediction. The RMSE values are similarly near zero, further confirming the reliability of the interpolation method (Johnston et al., 2003). Finally, the location of the known gold occurrences of the south segment, revealed through drill core data, attests the accuracy of the prediction.

Table 4. Cross validation diagnostics for IDW in GIS.

Diagnostics	**Soil Validation Statistics**
Mean Error (ME)	0.03
Root Mean Square Error (RMSE)	0.15

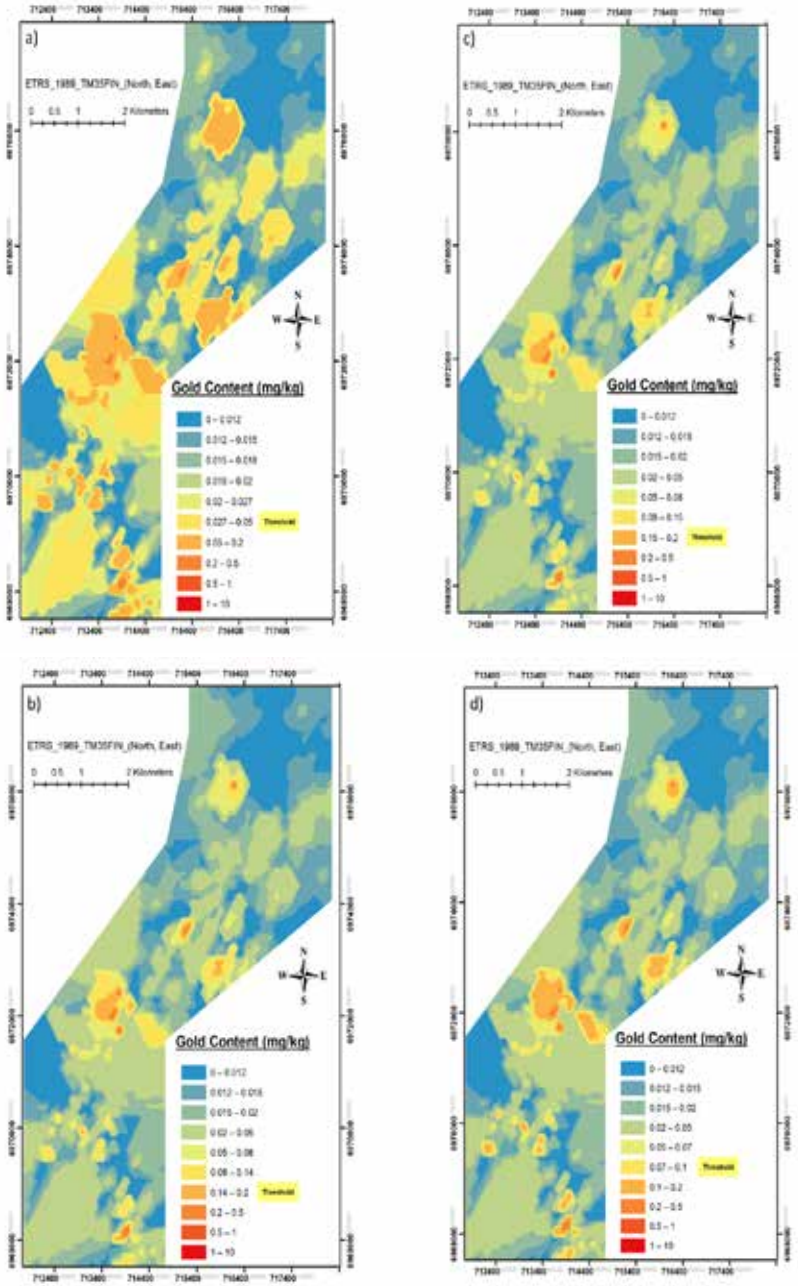

Figure 3. Gold geochemical distribution maps for soil, of the south HSB segment. The maps were generated with the IDW interpolation method using the different threshold in each case: (a) Median + 2MAD, (b) Mean + 2SD, (c) Upper Whisker, and (d) Percentiles.

Discussion and Conclusions

The soil geochemical dataset in this study represents a typical orogenic gold district, characterized by a predominance of low gold concentrations ranging from 0.01 to 0.5 mg/kg, along with a few exceptionally high gold values (up to 9 mg/kg). Like most gold deposits, including orogenic gold deposits, these geochemical concentrations deviate significantly from a Gaussian (normal) or near-normal distribution. Due to high skewness even after logarithmic transformation, the distribution remained non-Gaussian. Any multimodal distribution was not observed which implies a uniform dataset, not affected by secondary or complex geological processes.

The median +2MAD method detects the greatest number of geochemical anomalies, followed by the percentile method. Due to the dataset's extreme positive skewness, mean ±2SD was unreliable. The outliers exceed 10% giving similar threshold to the mean ±2SD. The median +2MAD, provided lower, more suitable threshold (0.027 mg/

kg), selected as more reliable in this work for mapping. This value corresponds to the thresholds (0.02 – 0.06 mg/kg) used in gold exploration programs worldwide as well as in previous HSB studies (Xuejing and Xueqiu, 1991; Hartikainen and Nurmi, 1993).

Validation and evaluation of the derived gold geochemical map based on spatial analysis and zonal statistics show an average geochemical anomaly value of 0.04 mg/kg across the mineralization zone, which is above the calculated 0.027 mg/kg threshold. In some areas, there is a weak association with geochemical anomalies falling below the threshold, even reaching zero gold concentration. The highest anomaly within the ore-body reaches 0.23 mg/kg confirming the geochemical anomaly mapping analysis and highlights these areas, among others, as promising zones for further exploration.

The total area of geochemical mapping aligning with the mineralization covers 1,046,328 square meters. The most significant gold anomalies (>0.027 mg/kg) which align with the well-defined mineralization line covers 634,427 square meters, which corresponds to approximately 60.7% of the total surface area (Figure 4). This indicates that threshold analysis with EDA and geochemical mapping has been very successful in tracing the bedrock mineralization.

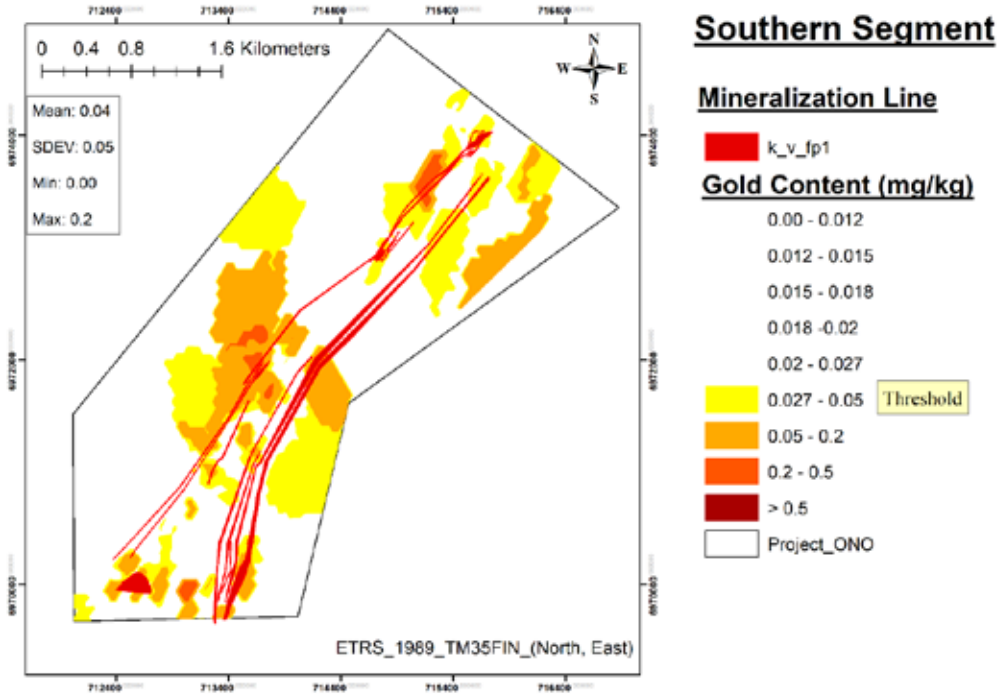

Figure 4. Geochemical anomalies that exceed the given threshold of the median+2MAD method, classified as the most promising gold anomalies in the southern HSB area, and their spatial relationship to the known bedrock mineralization zone depicted in red (drill core data).

Concluding, the independence of median +2MAD method from Gaussian distribution and transformations provides a powerful tool for estimating thresholds, thus geochemical anomalies in soil. The presented methodology can contribute to the development of cost-effective and efficient exploration strategies both in greenfields and brownfields settings.

Acknowledgements

We express our sincere gratitude to Endomines Oy company for their generous provision of the geochemical data set. The anonymous reviewers are especially thanked for their constructive comments and revisions, which greatly improved the initial manuscript.

EXTENDED ABSTRACT 303

Liquefaction risk assessment of airport infrastructure using geological data and remote sensing techniques

Taftsoglou M.[1], Valkaniotis S.[2], Papathanassiou G.[3], Argyroudis S.[4]

(1) Department of Earth and Marine Science, University of Ferrara, Italy, tftmra@unife.it , (2) Department of Civil Engineering, Democritus University of Thrace, Greece , (3) Department of Geology, Aristotle University of Thessaloniki, Greece , (4) Department of Civil and Environmental Engineering, Brunel University of London, UK

Abstract

This research serves toward safeguarding airport infrastructure in liquefaction-prone regions. Although airports contribute to the socioeconomic vitality of a region and serve as emergency means in cases of seismic events, their functionality remains vulnerable to disruption caused by secondary earthquake effects such as soil liquefaction. Hence, the risk and vulnerability assessment of airport facilities is crucial for their functionality and preparedness during and after the liquefaction events. This study introduces a practical and rapid assessment tool for the preliminary identification of areas prone to liquefaction and the risk analysis of airport infrastructure on a regional scale. As region of research was selected the Nestos delta in Greece, where the critical infrastructure of Kavala International Airport is placed (KVA). According to the results, a significant section of KVA's runway and taxiways are located on highly susceptible soils of abandoned meanders. Aiming to quantify the impacts of liquefaction in the susceptible areas, FEMA's HAZUS (FEMA, 2022) methodology is applied, estimating values of 20% of liquefaction probability and 3.1-12.3 cm of expected ground settlements for the class of very high susceptible units. The results of the liquefaction hazard analysis are used for the risk assessment of the airport infrastructure, estimating a total direct loss of €5 million. Validation of the proposed methodology was achieved using datasets from three international airports that sustained extensive seismic damage in the past.

Introduction

As it was concluded in the aftermath of major seismic events such as the Loma Prieta in 1989, the Northridge in 1994, the Kobe in 1994, the Nisqually in 2001 and the Türkiye-Syria in 2023, a significant part of the damage induced to airport facilities is correlated with the earthquake secondary effects of liquefaction. Highly correlated with the hydrogeological conditions and the depositional history of sediments, liquefaction is generally induced in fluvial and coastal environments and filled land areas that contain shallow layers of young, saturated, low density, granular sediments (Youd and Hoose, 1978; Holzer, 1998; Tinsley et al., 1985). As a result, liquefaction-related phenomena of ground settlement and cracking, lateral spreading and foundation failure can occur affecting airport's runways, air control towers, terminal buildings, power and communications and fuel systems. Therefore, it is crucial to have a comprehensive understanding of liquefaction mechanisms and their impacts on airport environments, to ensure that efficient mitigation measures are taken.

This paper presents a practical and quick tool for the regional assessment of airport susceptibility and risk to liquefaction events. Focusing on the critical infrastructure of Kavala International Airport (KVA) in the northern Greece, a geomorphological map is initially developed using remote sensing data and geological information. Based on this map, the susceptibility of the critical infrastructure's formations to liquefaction is assessed resulting to a related liquefaction susceptibility map, which is utilized to estimate the permanent ground displacement (PGD); caused by liquefaction; in the form of ground settlements. Subsequently, PGD is used as the intensity measure for the risk analysis of the infrastructure. The liquefaction susceptibility and vulnerability assessment are validated using datasets from Oakland, King County (USA) and Hatay.

Methodology

The proposed methodology is divided into two main phases of 7 individual steps. "Phase I" is based on a workflow described by Taftsoglou et al. (2022) and focuses on assessing the susceptibility of the investigation area following the four steps of: (1) data input and processing, (2) mapping geomorphological features, (3) classification of susceptible to liquefaction surficial geological units, (4) liquefaction susceptibility map of surficial geological features. On the other hand, "Phase II" aims to analyze the risk of the critical infrastructure located in the same region and is consisted by four additional steps of: (5) estimation of the probability to liquefaction phenomena, (6) estimation of permanent ground displacement (PGD), (7) Vulnerability and loss.

In step 1 geological and historical maps of the area, orthophotos and satellite images were collected in order to

examine the geological formations and the geomorphological evolution of the plain. Tracing geomorphological features such as abandoned stream/meanders, point bars, oxbow lakes, dunes and lagoons through processing of multi-temporal and historical layers in correlation with the local topography (DEM) was performed in step 2, resulting in a geomorphological map. In the 3rd step, the age of the delineated surficial geological units and their classification to susceptibility classes were assessed, with the latter conducted based on the criteria proposed by Youd and Perkins (1978). In step 4, a liquefaction susceptibility map was compiled, including four classes (Low, Moderate, High and Very High), where coastal and fluvial deposits were classified as high to very high susceptible units.
Having estimated the liquefaction susceptibility on a regional scale, "Phase II" with steps 5 to 8 took place to evaluate the related risk of these critical facilities. Specifically, HAZUS (FEMA, 2022) methodology was applied in step 5, according to which, a seismic scenario was selected, based on SHARE and GreDaaS databases of seismogenic sources (Caputo et al, 2012; Giardini et al, 2013). Taking into consideration the parameters of the susceptibility categories, a moment magnitude value of Mw 6.3, a ground shaking of PGA=0.36g and a groundwater depth of 6m, the probability of liquefaction according to HAZUS method was determined for the airport location, classifying the area into four probability classes. Therefore, based on the estimated probability in correlation with the ground settlement amplitude proposed by HAZUS, the expected ground settlement was assessed for each susceptibility class in step 6. Through the last step of this workflow, vulnerability and expected losses of airport facilities are estimated, following the fragility functions that are included in HAZUS methodology.

Results

Based on the spatial distribution of surficial geological units proposed by this study, application of Youd and Perkins criteria classified KVA area into four liquefaction susceptibility classes. According to the resulted liquefaction susceptibility map, 300m of the northwestern runway limit, 2.7 km of the adjacent taxiway and 78m^2 of the apron area are constructed in the very high susceptible zone of an abandoned Nestos River branch, while the rest of the facilities are located on regions of moderate susceptibility.
Application of FEMA's HAZUS methodology (FEMA, 2002) estimated 0.2 probability values for the zone of KVA classified as very high susceptible and 0.08 for the moderate one, while the corresponding average ground settlements values (PGD) for these classes were assessed as 6.1 cm (3.1 – 12.3 cm) and 0.4 cm (0.2 – 0.8 cm). As the critical facilities of runway, taxiway and apron are in moderate and very high susceptible zones, the estimated PGD values for these classes were used for the evaluation of the average loss ratios. Finally, multiplication of these values with the reconstruction cost and extent of its facility, resulted in direct losses of € 0,37 million for the case of runway, € 2,5 million for the taxiway and € 2 million for the apron and consequently a total loss of €5 million.

Validation

The liquefaction susceptibility assessment and risk analysis for the KVA airport are validated in the case studies of Oakland (OAK), Hatay (HTY) and King County (BFI) International airports, where the most extended liquefaction-related damages occurred to the runway's areas. A comparison of results estimated according to HAZUS methodology revealed that the observed damages of liquefaction after the earthquakes of Loma Prietta (1989), Turkey-Syria (2023) and Nisqually (2001) in the three airport locations align with the estimated ones, as all the records were detected in areas characterized as very high susceptible to these phenomena.
Particularly, 900 m of the northwestern runway in the OAK airport was damaged by sand boils, as well as by buckling and cracking of the pavement, while cracks were also detected in the adjacent taxiway (Holzer, 1998; Seed et al. 1991). Application of the proposed methodology shown consistency with these observations as according to it OAK is located predominantly in the zone of very high susceptibility, with probability of 0.22 for liquefaction occurrences and expected PGD values of 3.4 – 13.6 cm. Similarly, after the Nisqually earthquake, extensive liquefaction was recorded in the eastern runway of BFI airport (Nisqually Earthquake Clearinghouse Group, 2001; Bray and others, 2001), where application of the proposed method resulted in the classification of this region as very high susceptible and the estimation of probability and PGD values of 0.17 and 2.5 – 10.2 cm respectively. Moreover, the projection of liquefaction occurrences in HTY airport shown consistency with the maps obtained from the proposed methodology, since the entire airport infrastructure is characterized as highly susceptible to liquefaction, with a probability of 0.24 of observation of liquefaction phenomena and predicted PGD values ranging from 3.6 to 14.4 cm. However, it should be noted that the availability and the quality of the recorded data resulted in more qualitative comparisons between the observed and predicted values, since the extent of the observed failures is considerably more localized than anticipated.

Conclusions

This paper presents an efficient and rapid evaluation tool for assessing the risk of airport infrastructure located in

liquefaction-prone areas, using geological and remote sensing data. As the area of interest was selected International Airport of Kavala (KVA), built in the Nestos delta in Greece. Application of the proposed methodology initially resulted in a liquefaction susceptibility map of the study area. Afterwards the probability of liquefaction and the expected ground settlements were estimated according to a representative seismic event. The direct losses for the runway, taxiways and apron are estimated to €5 million. The methodology is validated using three cases study airports which sustained damage due to liquefaction. According to the application of the proposed approach, the observed damaged areas of these infrastructures align closely with the estimations of the expected ones, confirming the accurate identification of the areas susceptible to liquefaction phenomena.

The proposed methodology provides a useful guide to reducing the risk of liquefaction phenomena specifically affecting airport facilities, highlighting areas more susceptible to these processes and, through targeted prevention, reducing possible service interruptions due to seismic events.

Abstract
After the seismic sequences of 2021 in Damasi (Greece), 2023 in Kahramanmaraş (Türkiye) and 2010-2011 in Christchurch (New Zealand), extensive liquefaction phenomena were induced in the floodplain and point bars of the associated meandering rivers. As the identification of paleoenvironmental features plays a pivotal role in the assessment of the liquefaction susceptibility of an area, this research aims to statistically investigate the spatial distribution of liquefaction phenomena within point bar formations. By combining historical and remote sensing data, reconstruction of the evolution of each meandering fluvial system took place to delineate the different types of lithofacies encountered in point bars. Afterwards, correlation of the density of liquefaction manifestations (ejecta and lateral spreading) with sand- and mud-prone sediments occurred, based on a relationship proposed in this study. The outcome that arose from this procedure resulted in the attribution of weight values for each heterogeneity type, according to which, most of the liquefaction phenomena are correlated with the sandy sediments deposited on the upstream flow direction.

Introduction
During the last decade and especially following some major earthquakes associated with widespread secondary seismic effects, researchers started realizing that the triggering of liquefaction clustering phenomena tend to follow distinct patterns. This preferential behavior of the sediments to produce liquefaction manifestations has been extensively studied in notable events occurred in New Zealand, Italy, Greece and Turkey (Wotherspoon *et al*. 2012; Di Manna *et al*. 2012; Galli *et al*. 2012; Bastin *et al*. 2015; Papathanassiou *et al*. 2012, 2015, 2022; Civico *et al*. 2015; Taftsoglou *et al*. 2023; Abayo *et al*. 2023). In several cases, it was concluded that specific geomorphological areas within fluvial meandering systems such as old/abandoned channels, point bars and oxbow lakes favored the occurrences of liquefaction phenomena, showing a higher liquefaction density compared to other sectors of the same floodplain. Consequently, the reliability of a liquefaction susceptibility map is highly dependent on the scale and accuracy of the geological and geomorphological mapping of a floodplain.
Following this approach, this research focuses on the valleys of Piniada in Thessaly (Greece), Orontes in Hatay (Türkiye) and Avon in Christchurch (New Zealand) where the mainshocks of Mw=6.3 (March 2021), Mw=7.7 (February 2023) Mw =7.1 (September 2010) and Mw =6.2 (February 2011) occurred respectively. Covered mostly by Quaternary fluvial deposits, our study focused on the inner part of the meandering systems, i.e. point bars, where liquefaction manifestations were recorded after these seismic sequences. Considering the heterogeneity of the noncohesive material accumulated on the inner part of the meander (point bars), correlation between the distribution of liquefaction sites and sand- and mud-prone sediments was examined. To achieve this, the method introduced by Russel (2017) applied in the first step, resulted in the delineation of different types of lithofacies. In order to correlate the density of liquefaction phenomena with the different types of lithofacies, a relationship was proposed afterwards, which resulted in the attribution of weight indexes to each heterogeneity type.

Methodology
For the purposes of this study, the methodology proposed by Russell (2017) was applied to analyze point-bar formations in the Piniada, Avon and Orontes Valleys. According to this method, point-bar deposits are characterized by lateral discontinuity (Allen, 1965) and a complex distribution of lithofacies of sandstone and mudstone beds (Thomas, 1987, Tye, 2004, Miall, 2006, Durkin *et al*., 2015), while their sedimentation is influenced by the meander system evolution and its associated variations in channel geometry and deposition patterns. Moreover, grain size distribution within these formations reflects the flow direction and speed of a meander, with finer materials predominating downstream and coarser deposits upstream (Jackson, 1976, Fustic *et al*., 2012, Nardin *et al*., 2013).

Based on Russell's (2017) methodology during the first step meander shapes were classified according to their geometric shapes into the four groups of open asymmetric, angular, bulbous, and open symmetric. Afterwards, utilization of high-resolution satellite images and historical aerial imagery for each case took place in order to map meander's thalweg lines and apexes as well as the inflection points, which indicate the transitional zones between sand- to mud-prone sediments (Smith et al., 2009). Combination of sediment deposition patterns with meander geometry resulted in a map classifying the meander heterogeneity into four types of Sand-I, Sand-II, Mud-I, and Mud-II.

Having compiled this map, the liquefaction areas (polygons) of ejecta phenomena for Piniada, Avon and Orontes valleys and lateral spreading for the last two were projected in order to examine their distribution to each type of sediment. Particularly, based on the factors of (a) density of liquefaction manifestations per heterogeneity type (DenseHT) and (b) the total density of liquefaction sites in point bar formations (DensePB), a relationship is proposed expressed by the equation:

$$\text{Weight HT} = \ln(\text{DenseHT} / \text{DensePB})$$

Application of this relationship for each case study and for the different categories of liquefaction phenomena (ejecta, lateral spreading) resulted in the estimation of four total weight indexes attributed to the heterogeneity types of Sand-I, Sand-II, Mud-I and Mud-II.

Results

In order to examine the correlation between the density of liquefaction phenomena and the distribution of sand and mud rich deposits, we initially delineated the different lithofacies on selected point bars in Piniada, Avon and Orontes Valleys.

Specifically, 4.7km^2, 1.57 km^2 and 6.9 km^2 of point bar formations were examined for each case respectively and characterized according to their meander shape into the four groups of open asymmetric, angular, bulbous, and open symmetric. Based on the high resolution satellite images and the historical aerial imagery, geometrical characteristics of the meander evolution, such as thalweg lines, apexes, inflection points and scroll bar formation were detected resulting in the mapping of the four heterogeneity types. Projection of the liquefaction phenomena of ejecta in the case of Piniada Valley, shown that 81% of the total records covered the coarser deposits of the upstream limb, while in Orontes Valley 57% were observed in Sand-II type. Similarly, liquefaction phenomena triggered by the Christchurch major events of September 2010 and February 2011 indicated that most of the ejecta occurred in the Sand-II type, covering 60% of these deposits. Regarding the lateral spreading manifestations in Orontes and Avon Valleys, most of them were detected in sandy types I and II, with 70% coverage in the case of Orontes and more than 85% in Avon.

Conclusion

The spatial distribution of liquefaction phenomena in Piniada, Orontes and Avon Valleys clearly indicate that one of the most susceptible to liquefaction geomorphological features are the point bars formations. As these features are characterized by different heterogeneity types with alterations between the ratio of coarse and fine materials, a detailed mapping of the different lithofacies is considered in order to analyze the preferential behavior of the areas more or less susceptible to liquefaction phenomena.

For the purposes of this study, point bar features were traced and classified into four heterogeneity classes of Sand-I, Sand-II, Mud-I and Mud-II, based on geological, geomorphological and remote sensing. Comparison between the spatial distribution of different lithofacies with liquefaction manifestations indicated that most of the effects were triggered in deposits mainly consisted of sandy materials.

Based on the density of ejecta and lateral spreading phenomena per heterogeneity type and their total density in point bar formations, a relationship is proposed according to which different weight values were attributed for Sand-I, Sand-II, Mud-I and Mud-II deposits. The outcome that arose from this procedure resulted in weight values of 0.13 and 0.10 for Sand-I and Sand-II types respectively, while for the lateral spreading phenomena, the attributed coefficients for the same types are -0.19 (Sand-I) and -0.09 (Sand-II).

Earthquake hazard implications for Lesvos (Midilli) and the surrounding region

Tan O.[1], Karagöz Ö.[2]

(1) İstanbul University-Cerrahpaşa, Faculty of Engineering, Department of Geophysical Engineering, İstanbul, Türkiye. onur.tan@iuc.edu.tr, (2) Çanakkale Onsekiz Mart University, Faculty of Engineering, Department of Geophysical Engineering, Çanakkale, Türkiye.

Introduction

The most recent seismic activities around Lesvos Island and the coastal area of western Turkey show that the potential for earthquake hazards is evident. The shallow soil structure beneath an urban area is more dominant than the source features for earthquake damage.

The western part of the Türkiye and the Greek islands in the east of the Aegean Sea have suffered from destructive earthquakes throughout history. The 1912 Mürefte (Mw 7.3), 1944 Edremit (Ms 6.8), 1953 Yenice-Gönen (Ms 7.2) and 1964 Manyas (Ms 6.9) earthquakes shake the NW Türkiye in the 20th century. There were three significant events in the coastal areas of in the eastern Aegean Sea. In south, the 20 July 2017 Kos (Mw 6.6) earthquakes shake the island and city of Bodrum. In north, the Ayvacık swarm in February and the Lesvos (Midilli) earthquake (Mw 6.3) in June were strongly felt in the region and moderately damaged the villages. Then, the most recent 2020 Samos (Mw 7.0) earthquake affected the Samos Island and city of Izmir. The mainshock, which generated high damage especially in the Bornova Basin (Izmir), showed that the importance of the effect of deep basin structure and building quality in urban areas. The effect of the recent earthquakes broadly in the eastern Mediterranean region indicate that the knowledge of earthquake sources, seismic wave propagations and characteristics of ground motions is critical for urban hazard mitigation and planning in active seismic zones.

In this study, the earthquake hazard of Lesvos Island and the western coast of Türkiye where contain high populated cities, historic heritage and important touristic destinations were investigated considering (1) faulting and rupture features of the 12.06.2017 Lesvos mainshock, (2) numerical waveform simulations with regional 1D velocity structure and shallow soil amplification, (3) relocated earthquakes and (4) cumulative crustal Coulomb stress change due to the destructive earthquakes in the region. The inversion algorithm by Kikuchi and Kanamori (1991) for the teleseismic body waveforms is used to obtain the mainshock's focal mechanism parameters and the rupture propagation. Different from the routine approach in seismological studies, we compared the rupture models of the mainshock using numerical waveform simulations (Karagoz et al., 2018). For this aim, the synthetic seismograms were generated utilizing the discrete wavenumber method with a characterized source model, 1D velocity model between event and stations and amplification of shallow soil beneath stations. The simulation let us not only validate the source model and 1D regional velocity structures but also understand the high damage in the region. We also relocated the earthquakes in the study area with the double-difference inversion method (Waldhauser and Ellsworth, 2000) to understand the seismicity with reliable horizontal and vertical uncertainties. Finally, Coulomb stress change analyses (Lin and Stein, 2004) are performed to calculate the static stress loading areas where the next destructive earthquake may occur.

Results and Conclusions

We invert teleseismic waveforms to determine fault plane solution and rupture propagation of the mainshock. The fault plane parameters are 127°, 47° and -97° for the strike, dip and rake angles, respectively. The finite fault slip model indicates that the rupture propagates circularly from the focal in the first 2-3 s with maximum energy release. Then, it moves to the surface in the next 7-8 s. The maximum slip is 1.8 m, and the average stress drop is 3.6 MPa. The aftershock activity (Papadimitriou et al., 2018) is low in the high-slip patch on the rupture area and vice versa, as observed in the recent 2020 Samos and 2023 Kahramanmaraş destructive earthquakes.

The numerical waveform simulation considering the local soil information is applied to the Lesvos stations to understand the reason for the structural damage on the island. The frequency of the synthetic waveforms with the highest horizontal amplitude (PGV, PGA) is around 3 Hz in Vrissa, which agrees with the fundamental frequency determined from the reported shallow soil Vs model for the region (Figure 1). This frequency match may generate a resonance phenomenon in the soil-covered western part of Vrissa. Thus, we can conclude that the damage in Vrissa is caused mainly by site effects of soil structure, not rupture propagation of the mainshock.

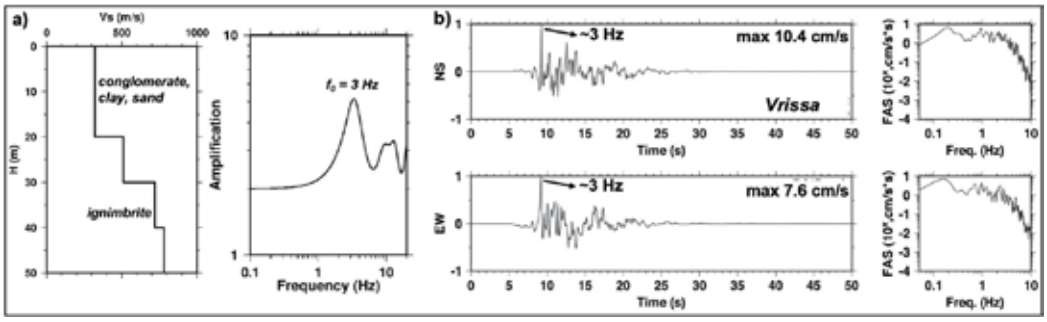

Figure 1. a) Shallow S-wave velocity (Vs) model near Vrissa (Karastathis et al., 2020) and its calculated SH soil amplification. The fundamental frequency is about 3 Hz. b) Synthetic velocity seismograms (normalized) in Vrissa. The wave phase with the maximum peak has a frequency of 3 Hz.

The relocated earthquakes with the double-difference inversion method show the detail of the seismic activity in the region (Figure 2). The 2019 (ML 5.0) and 2024 (ML 4.9) earthquakes in Ayvacık are on the southwest of the right-lateral Evciler Fault, and their oblique focal mechanism solutions indicate that the strike-slip motion extends to Ayvacık. However, the 2017 Ayvacık swarm has a NW-SE normal faulting mechanism. Different characteristics of these earthquakes indicate a complex tectonic structure in a small area on the Biga Peninsula (NW Türkiye). One of the important observations in this study is that the two notable clusters in 2021 and 2023 are at the two ends of the Agia-Paraskevi Fault. Each cluster has more than 300 events appearing in a limited period and has a right-lateral strike-slip mechanism. The spatio-temporal characteristics of seismicity show that there are several earthquake clusters in the region, and they show a high activation rate in a short period, like in different regions in western Türkiye. We consider that the Psara-Lesvos and Agia-Paraskevi faults are the principal displacement zone of a SW-NE right-lateral strike-slip shear zone (SW continuation of the southern branch of the North Anatolian Fault Zone), and the 2021 and 2023 earthquake clusters are on its right-lateral synthetic shears (R).

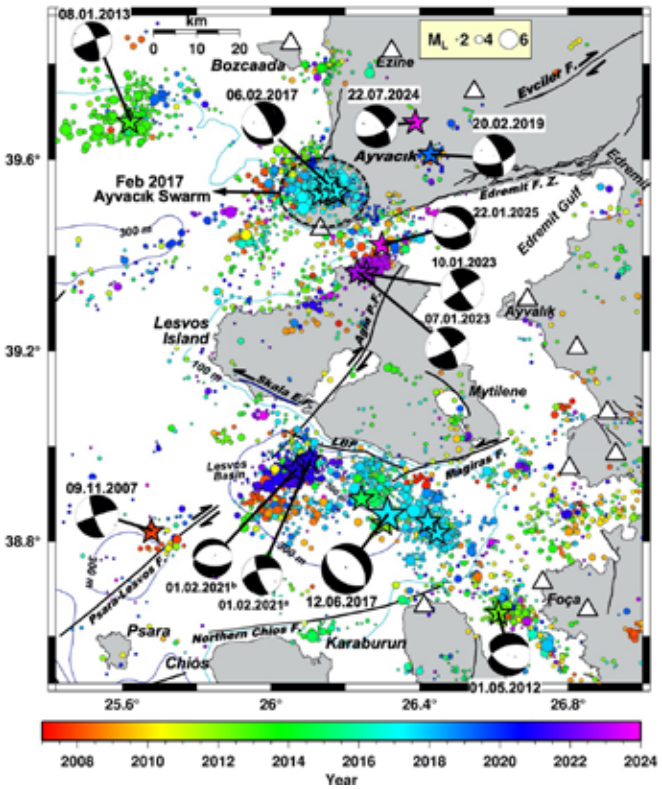

Figure 2. Relocated earthquakes with the double-difference algorithm in the study area. The color scale shows the event date. Stars are events with $M_L \geq 5.0$. Triangles are the seismological stations. The bathymetry contours are from the GEBCO databases.

The Coulomb stress change analyses utilizing the well-known destructive earthquakes in the last 150 years argue that the final stress loading stage on the faults infers continuity of earthquake hazard possibility for Lesvos Island and its surroundings. The cumulative stress change calculations for the events on optimal normal and strike-slip faults are shown in Figure 3. In general, positive and negative stress lobs for both fault types are similar; there is no important difference. The stress load in the region and the most recent 22.01.2025 earthquake are evidence of the future earthquake hazard for the study area.

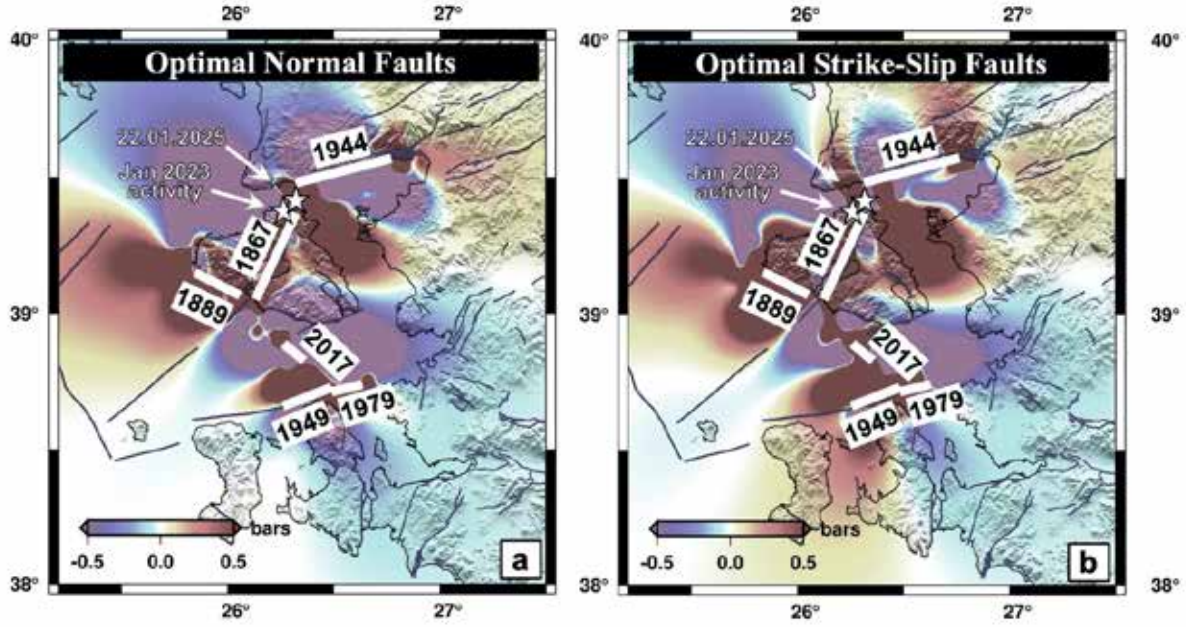

Figure 3. Coulomb stress changes on optimal normal (a) and strike-slip (b) faults for large earthquakes since 1867. The January 2023 and the latest 22 January 2025 (Mw 5.3) activities are shown with small stars.

Acknowledgments

We gratefully thank George Karviris and Vassilis Karakostas for sharing aftershock data of the 2017 Lesvos earthquake.

Introduction

Epithermal gold ± silver deposits are major commodities for precious and critical metals (i.e. Au, Ag, Te, Se, Sn, Bi, In, Ga, Ge) (John et al. 2018). They are subdivided in three categories based on the sulfur fugacity of the mineralizing fluids: low- (LS), intermediate- (IS), and high-sulfidation (HS), following the classification schemes of Hedenquist *et al.* (2000) and Einaudi *et al.* (2003). Among the low-sulfidation class, the so-called alkalic-type gold deposits are spatially associated with alkaline igneous rocks and display specific mineralogical and geochemical characteristics, as for example, the presence of tellurides, fluorite and the vanadium-bearing mica roscoelite (Jensen and Barton, 2000; Cook *et al.*, 2009; Kelley and Spry, 2016; Kelley *et al.*, 2020; Keith *et al.*, 2020).

Northeastern Greece (Western Thrace and the Greek Aegean islands of Limnos and Lesvos) hosts a variety of porphyry-epithermal systems enriched in tellurides (i.e.,Pagoni Rachi-St Philippos, Pefka, Fakos and Stypsi-Megala Therma), which are spatially and genetically associated with Oligocene to Miocene, high-K calc-alkaline to shoshonitic magmatic rocks (Arikas and Voudouris, 1998; Voudouris and Alfieris, 2005; Voudouris *et al.*, 2013,2019a,b,2022; Fornadel *et al.*, 2012; Melfos and Voudouris, 2012,2017, Mavrogonatos *et al.*, 2020; Börner *et al.*, 2022). Thus, it emerges as one of the most favorable exploration provinces in Europe for precious, critical and energy-transition elements. On Lesvos island, the Megala Therma-Katsilemonas (i.e., Argenos-Mythimna) epithermal mineralization was mined during Antiquity for silver, gold and lead, which is located about 5 km to the north of the Stypsi porphyry Cu-Mo-Re-Au prospect (Kontis *et al.*, 1994; Voudouris *et al.*, 2019b). The mineralization was suggested to be a fossil equivalent to active geothermal systems in northern Lesvos, as evidenced by hot springs in the Megala Therma area (Kontis *et al.* 1994). This work expands on previous work by Kontis *et al.* (1994), Vamvoukakis (2009) and Voudouris *et al.* (2018, 2019b) and presents new mineralogical, geochemical and geological information of the Megala Therma-Katsilemonas deposit. Here, we present new metallic phases from Megala Therma, a revised paragenetic sequence, and new bulk ore analyses for the mineralization. Based on existing geothermometric data, we constrain the physicochemical conditions of ore formation. We compare the data with the adjacent mineralization at the Biga Peninsula and we discuss similarities between Megala Therma-Katsilemonas and other epithermal-style mineralization hosted in alkaline igneous rocks with implications for similar settings in the Aegean alkaline igneous provinces.

Methods

Fourteen polished-thin sections and fourty five polished blocks of surface samples of host-rocks and sulfide mineralization were studied by optical microscopy and a JEOL JSM 5600 scanning electron microscope, equipped with back-scattered imaging capabilities, at the Department of Mineralogy and Petrology, National and Kapodistrian University of Athens (NKUA). The chemical composition of sulfides, sulfosalts, tellurides and native elements were carried out using a JEOL JXA 8200 Superprobe electron-microprobe at the “Eugen F. Stumpfl” Laboratory, Leoben University, Leoben, Austria. The operating conditions were an accelerating voltage of 20 kV, a beam current of 10 nA and a beam size of 1 μm. Counting times were 20s on the peak and 10s on the backgrounds for major elements. The counting times were increased to 60s and 30s for peak and background measurements, respectively, when analyzing trace elements. The following X-ray lines were used: AsLα, AuLα, SeLα, BiMα, TeLα, CuKα, FeKα, PbMα, SKα, SbLα, NiKα, CoKα, and ZnKa. The following standards and their detection limits included synthetic GaAs for As (350 ppm), synthetic electrum for Au (100 ppm), synthetic AgBiSe2 for Se (200 ppm) and Bi (200 ppm), Bi_2Te_3 for Te (150 ppm) cinnabar for Hg (400 ppm), chalcopyrite for Cu (150 ppm), pyrite for S and Fe (150 ppm), galena for Pb (700 ppm), stibnite for Sb (350 ppm), skutterudite for Co (150 ppm), millerite for Ni (150 ppm), and sphalerite for

Zn (400 ppm). In addition, bulk mineralized samples were analyzed for their trace element composition by 1:1:1 Aqua Regia digestion by ultra-trace ICP-MS analysis at ACME analytical laboratories (Vancouver, Canada).

Results

Geology and Mineralization

Lesvos island comprises early to middle Miocene volcanic to subvolcanic rocks of shoshonitic to calc-alkaline affinity (Pe-Piper and Piper 1993) that overlie the metamorphic Paleozoic-Mesozoic basement, which belongs to the Sakarya Zone of the Rhodope-Pontide Fragment (Pe-Piper *et al.*, 2001). The volcanic rocks occur in a series of stratovolcanoes, which extend SW–NE across the center of the island (Pe-Piper and Piper 1993). The early volcanism (~21.5 Ma) as calc-alkaline, while the main shoshonitic phase occurred from 17.3 to 18.4 Ma and was followed by minor calc-alkaline volcanism at about ~16.5 Ma based on K-Ar and Ar-Ar geochronology (whole rock, hornblende and biotite; Borsi *et al.*, 1972; Pe-Piper and Piper, 1993; Voudouris *et al.*, 2019b).

The Megala Therma-Katsilemonas deposit, in the northern part of the island, consists of NNE-, NNW, NE- and NW-trending epithermal quartz veins and stockworks, hosted in propylitic, to sericite-adularia altered trachyandesitic lavas (21-18 Ma) of the lower lava unit (Kontis *et al.*, 1994; Voudouris *et al.*, 2018, 2019b). The veins that are up to 5 m wide and up to hundreds m in length are crustified, colloform banded and brecciated (Fig. 1). Other textures such as cockade, drusy, comb and quartz pseudomorphs after bladed calcite, were observed. The total amount of sulfide minerals in veins does not exceed 10 vol%, with more sulfide-rich zones being locally developed. Gangue minerals include quartz (e.g., amethyst), chalcedony, carbonates, adularia, chlorite, barite and fluorite (Kontis *et al.*, 1994; Voudouris *et al.*, 2018). The ore assemblage comprises pyrite, marcasite, sphalerite, chalcopyrite, galena, tetrahedrite–tennantite, polybasite–pearceite, famatinite, argentite, native gold, electrum, and the telluride altaite. Paragenetic relationships indicate early deposition of pyrite, followed by sphalerite and chalcopyrite, and then by Ag-Te bearing phases, such as Sb-As-Cu sulfosalts, argentite and altaite, and finally by galena and native gold/electrum (Figs 1 and 2).

Ore mineralogy and mineral-chemistry

Pyrite forms euhedral to subhedral crystals, which contain small amounts of As (up to 0.96 wt%), Co (up to 0.44 wt%), and Au (up to 0.07 wt%). Sphalerite is characterized by chalcopyrite disease and contains minor Mn (up to 0.20 wt%) and Cd (up to 0.47 wt%). Iron reaches concentrations of up to 5.53 wt%, which corresponds to 10.43 mol% FeS. Chalcopyrite contains up to 0.10 wt% Au and up to 0.07 wt% Ag. Galena is the major ore phase at Megala Therma (Fig. 2). It includes Ag-bearing sulfides/sulfosalts, tellurides and native gold/electrum (Fig. 2). Galena is Ag-free, but contains up to 0.20 wt% Te, up to 0.36 wt% Bi, and up to 0.18 wt% Hg. A positive correlation between Bi and Te probably suggests the presence of submicroscopic bismuth-telluride inclusions in galena. Tellurium-Cu-bearing argentite forms small grains (up to 10 μm) hosted by galena Fig. 2a). Concentrations of up to 5.7 wt% Cu and up to 5.1 wt% Te were found (Table 1). Tellurium-bearing polybasite and pearceite are Ag-rich sulfosalts with the general formula $[(Ag,Cu)_6M_2S_7][Ag_9CuS_4]$ with M = Sb (i.e. polybasite) and As (i.e. perceite) (Bindi et al. 2007). A Te-rich variety of polybasite has also been reported from the Kalianou deposit, Evia island, Greece (Bindi *et al.*, 2013; Tombros *et al.*, 2021), where Te partially substitutes for S. At Megala Therma deposit polybasite-perceite solid solution forms small grains (up to 40 μm length and ~ 10 μm width) hosted in galena (Fig. 2b). The studied polybasite contains up to 4.12 wt% Te (up to 0.719 apfu), thus corresponding to at Te-rich polybasite, similar to the occurrence of Kallianou, which is the second occurrence in Greece (Table 1). Tetrahedrite group minerals are minor but ubiquitous constituents within the deposit. At Megala Therma, both tetrahedrite and tennantite occur, and are associated with galena and chalcopyrite (Fig. 2c). Silver-rich (up to 10.2 wt% Ag, Table 1) zincian tetrahedrite is present as subhedral grains inside galena, chalcopyrite and sometimes pyrite. Zincian tennantite occurs at the margins of galena crystals. Selenium, Te, Bi and Hg are below the detection limit in both tetrahedrite and tennantite. Altaite (PbTe) is present as small grains hosted in galena (Fig. 2d). Native gold and electrum are mainly found as isolated grains in gangue quartz (Kontis *et al.*, 1994) and/or as inclusions in galena (Figs 2e,f, this study). Silver substituting for Au ranges from 7.74 to 28.9 wt% (Table 1). Native gold and electrum contain up to 0.50 wt% Bi, and up to 0.05 wt% Hg. Most of the analyzed grains are electrum as they contain between 60 and 75 atomic % Au. Few native gold grains with ~90 atomic % Au occur disseminated in the gangue quartz.

Bulk Ore Analyses

Results of multi-element analyses for selected (n=14) samples indicate that the mineralization is enriched in the so-called epithermal suite of elements as follows: Bi up to 396 ppm, Co up to 320 ppm, Ag > 100 ppm, Se up to 80 ppm, Au up to 26 ppm, Te up to 7 ppm, Mo up to 8 ppm, and Pd up to 77 ppb. In addition, Pb reaches values > 1wt%, Zn up to 0.7 wt%, Cu up to 0.65 wt%, As up to 69 ppm, Sb up to 99 ppm, Ga up to 2.7 ppm, Sn up to 1.2 ppm, and Hg up to 155 ppb.

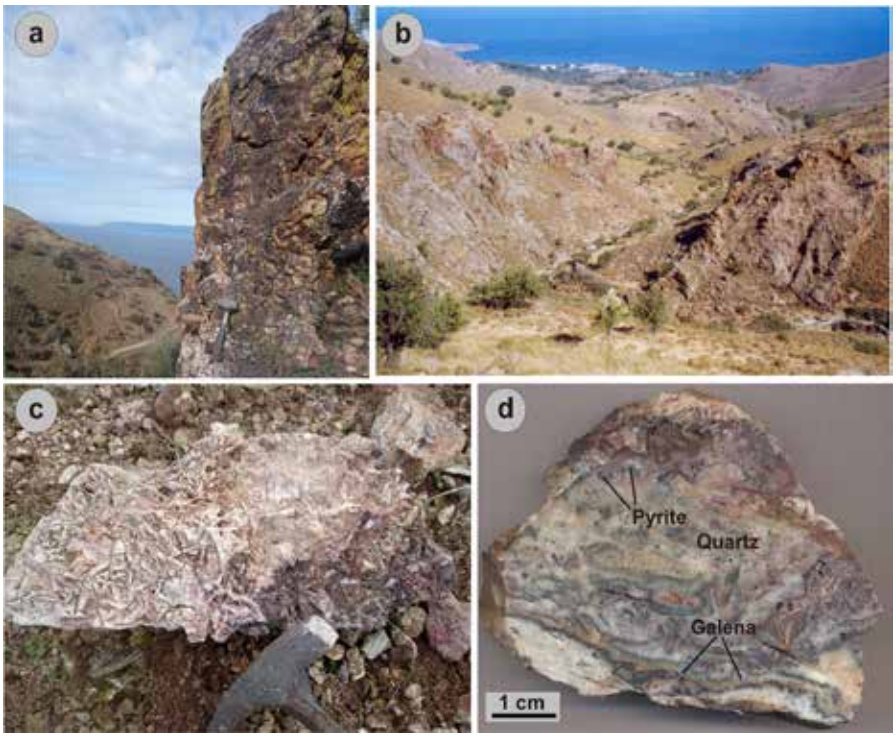

Figure 1. Field photographs (a,b) and hand specimens (c,d) from the Megala Therma-Katsilemonas mineralization. (a) Brecciated quartz vein crosscutting propylitic altered lavas at Megala Therma. Biga Peninsula is seen in the background; (b) Katsilemonas quartz-fluorite veins (view from S to N); (c) Quartz pseudomorph after bladed calcite at Megala Therma; (d) Crustiform/colloform banded quartz/chalcedony vein with minor galena from Megala Therma.

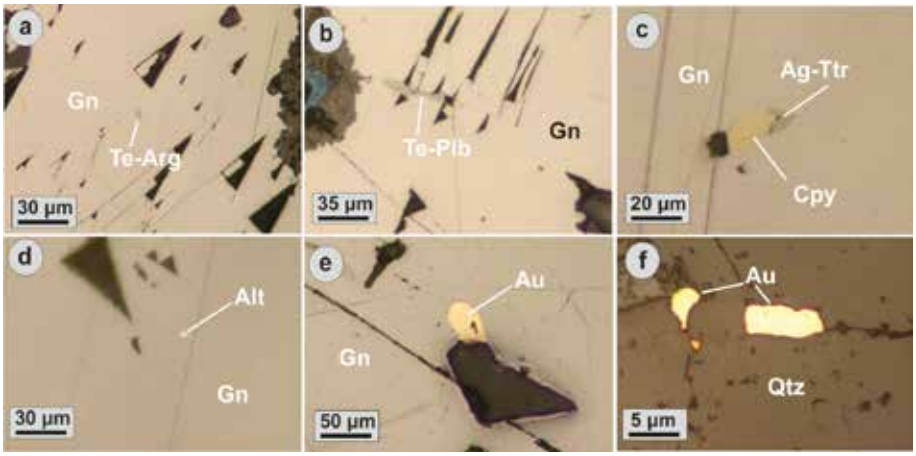

Figure 2. Photomicrographs (reflected light) showing Au, Ag and Te-bearing phases at Megala Therma deposit. (a) Te-bearing argentite (Te-Arg) included in galena (Gn); (b) Te-bearing polybasite (Te-Plb) included in galena; (c) Ag-bearing tetrahedrite-(Zn) included in galena and associated with chalcopyrite (Cpy); (d) Altaite (Alt) included in galena; (e) Native gold (Au) included in galena; (f) Native gold included in quartz (Qtz).

Discussion and Conclusions

The Megala Therma-Katsilemonas mineralization occurs at the northern flank of the Stypsi caldera, and resembles intermediate- to low-sulfidation quartz-calcite veins overprinting the Stypsi porphyry Cu-Mo±Re±Au mineralization, exposed about 5 km to south within the caldera (Voudouris and Alfieris, 2005; Voudouris *et al.*, 2019b). Previous fluid inclusion studies at Megala Therma indicated that the mineralization formed at temperatures between 244 and 315 ˚C by hydrothermal fluids of low salinity (<3.7 wt % eq. NaCl) (Kontis *et al.*, 1994; Vamvoukakis, 2009). These authors suggested boiling and fluid mixing as potential mechanisms for ore deposition. Voudouris et al. (2018) indicated for amethystine quartz-carbonate veins in the broader area that the homogenization temperatures range between 211 and 250 ˚C, with a mode at 230 ˚C. The salinity of the fluid inclusions in amethystine quartz range from 3.1 to 4.8 wt% NaCl equiv., according to previous results (i.e., Kontis *et al.*, 1994; Vamvoukakis, 2009). Here we used, the sulfide/sulfosalt and telluride mineralogy, the composition of sphalerite (1.1-10.5 mole% FeS), as well as the published fluid inclusion data, to determine fTe_2 and fS_2 values of the hydrothermal solutions in the Megala Therma prospect (Fig. 3). Telluride stabilities were calculated for an average temperature of 250 ˚C. For the tetrahedrite/tennantite-chalcopyrite assemblage, maximum $logfTe_2$ values can be defined by the calaverite-native gold boundary at about –9.1. The presence of native gold suggests that the $logfTe_2$ values did not exceed the calaverite-native gold boundary. The minimum $logfTe_2$ values can be defined by the hessite (Ag_2Te) - argentite (Ag_2S) boundary at about –15. The minor presence of altaite in galena, suggests that the mineralization also took place at conditions along the galena-altaite boundary at $logfTe_2$ values of about –10.5. The $logfS_2$ values calculated from sphalerite composition vary between –10.78 and –12.78 (Fig. 3).

The studied mineralization occurs in the western extension of the Biga and Bergama metallogenic districts, located in the northeastern sector of the Aegean extensional province (Sanchez *et al.*, 2016; Rabayol *et al.*, 2019). Continental extension in the Biga and Bergama areas resulted in E-W to NNW-SSE back-arc extensional sedimentary basins, and Miocene magmatism on Lesvos can be further traced eastwards to western Anatolia (e.g. southern Biga Peninsula and Menderes massif) (Yigit, 2012; Sánchez *et al.*, 2016). Although most porphyry and epithermal prospects in Biga are associated with Late Eocene-Oligocene magmatism (Yigit, 2012; Sanchez *et al.*, 2016), some low-sulfidation epithermal deposits (e.g. Kisacik, Küçükdere and Çoraklık Tepe, Karadere) are located within lower-middle Miocene volcanic rocks (Yilmaz *et al.*, 2007; Yigit, 2012; Oyman, 2019), similar in age to that of Megala Therma. In addition, the low-sulfidation epithermal Ovacik (Au-Ag) deposit, located in the Menderes massif on the mainland of Turkey to the west of Lesvos island is a quartz-carbonate vein system with mineralized E-trending and NW-trending veins hosted in Early Miocene (19.76 ± 0.14 Ma) andesites (Yilmaz *et al.*, 2007). Epithermal-style mineralization at Megala Therma cannot be classified as typical low-sulfidation mineralization, but rather as a low- to intermediate sulfidation transitional style, a feature also described from several Mexican deposits, where the low- and intermediate sulfidation veins coexist in an extensional environment (Camprubí and Albinson, 2007). These authors suggested that a process of progressive neutralization and/or sulfur consumption may result to low-sulfidation styles of mineralization as a natural evolutionary consequence of neutralizing intermediate-sulfidation-type fluids. According to Menant *et al.* (2018), the progressive north-south shift of the magmatic and hydrothermal activity in northeastern Aegean (i.e. Lesvos island) and western Anatolia was coeval with the southward migration of back-arc extension and the associated Kazdağ and Menderes metamorphic core complex exhumation.

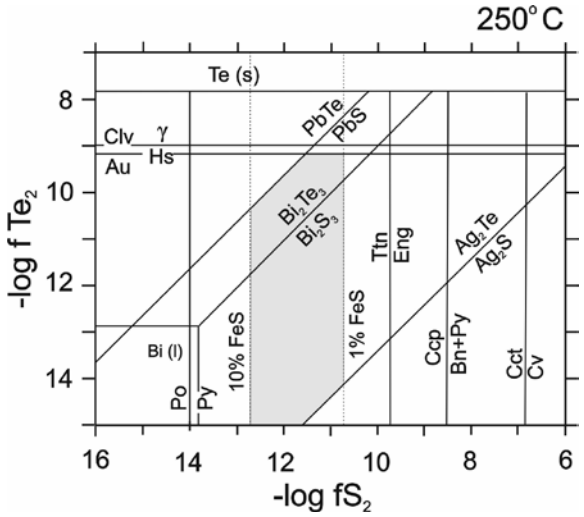

Figure 3. LogfTe_2-logfS_2 diagrams indicating equilibria between tellurides and sulfides at 250 °C. The shaded area indicates approximate conditions of gold deposition at Megala Therma, calculated from the composition of sphalerite and observed mineral assemblages. Thermodynamic data for sulfides and tellurides used for calculating fTe_2 and fS_2 were derived from Barton and Skinner (1979) and Afifi et al. (1988). Abbreviations: (Clv) calaverite, (Hs) hessite, (Tnt) tennantite, (En) enargite, (Ccp) chalcopyrite, (Bn) bornite, (Py) pyrite, (Po) pyrrhotite, (Cct) chalcocite, (Cv) covellite.

The Megala Therma-Katsilemonas deposit also shares some characteristics with alkalic-type epithermal gold deposits. These include the presence of fluorite and tellurides, and the elevated Pd content in the mineralization (Kelley and Spry, 2016; Kelley *et al.,* 2020). It is suggested that Megala Therma-Katsilemonas mineralization represents a transitional LS-IS Au-Ag-Pb-Cu mineralization with affinities to the alkalic-type epithermal Au deposits. Similarly, Fornadel et al. (2012); Kelley *et al.* (2020; Börner *et al.* (2022) characterized the Lower Miocene epithermal type Au-Te deposit in the Fakos area of Limnos Island as alkalic-type. This system consists of polymetallic quartz veins including tetrahedrite/tennantite, Au-Ag tellurides, altaite, native gold and electrum, similar to Megala Therma. However, also some calc-alkaline related mineralization with mineralogical characteristics of alkalic-type porphyry-epithermal systems exist. An example is the Oligocene Pagoni Rachi porphyry-epithermal deposit, which contains fluorite, Pd anomalies and abundant tellurides, in both porphyry and sub-epithermal ores (Voudouris *et al.*, 2013). Based on the less attention given to the alkalic-class of epithermal Au deposits in Greece, we emphasize here that Miocene magmatic belts in the Aegean domain are prospective for alkalic-type low-sulfidation precious and critical metal mineralization.

EXTENDED ABSTRACT 307

Source rock potentiality of the late Miocene sapropelic layers of Gavdos Island, Greece, based on geochemical and stratigraphic data

Telemenis D.[1,2], Bellas S.[2], Vavouranakis E.[1], Manoutsoglou E.[1]

Introduction / Background

The island of Gavdos is the southernmost part of Greece and at the same time represents the southernmost island of whole Europe. It is located in the eastern part of central Mediterranean Sea, south of the western Crete Island (Figure 1, left). It is rather considered a small island with an overall size of ca. 33 km^2. Based on the general geological framework, the island is directly connected to the subduction of the African lithospheric plate beneath the European one, precisely the Aegean microplate. It is placed right at the north of the Hellenic trench, that is developed due to the subduction, with a peculiar position, where the latter bends from a NNW-SSE to a NNE-SSW direction. Gavdos may have been related to the late N-S shortening that followed the N-S extension and graben formation and created the accretionary wedge of the Mediterranean ridge commencing by 11 Ma (Ring and Yngwe, 2018).

Mesozoic limestones, Eocene flysch, a few ophiolites (Sarakiniko Bay, located at the north-northwest) and Neogene to recent carbonate to clastic deposits build the island. The limestones occur at the south, southwestern part of the island, and are developing along a NNW-SSE direction, parallel to the general Hellenides trend of western Greece and Peloponnesus, while flysch is present in spot locations.

The Neogene unconformably overlies the pre-Neogene rocks and covers most of the central and northern part of the island, while a Pleistocenic marly limestone marine terrace (detailed literature review in Antonarakou, 2001; Tsaparas, 2005) and recent-subrecent aeolianites are among the youngest strata of the island. According to Anastasakis *et al.* (1995) in (Antonarakou, 2001), the Neogene deposits consist of two formations, namely these of Potamos and Metochia. Based on biostratigraphic data, Potamos Fm represents the oldest strata of Middle Serravallian to lower Tortonian age, while sedimentation in Metochia developed from the Middle/Lower Tortonian and ranged up to the Messinian (Triantaphyllou *et al.*, 1999) in (Antonarakou, 2001). The Metochia section was initially studied by (Postma *et al.*, 1993: Metochia-B), (Krijgsman *et al.,* 1995: Metochia-B/C) and (Postma and Ten Veen, 1999: Metochia-B/C). Based on the mostly regular alternations of brownish, organic rich layers and grey to blue hemipelagic marlstone, they first recognized consistent sedimentary cycling of late Miocene, and connected them to the Earth's orbit, and more precisely to the precession cycles, while by applying magnetostratigraphy they assigned an age of 9.642 Ma to the sections' basal strata. Initially, fifty-eight (58) such sapropelic layers (i.e. successive cycles) were distinguished in Metochia-B (56 in Krijgsman *et al.*, 1995), while additional forty (40) cycles were documented in Metochia-C, which represents the upper part of the section (Krijgsman *et al.,* 1995). Based on the later author's samples from the Metochia sections, Schenau *et al.* (1999) investigated the mechanism of formation for specific sapropelic layers, while Köhler *et al.* (2008) studied provenance changes of the material during the late Miocene The later authors concluded on changes a) from arid to more humid conditions (paleoclimatic) and b) from terrigenous input material to marine dominated (base to top of the section, respectively). By studying paleoflora from Gavdos locations of Tortonian age, Mantzouka *et al.* (2015) suggested that rather the paleogeographical setting than (paleo-)temperature changes affected the island during that time. Recently, Zachariasse and Lourens (2021), by studying the uppermost part of Metochia section (namely part D) concluded that the intercalated limestones are evaporitic, and that their formation onset is placed at 6.00 Ma, indicating abrupt sedimentation changes and a distinct rise in salinity, which in turn is connected to the MSC onset.

Objectives

By using Rock-Eval pyrolysis, this study focuses on the geochemical analysis of two sets of sapropelic layers from Gavdos Island (Figure 1, right): a) The first set correlates to the lowermost eight of those (L1-L8) described by Postma *et al.* (1993) and represents the lateral equivalent of the basal part of Metochia-B (compare Pyliotis *et al.*, 2013), and b) the second sampling set comes from the uppermost part of these sapropelic successions, located just below the sandstones of the MSC, which has never been geochemically studied up to now. The aim is to unravel the hydrocarbon generation potentiality of the late Miocene sapropelic deposits of the eastern Mediterranean, closing the gap between the basal (Tortonian) and the top sapropelic layers deposition (Messinian) of Gavdos and further to investigate the development of lateral continuity or differentiation of the geochemical properties of these strata relevant to gas prospectivity south and southwest of Crete, that is currently under way in two major offshore blocks southwest and south of Crete.

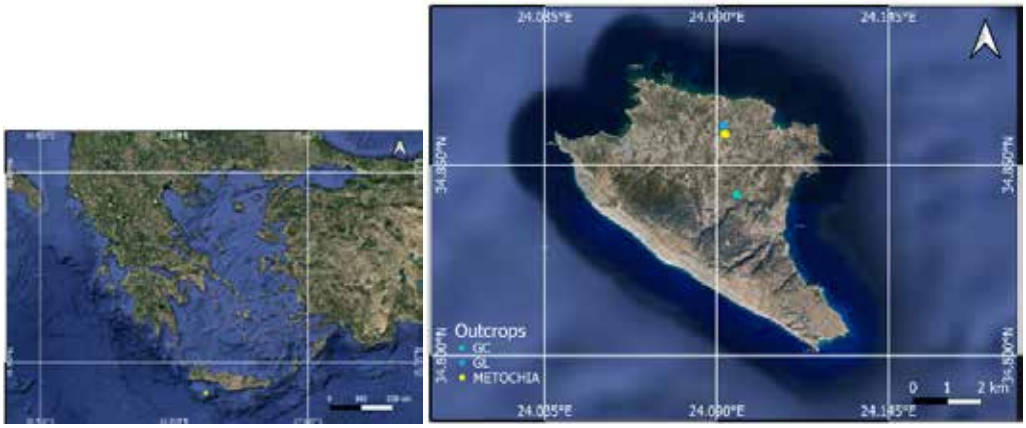

Figure 1. Gavdos Island with the investigated outcrops position.

Material and Methods

Two outcrops were investigated for this study. The first one is GL# outcrop and is located north of the main Metochia-B outcrop (Postma *et al.,* 1993). It consists of alternations of sapropelic layers and marlstones (silty mudstones) and specifically 8 levels/ intervals of sapropels (approximately 7 m thick). In the basal part of the outcrop, a 2.4 m marly sandstone prevails and underneath of it, a 1-m-thick, grey to green muddy siltstone (GL#1 and GL#2 samples) was monitored, with noticing oxidations occasionally. As we proceed to the uppermost levels, thick sandstones (over 5 m) close the section. Regarding the second section, which is named GC#, it is situated south-east from Metochia section near the buildings of University of Crete. The total thickness of the outcrop is almost 16.5 m. Its bottom part (GC#0 sample) is a few meters eastern from the main body of the section and is considered as its base. Furthermore, a 12-m-thick section with similar alternations of sapropelic levels and marls is observed. The main issue in this section is the presence of oxidation levels in some of the intervals, which renders the distinction of the lithologies more difficult. Proceeding to the top part, bioclastic sandstones over 2.5 m thick close the outcrop.

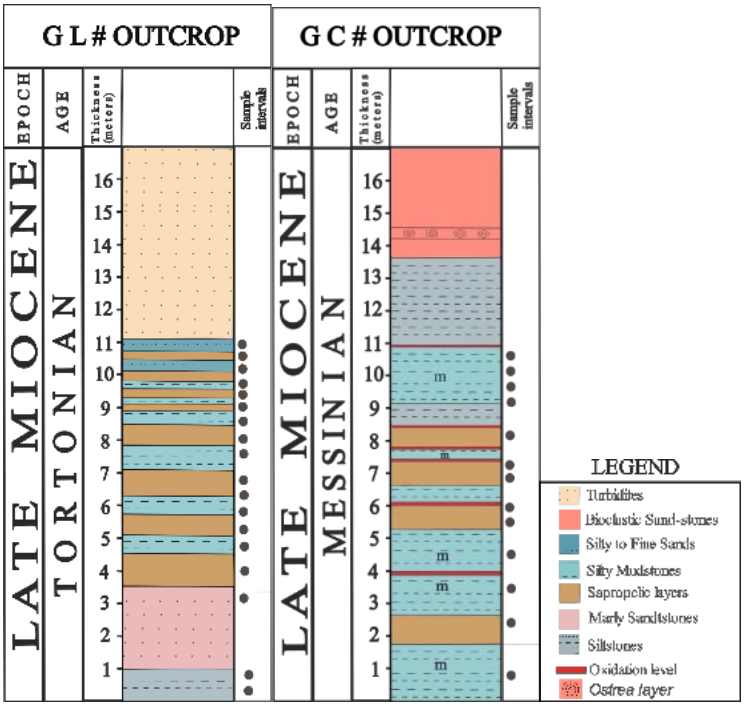

Figure 2. Lithostratigraphy of the studied GL and GC outcrops from Gavdos Island.

Bulk sampling was carried out in both outcrops. The total number of samples is fifty-nine (59). Thirty-five (35) come from the GL# outcrop and twenty-four (24) from the GC# outcrop. Both sapropelic layers and marlstones (mudstones, siltstones etc.) were collected. Rock-Eval pyrolysis was conducted to those samples, utilizing a Rock-Eval VI® (RE6) anhydrous open system pyrolyzer (Vinci Technologies; Lafargue *et al.,*1998) following the standard organic matter (OM) analysis setup (Behar *et al.*, 2001).

Samples, finely ground (<250 μm or 60 mesh) and dried at 60°C (overnight drying), were subjected to sequential pyrolysis and oxidation (Espitalie *et al.,* 1984). Various authors have provided analytical details of the RE VI methodology and interpretations of the resultant data (Behar *et al.,* 2001; Lafargue *et al.,* 1998, and other researchers). The volatile hydrocarbons produced were identified and quantified using a flame ionization detector (FID). Pyrolysis was conducted isothermally, commencing at 300 ◦C and escalating with a gradient of 25 ◦C/min until reaching a peak of 650 ◦C. Subsequent to pyrolysis, oxidation was performed from 300 to 850 ◦C at a heating rate of 20 ◦C/min. Consequently, key parameters such as S1 (mg HC/g rock), S2 (mg HC/g rock), S3 (mgCO_2/g rock), Tmax (◦C), TOC [(total organic carbon content) (%wt)], Hydrogen Index [(HI) (mg HC/g TOC)], and Oxygen Index [(OI) (mgCO_2/g TOC)] were determined (Espitalie *et al.*, 1984; Lafargue *et al.*, 1998). The evaluation of the data relied upon the studies by Tissot and Welte, (1984) and other researchers.

Results and Discussion

Based on the Rock-Eval pyrolysis data (RE-VI), all important parameters that measured and calculated, such as TOC, S2, HI and OI are presented in Figures 3 and 4 (for the studied outcrops GL# and GC#, respectively), from bottom to the top, according to the stratigraphic development of the deposits from older to younger.

A. GL# outcrop (lateral equivalent to the lower part of Metochia-B).
   The TOC content of the sapropelic layers fluctuates from 0.06%wt (GL#8b) up to 0.5%wt (GL#14). The rest lithologies' samples (silty mudstones, siltstones and sandstones) provide similar TOC results with a minimum of 0.03%wt (GL#5) and a maximum of 0.44%wt (GL#9). The average TOC content of this studied section is 0.24%wt with maximum S2 value of 0.52 mg HC/g rock at the basal samples. Additionally, the HI and OI values range between 0-130 mg HC/g TOC and 133-917 mg CO_2/g TOC.
B. GC# outcrop (uppermost part of Metochia-C).
   The TOC content varies from 0.13%wt (GC#7) to 0.43%wt (GC#4b) with an average value of 0.28%wt for the whole studied section. The HI and OI values found to range between 6-115mg HC/g TOC and 365- >1000 mg CO_2/g TOC.

Considering all above values distribution for both studied outcrops of the late Miocene (Tortonian and Messinian) of Gavdos Island, it can be concluded that they are indicative of a rather poor to fair H/C potential generation.

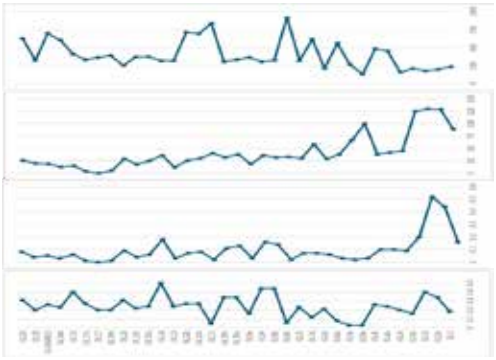

Figure 3. GL# outcrop; Vertical distribution of the main Rock-Eval VI parameters that have been recorded. Shaded intervals correspond to the sampled sapropelic layers.

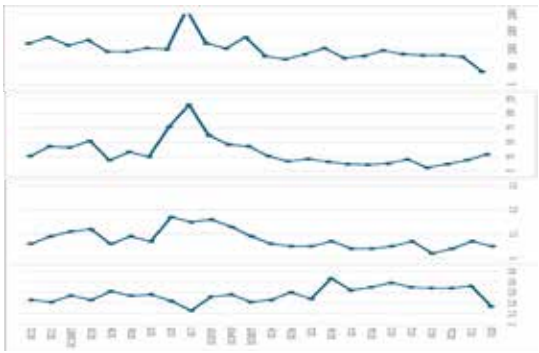

Figure 4. GC# outcrop; Vertical distribution of the main Rock-Eval VI parameters that have been recorded. Shaded intervals correspond to the sampling positions of the sapropelic layers.

Following the laboratory analysis and based on all RE-VI pyrolysis data, and in order to evaluate the maturity and hydrocarbon potentiality of the samples, a number of XY-diagrams were created, where all values obtained have been plotted. In the present work only two of them are presented, namely a) the HI vs Tmax diagram and b) the TOC (log) vs S2 (log) diagram.
The first one (Fig. 5, left), is representative of the kerogen types of the analyzed samples. As it is clearly shown, the majority of the plotted samples' values reveal a Type IV kerogen, while a small amount of them tends to a Type III kerogen and a possible gas-prone source rock.
The second diagram (Fig. 5, right) indicates the hydrocarbon generation potential of the rocks. All values are plotted in the lower left quadrate of the diagram, therefore, as we mentioned before, the analyzed samples exhibited a poor to fair H/C potential generation for both outcrops. A slightly poorer indication is apparent for the GC#, which represents the Messinian samples, where a number of oxidized layers occurred at various stratigraphic levels (Fig. 2: GC#). Despite the careful sampling procedure, being conducted to minimize the effects of weathering and oxidation, it is highly likely that the analyzed samples could display more favorable organic geochemical signatures.

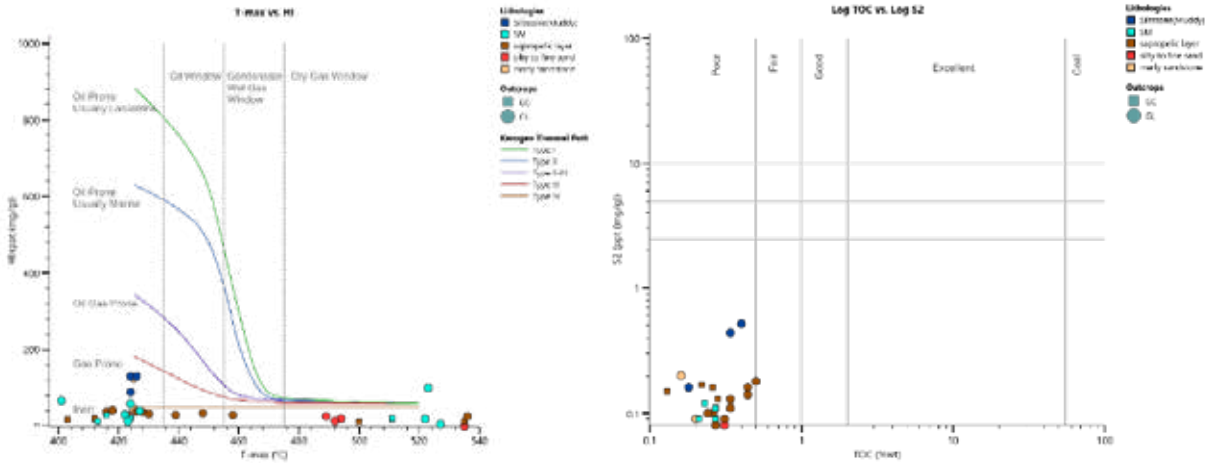

Figure 5. At the left: HI (mg HC/g TOC) versus Tmax (°T) showing idealized kerogen types and thermal maturity of the studied samples and (at the right) Logarithmic plot of TOC (%wt.) versus S2 (mg HC/g rock) illustrating the source-rock potential. As in the legend, squares represent samples of the GC# outcrop, while circles the GL#.

This study completes previous research for the organic-rich layers of Metochia [(Schenau *et al.*, 1999); who studied particularly three sapropelic layers of the basal section: L5-L7], the source rock potentiality of Gavdos (Pyliotis *et al.*, 2013), as well as the review work for the organic geochemistry signature of various Crete Neogene sediments of (Maravelis *et al.,* 2022) by contributing additional data to compare the geochemical analysis of the Gavdos Metochia-B lower part section with its lateral equivalent (GL#). The first set of samples of the present work (GL#), represents the sapropelic/mudstones interval that stratigraphically is situated below the turbiditic sequence (Krijgsman *et al.*, 1995). Furthermore, by extending this type of analysis to locations that have not yet undergone geochemical investigation (Metochia-C), the gap with the analysis of samples from the GC# outcrop is closed. The latter appears to correlate with the upper cycles of the Metochia-C section (M92-M96) as an equivalent. Gaining a comprehensive understanding of the entire area through its stratigraphic evolution is crucial for its paleogeographic development prior to the Messinian Salinity Crisis, and at the same time for the hydrocarbons exploration that is currently underway.

Conclusions

A geochemical analysis has been conducted on samples obtained from outrcrops on Gavdos Island to reveal new potential source rocks. Fifty-nine samples of two outcrops (GL# and GC#) have been studied by using RE-VI pyrolysis. These samples included mainly sets of sapropelic layers and mustones/siltstones alternations. GL# samples are of Tortonian age, while GC# samples are of Messinian age (Metochia-C, upper part).

1) The RE-VI results have shown that hydrocarbons generation potential varies from poor to fair in both studied outcrops.
2) The lateral equivalent GL# outcrop (to Metochia-B, basal part, cycles L1-L7/L8) provided lower values in relation to data from previous authors, indicating that the outcrop was located at a more marginal sector of the sedimentary basin.

3) Samples of the GC# outcrop, proved of poor H/C potential generation, indicating that locally, the productivity was rather decreased approaching the onset of the Messinian Salinity Crisis (MSC).
4) By studying these two outcrops, a research "gap" is partially covered, particularly in relation to the Messinian record (GC# outcrop samples). However, more analyses need to be conducted to get a better and more detailed understanding of the maturation of these rocks under proper burial conditions.
5) These analyses and their findings have enriched the hydrocarbon map of the Eastern Mediterranean and made an additional contribution to the energy sector, which should expect enhanced results moving to the offshore area, due to better organic matter preservation.

Acknowledgements
Financial support was partly provided by the HelleniQ Energy (Upstream Sector), through a project assignment to Dr. S. Bellas (PI). N. Pasadakis (Professor of TUC) is acknowledged for his support throughout the work, while providing older samples and raw geochemical data for correlation to present ones.

Introduction

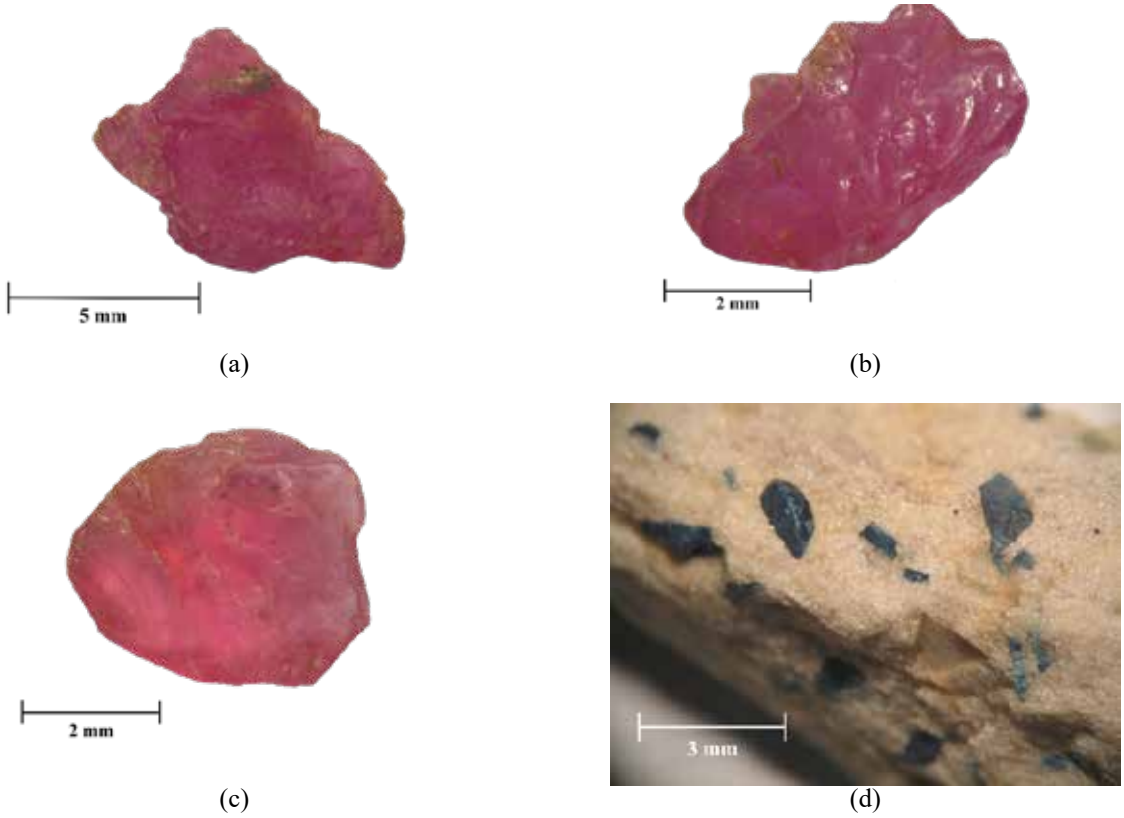
This study focuses on the mineralogical and chemical characterization of four unknown samples from the Mineralogical and Petrological Museum in School of Geology at Aristotle University of Thessaloniki. According to the museum's records, three samples with pinkish red color are referred as rubies, while the fourth, which exhibits a blue color, is classified as a blue sapphire; both primary gem varieties of corundum (Al_2O_3). The most significant chromophore of corundum is Cr^{3+} and Fe^{2+}-Ti^{4+} intervalence charge transfer pair is responsible for the blue color in blue sapphire (Fritsch & Rossman 1988; Dubinsky et al., 2020). In gemology, corundum holds a prominent position due to its exceptional optical and physical properties, making it highly valued in the jewelry industry. For this reason, many corundum crystals undergo heat treatment to enhance their color and transparency (Nassau, 1981). Additionally, synthetic rubies and sapphires are produced using various methods, including the Verneuil process, the flux growth method, and the Czochralski method. The identification of corundum, including its treatments and whether it is natural or synthetic, requires specialized gemological techniques. such as UV fluorescence analysis and microscopic examination of inclusions (Hughes et al., 1997).

For the analysis of these samples, mineralogical techniques were utilized, including Scanning Electron Microscopy (SEM), Energy Dispersive X-ray Fluorescence spectroscopy (EDXRF) along with Visible-Near Infrared (Vis-NIR), Raman and Photoluminescence (PL) spectroscopies. The aim of this study is to highlight the significance of non-destructive minerals and gemstones analyses with museum and collector value, ensuring their precise scientific documentation and mineralogical characterization.

Materials & Methods

For this study 4 samples (Fig. 1) from the Mineralogical – Petrological Museum of AUTh were studied with advanced spectroscopic and analytical methods. Raman and Photoluminescence (PL) spectra were obtained by using a micro-Raman Renishaw inVia spectrometer, coupled with an optical microscope and with a 514 nm laser excitation (diode-pumped solid-state laser). Raman spectra from 100 to 2000 cm^{-1} region were obtained with 10 accumulation and 15 s exposure time with laser power at 100%. PL spectra (520–900 nm) were acquired with 10 s of exposure time, 1 accumulation and 0.1% laser power. A diamond was used for the calibration of the Raman spectrometer by considering its 1331.8 cm^{-1} Raman peak. For the Visible-Near Infrared (Vis-NIR) spectra (from 400 to 1000 nm), a mobile spectrometer was used, equipped with an integrating sphere, and with an acquisition time of 0.05–0.50 s and 20 accumulations. Raman and Vis-NIR experiments were conducted in the Laboratoire Français de Gemmologie (LFG).

The chemical analyses were conducted using a Scanning Electron Microscope (SEM). In order to obtain conductivity, the samples were carbon coated. The scanning electron microscope is equipped with an Energy Dispersive Spectrometer (EDS), specifically a JEOL JSM-6390LV (Tokyo, Japan) and using an EDXRF, model S4-Pioneer (Bruker-AMS, Germany), at the Interdepartmental Laboratory of the School of Sciences at Aristotle University of Thessaloniki (AUTh). For the optical observation of the samples a ZEISS Stemi 2000-C microscope was used and reaction under 3 W longwave ultraviolet (LWUV) emitting at 365 nm.



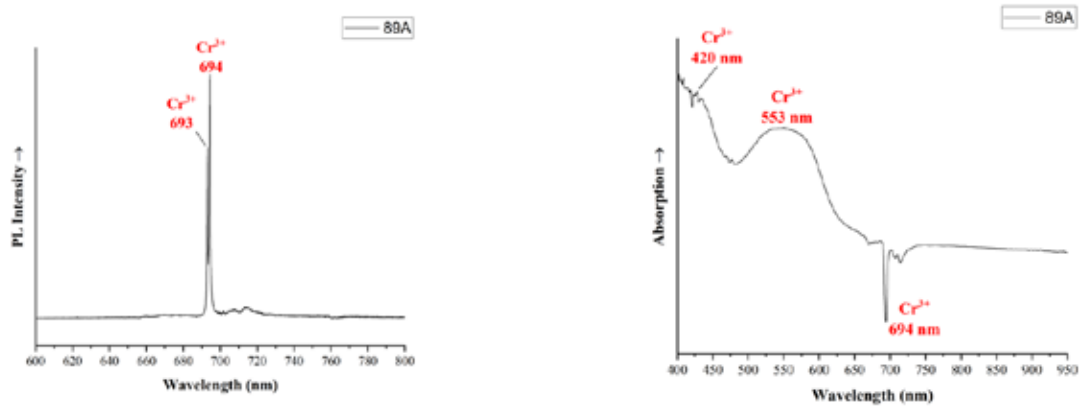


Figure 1: Macroscopic pictures of the studied samples. (a) 89A, (b) 89B, (c) 89C, (d) 89D.

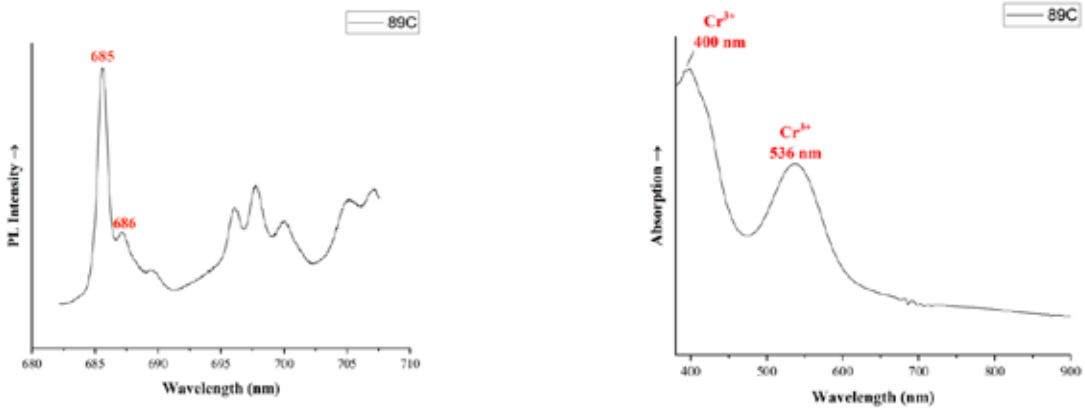
Results

All samples were tested under a UV-lamp (3 Watt) of 365 nm. The 89A and 89B samples presented red fluorescence of medium intensity. The rest samples were inert under UV light. Both 89A and 89B samples presented similar spectroscopic and chemical results. PL spectra exhibit absorption peaks at 693 and 694 nm, (Fig.2a) which are characteristic to the presence of chromium ions (Cr^{+3}) in corundum (Hughes et al., 1997). These peaks are related to the red color in ruby. Vis-NIR spectra revealed characteristic absorption peaks of chromium at around 420 and 550 nm Additionally, they exhibit a characteristic negative chromium peak at 694 nm in the Vis-NIR spectra (Emmett et al., 2017) confirming that both 89A and 89B samples can be determined as rubies (Fig.2b). Under optical microscope, the samples present a foggy appearance due to numerous particles; no indication of treatment is observed.



In the case of the 89C sample, the PL spectra (Fig. 3a) presents a main peak at 685 nm and a lower peak at 686 nm which are characteristic of Cr^{3+} impurities in spinel structure and responsible for its red color (Fritsch & Rossman, 1987). The examined spinel also exhibits characteristic Cr^{3+} absorption bands at 392, 415, and 538 nm in the visible absorption spectrum (Chankhantha et al., 2020). Absorption spectra in the Visible-Near Infrared region recorded two Cr^{3+} absorption peaks at 400 nm and 536 nm respectively, which are also the characteristic to red spinel (Bootkul et al., 2016; Chankhantha et al., 2020; Zhang et al., 2023) The position and the width (FWHM) of the main PL bands at 695 – 700 nm confirm that the studied spinel sample is unheated (Widmer et al., 2015; Bootkul et al., 2016). Under optical microscope numerous inclusions are observed.

Raman spectroscopy was performed only for the 89D sample because neither Vis-NIR spectroscopy nor PL spectroscopy provided a clear result. The sample 89D exhibited one peak at 413 cm^{-1} due to H_2PO_4 bending modes and two large peaks at 1030 and 1060 cm^{-1} attributed to PO stretching vibrations (Fig. 4). According to Frost et al. (2013), the Raman the above peaks are related to the mineral lazulite. Lazulite is a mineral with a deep blue color and the chemical composition $(Mg, Fe)Al_2(PO_4)_2 \cdot (OH)_2$. The blue color is related to its chemical composition, and it is not attributed to any chromophore such as in the case of blue sapphire (Frost et al., 2013).

Figure 3: Representative spectra of the 89C sample. (a) Photoluminescence (PL) spectra, (b) Vis-NIR absorption spectra.

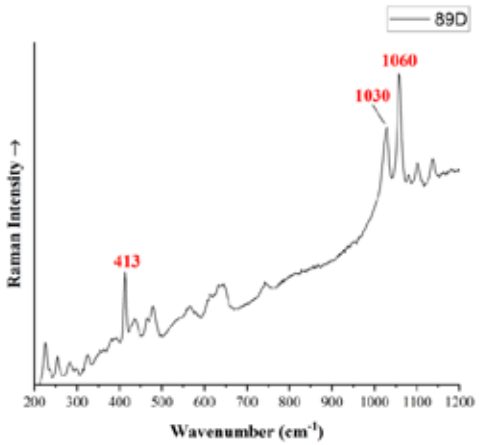

Figure 4: Raman absorption spectra of the 89D sample.

In the Scanning Electron Microscope (SEM), samples 89A, 89B, 89C, and 89D exhibited the results shown respectively in Table 1, Table 2 and Table 3. It is observed that samples 89A and 89B exhibit similar results. Both samples have an average Al_2O_3 content of 97.41 wt.% and 96.18 wt.%, respectively, a composition consistent with corundum. In both samples, the presence of Cr□O□, V□O_5, FeO, and TiO□ were confirmed, with average concentrations below 1 wt.%, Additionally, the chemical composition of the ruby samples is presented in Table 1.

Table 1: Results of microanalyses on samples 89A and 89B.

Oxides (wt.%)	89A			89B			
	Spot 1	Spot 2	Spot 3	Spot 1	Spot 2	Spot 3	Spot 4
Al_2O_3	99.23	98.66	99,06	99.28	99.43	99.64	99.64

Total	100	100	100	100	100	100	100
bdl: below detection limits							

In contrast, sample 89C shows a variation in the results. The Al_2O_3 content ranges from 61.79 to 70.04 wt.%, MgO from 24.65 to 28.01 wt.%, while FeO varies between 0.37 and 1.84 wt.%, Additionally, the chemical formula of the sample 89C is presented with distribution based on 4 O ions in Table 2.

Table 2: Results of microanalyses of sample 89Γ (in weight %) and calculation of the chemical formula of spinel based on 4 O ions.

Oxides (wt.%)	1	2	3	4	5	6	7

Total	2.983	2.999	3.003	3.014	2.996	2.971	2.998

Finally, sample 89D exhibits high concentrations of P_2O_5 (46.28 - 46.48 wt.%) and Al_2O_3 content (from 33.15 to 33.78 wt.%), with lower contents of MgO (from 11.09 to 11.94 wt.%), and FeO (from 3.02 to 3.71 wt.%). The chemical analysis does not point to a sapphire but rather to another mineral that was considered as such. Additionally, the chemical formula of the sample 89C is presented with distribution based on 2 P ions (Table 3).

Table 3: Results of microanalyses of sample 89D (in weight %) and calculation of the chemical formula of lazulite based on 2 P ions.

Oxides (% wt.)	1	2	3	4	5	6	7

Mg/(Mg+Fe)	0.889	0.935	0.872	0.877	0.846	0.839	0.844

XRF analyses of the samples 89A and 89B showed concentrations of Cr_2O_3 from 0.34 wt.% to 0.85 wt.%, FeO from 0.21 wt.% to 0.72 wt.%, and Ga_2O_3 at around 0.04 wt.% for both samples. The sample 89C revealed Al_2O_3 at around 67.40 wt.%, Cr_2O_3 at 1.72 wt.% and FeO at 0.59 wt.%. The 89D sample was not examined by the XRF method due to its small size. Based on observations with optical microscope, as well as both SEM-EDS and XRF results, the studied ruby samples contain V and Ga impurities revealing their natural origin in contrast to synthetic rubies which do not contain measurable amounts of these trace elements (Muhlmeister et al., 1998; Dele et al., 1997). They also contain relatively high amounts of Fe (over 300 ppm). Therefore, they can be characterized as high-iron rubies (Palke et al., 2019) probably originating from amphibolite or basalt related rocks. Main high-iron ruby deposits can be found in Cambodia, Thailand, Madagascar and Mozambique as well as Sri Lanka for pink to pinkish-red samples.

Conclusions

This study utilized a combination of spectroscopic and analytical techniques to characterize four gem samples from the Mineralogical - Petrological Museum of Aristotle University of Thessaloniki. The samples provided valuable insights into their mineralogical composition and gemological properties. Samples 89A and 89B were confirmed as natural rubies, based on their high Al_2O_3 content (over 97 wt.%) and the presence of Cr_2O_3 (<1 wt.%), responsible for their red coloration. Their PL and Vis-NIR spectra exhibited the characteristic chromium bands which further support their classification. The presence of V and Ga impurities, detected through SEM-EDS and XRF analyses, indicates their natural origin and distinguishes them from synthetic counterparts. Sample 89C, initially presumed to be a ruby, was identified as a red spinel. Its high MgO and Al_2O_3 are inconsistent with corundum but align with the composition of spinel. PL and Vis-NIR spectroscopy revealed absorption peaks at 400 nm and 536 nm, characteristic of natural, untreated red spinel. These findings underscore the importance of advanced spectroscopic techniques in accurately distinguishing between visually similar gemstones.

Sample 89D, initially classified as a blue sapphire, was determined to be lazulite. Its high P_2O_5 content and Raman absorption peaks at 413 cm^{-1} and 1060 cm^{-1} confirmed this identification. Unlike blue sapphire, whose coloration is attributed to chromophore elements like Fe^{2+} and Ti^{4+}, lazulite derives its blue color from its intrinsic chemical composition. These findings highlight the critical role of multi-technique analytical approaches in gemstone identification.

Acknowledgements

The authors wish to thank Laboratoire Français de Gemmologie (LFG) for providing the micro-Raman and Vis- NIR spectrometers for this study.

Climatic Variability and Wind Pattern Shifts in Alexandria: Twenty Years of Data to Guide Coastal Resilience in Northern Egypt

Tonbol K.M.[1],

(1) Arab Academy for Science, Technology & Maritime Transport (AASTMT), ktonbol@aast.edu

For the monitoring of the climate and assessing the risks related to the coast in port cities, it is important to track the meteorological variability over longer time periods.

This research examines the weather patterns of Alexandria in Egypt by using twenty years of observational data (2007-2025) from weather stations located around Alexandria Port. The main variables studied are: temperature, wind speed and direction, humidity, precipitation, and atmospheric pressure.

The work has shown that by applying the methods of statistical trend analysis and seasonal decomposition, there are significant changes in the climatic characteristics of Alexandria such as the growth of the mean annual temperature. Of particular concern is the shift in the seasonal wind circulation. The findings also confirm the Eastern Mediterranean climate change projections, which increases the concern about the coast's climate vulnerability. This study does not analyze the operational data from the ports; however, it's motivated by the need for continuous local meteorological observations in support of port climate adaptation strategies in maritime regions. These observations are essential for urban designers, climate change researchers, and decision-makers to strengthen the policies and frameworks aimed at developing warning networks for coastal infrastructure in the northern coastal region of Egypt.

The effect of microorganisms in the fossilization of skeletal material

Toska A.[1], Stathopoulou E.[2]
(1) School of Geology, Aristotle University of Thessaloniki, 54124, Thessaloniki, Greece, aris_toska@outlook.com
(2) Department of Geology & Geoenvironment, National and Kapodistrian University of Athens, Athens, Greece.

Research Highlights

Secondary bone microstructures are identified and correlated with specific microorganisms (bacteria, cyanobacteria, fungi, etc.).

The presence of these micro-organisms are correlated to specific geochemical conditions and specific environments of activity (terrestrial or aquatic).

Introduction / Background

Microorganisms play a profound role in bone diagenesis, affecting the preservation, mineralization, and structural integrity of fossilized remains across various environments (Jans *et al*., 2004). The action of microorganisms in bones, referred to as microbial activity or MFD (microbial focal destruction) influences the survival of bone through time and causes collagen hydrolysis, deterioration of bone microstructure and an increase of macroporosity. It is believed that bacteria follow the orientation of the collagen fibres and exploit planes of weakness in bones e.g. fractures, breakages (Turner-Walker, 2008), while the different sizes and morphologies of microbial activity, are the result of one or more, closely related species of bacteria and their interaction with bone microarchitecture and the local hydrologic flow (Kendall *et al*., 2018). MFD is controlled by the local physicochemical conditions of the burial microenvironment (Hackett, 1981; Turner-Walker, 2008). Cyanobacteria occur in aquatic environments, both marine and freshwater, including lacustrine and waterlogged sediments (Kendall *et al.*, 2018).

On the other hand, the possibility that microbes themselves may be mineralized and thus preserved through geological time has also been reported, often in detail with surface ornamentation, including spines, substrate mycelia and aerial hyphae appearing in or close to their original growth positions (Jones, 2009).

Objective

This study concerns the geobiological dimension of the influence of microorganisms on skeletal elements in relation to the fossilization/conservation environment. Our first aim is the identification of microstructures and their correlation with specific microorganisms (bacteria, cyanobacteria, fungi, etc.). The second aim is to correlate the presence of micro-organisms to specific geochemical conditions and to specific environment of activity (terrestrial or aquatic). However, it is also important to determine the exogenous or endogenous origin of microorganisms.

Materials

The skeletal material studied, comes from the prehistoric settlement of Dispilio (on the southern shore of Lake Orestias, in Kastoria, Northern Greece), the only lake settlement in Greece to have undergone systematic investigation (Hourmouziadis, 2002).

The samples were selected to cover the different microenvironments of the site. Some excavation squares are in purely terrestrial zones, while others are in aquatic environments. Another criterion was the origin of the bone fragments (mammals/fish). A total of 28 fish bone samples and 16 mammal bone samples were chosen for this study. Additionally, the color of the samples played an important role, with both light-colored and dark-colored bones being carefully studied. According to Stathopoulou *et al.,* (2013) the bone samples at the site can be classified based on their discoloration into 7 color types, from red dark (1) to yellow (7). The bones selected belong to colour groups 3, 5 and 6,7.

Methodology

To study the bone tissue histology of the selected samples, small compact bone fragments from all specimens were manually extracted, mounted on stubs using conductive carbon cement, and coated with Au-Pd. They were then examined using a JEOL JSM – 6390 Scanning Electron Microscope.

Results-Conclusions

The bone microstructure of our samples does not seem to have been heavily affected. The histological structural features that characterize mammal and fish bone are well preserved in most samples. Their observation under the

SEM indicated restricted microbial activity. Only three mammal samples suggested possible MFD, at a very initial stage. Also, only six of the fish bone samples exhibited MFD, recognized as spongiform porosity with a diameter of micropores of around 1 μm. Bone was found to be affected around the vascular canals and along the periosteal/outer margins. In some cases, though microbial activity expanded towards the inner surface. In most cases the affected areas were surrounded by a halo which delineated them from healthy bone surface and filled the space between the micropores. This halo appears bright under the BSE mode and is associated with the dissolution and reprecipitation of Hydroxylapatite (Hap). It is worth mentioning that we also observed such local hypermineralized areas without the co-presence of micropores.

The fact that most of the studied bones did not exhibit MFD means that they were probably preserved in conditions that did not allow for such an activity throughout their diagenetic history. Microbial activity was detected mainly in fish bones. Fish bone is characterized by a higher macroporosity, a lack of mineralization and less tightly packed collagen fibrils. This may provide additional opportunities for microbial degradation of bone.

This type of microstructural destruction can be attributed to the action of bacteria (Jackes et al., 2001). Bacterial activity in our samples is very restricted and seems to have stopped before it could develop more extensively. The latter could mean that these samples were initially buried under geochemical conditions that allowed for such activity (relatively humid aerobic terrestrial environments with high temperature and a pH: 4–9) but an undetermined event led to the modification of the conditions of the burial site. From then on, a low–temperature and/or anoxic local burial microenvironment can be deduced (Child et al., 1993). Bacteria seem to prefer open-air environments and do not affect sites that are constantly under water or in a very wet/extremely dry environment. A possible change from an open-air site to a waterlogged site for example, could explain the above. Or a change of geochemical conditions due to climatic fluctuations. Anoxic (oxygen-deprived) burial conditions can significantly slow down or halt the process of bodily putrefaction and are consistently noted for preventing bacterial bioerosion in bone microstructures (Hollund et al, 2012).

On the other hand, meandering tunnels with a diameter of about 10–15 μm along the outer surface of the bone were observed in a sample. In addition, some of these tunnels were found to host spherical grains whose semi-quantitative analysis did not show a differentiation from the analysis of the surrounding surface of unaffected bone. These can be attributed to cyanobacteria, that create tunnels that do not align with the bone's micro-architecture and show ragged, branched tunnels, differing from terrestrial bacterial degradation (Davis, 1997). Cyanobacteria, found in tidal or estuarine deposits, exhibit a different attack pattern, moving from the periosteal surface inward.

Alongside organisms such as fungi, green and red algae, and sponges, cyanobacteria are also known to exhibit a euendolithic lifestyle, meaning they penetrate and live within substrates like rocks (Gleason *et al.,* 2017). In this study we managed to observe such structures that are most likely made by cyanobacteria and euendolithic microorganisms such as actinobacteria.

In many of our samples, both mammal and fish, the presence of microbes themselves were observed. The question is whether these microbes have been mineralized and thus preserved through geological time or if they have developed recently due to storage conditions of the skeletal material. Evidence of their occurrence includes substrate mycelia and aerial hyphae appearing in or close to their original growth positions, microbial mats, spores and chains often in detail with surface ornamentation such as spines etc. Various morphotypes of each category were observed. It appears that most of these occurrences can be attributed to Actinobacteria, which are filamentous Gram-positive bacteria, classified within the phylum Actinobacteria and the order Actinomycetales (Segaran *et al*., 2017). They are predominantly aerobic, but some are facultative anaerobes or obligate anaerobes. These bacteria produce mycelium and often reproduce by sporulation, resembling filamentous fungi in this aspect.

In many of our samples, various purely aquatic species of diatoms were also observed, often in large numbers, indicating that the specific bone samples have at some time been deposited in the lake.

Clearly, the taphonomic pathway followed by the samples is largely reflected in the findings observed through the electron microscope. The structures and microorganisms identified can be correlated with the environment in which they were found. For example, the presence of microstructures from cyanobacteria indicates the bones' residence in an aquatic environment, at a depth and clarity that allows photosynthesis. Equally significant is the presence of diatoms, which could be associated with a longer residence in a deeper environment as well as an extended period of time for the samples. All the above is considered in relation to the archaeological context of the site and the characteristic features of the different parts (terrestrial and waterlogged). The discolouration of the skeletal material by Mn and Fe can also be correlated to the microbial activity, but also to the post depositional organic environment that enhances the discolouration as well as the migration of Mn to the bones (Marin Arroyo *et al.,* 2008).

Ecuadorian candidates for the World Natural Heritage List - The Triple Volcano and Tayos caves

Theofilos Toulkeridis[1,2], Aaron Addison[3], Silviu Constantin[4], Grace Tatiana Páez-Barrera[5]
(1) Aristotle University of Thessaloniki, Thessaloniki, Greece (2) Universidad UDET, Quito Ecuador (3) Fellow Cave Research Foundation, Fellow National Speleological Society, Fellow Explorer's Club, USA (4) "Emil Racoviţă" Institute of Speleology, Dept. of Geospeleology and Paleontology, Frumoasă 31, Bucharest, Romania (5) Universidad de las Fuerzas Armadas ESPE, Sangolquí, Ecuador

Research Highlights

Two significant subterranean environments in Ecuador have been chosen as proposed candidates for the UNESCO World Heritage List. These are the Tayos cave in the Amazonian basin, and the Triple Volcano Cave in the Galapagos, because both sites represent a unique beauty and meet several criteria of the UNESCO conditions to be considered exceptional Natural Heritage.

Introduction / Background

Since 1978, there have been a variety of sites in Ecuador that have been declared as Natural and Cultural Heritage of Humanity by the UNESCO Organization. This list includes Quito, the capital of Ecuador, with its colonial center, rich history and architecture, which is the largest historical center in the Americas. Next in line is the Galapagos as a Biosphere Reserve in 1978 and Cuenca, the "Athens of Ecuador" for its buildings and natural environment in 1999. Other Ecuadorian icons on this list include the Sangay National Park, the Zárapa language, the traditional weaving of the Ecuadorian straw hat, also known as the Panama Hat and, finally, the Qhapaq Ñan (Inca Trail, in Quechua), a masterful road communication network, with its 6,000 km from south to north covering and crossing the countries of Argentina, Chile, Bolivia, Peru, Ecuador and Colombia.
UNESCO is the global organization responsible for including exceptional and extraordinary sites for protection or preservation for humanity. The criteria for inclusion on the World Heritage List are explained in the Operational Guidelines for the Implementation of the World Heritage Convention which, in addition to the text of the Convention, is the main working tool on World Heritage. Among the ten criteria for inclusion on the World Heritage List are that they must (a) Contain superlative natural phenomena or areas of outstanding natural beauty and aesthetic importance; (b) Be eminently representative examples of major stages in the history of the earth, including testimony to life and significant ongoing geological processes in the development of landforms, or significant geomorphic or physiographic features; (c) Be eminently representative examples of significant ongoing ecological and biological processes in the evolution and development of terrestrial, aquatic, coastal and marine plants and animal communities; and (d) To contain the most representative and important natural habitats for the in situ conservation of biological diversity, including those containing endangered species of outstanding universal value from an aesthetic or scientific point of view.
To be included on the World Heritage List, sites must have universal value and meet at least one of the ten selection criteria. The List includes 962 properties that are part of the cultural and natural heritage that the World Heritage Committee considers having outstanding universal value. Among the 962 properties, it is noted that the great majority are located in the developed regions of the world, especially in Europe. Among the 188 natural sites, there are 14 caves, of which 6 are in Europe, 5 in Asia, 2 in the USA and one in Mexico.
There are no caves located in South America on the list. Our research of the last two decades with an interdisciplinary group included several dozen selected caves, which are carefully mapped (geology, geography etc.) and investigated for their biological content (bacteria, insects, mammals etc.). We have aimed to find some caves of karst origin in the Amazon or volcanic origin in the Galapagos, which meet one of the World Heritage Committee's selection criteria for inclusion on the World Heritage List.
Thus, based on several investigations during dozens of explorations, workshops and symposia in Ecuador by a multidisciplinary group together with a wide variety of national experts and from several other countries, interesting discoveries have been realized which are in international focus. Based on these investigations, two objectively spectacular natural sites are proposed to be included as candidates for the World Heritage List, being the Tayos cave in the Province of Morona Santiago in the Ecuadorian Amazon and Triple Volcano cave on the Sierra Negra volcano on Isabela Island, Galapagos (Toulkeridis and Angermeyer, 2019).

Previous and recent speleological studies in Ecuador and the Galapagos

Very little is known about the cartographic part of the caves in the Amazonian part of Ecuador, except for a few maps from a French expedition in the last century (Besson *et al.*, 1982) and from two Belgian and Spanish campaigns in the Galapagos

in the seventies and early nineties respectively (Hernandez *et al.,* 1991 and references within this study). Entomological and paleontological studies have recorded only a few species in the Galapagos. Recent studies of our research group include a variety of findings of worldwide interest, including new species and an unusual behavior of a wall-climbing catfish (Constantin *et al.*, 2019; Miller *et al.*, 2020; Katz *et al.*, 2016; Kempe *et al.*, 2021; Espinasa *et al.*, 2018; Martin-Solano *et al.*, 2016; Hoese *et al.*, 2015; Basantes *et al.*, 2017; Zambrano *et al.*, 2017). Additionally, there has been the production of a variety of cinematographic arts, including documentaries especially about the Tayos cave, by known producers such Expedition Unknown of the Travel Channel (Hunt for the Metal Library), Discovery Channel, National Geographic and Disney+.

The Tayos Cave in the Ecuadorian Amazon

The Tayos cave is located within the geological formation called Santiago, which extends from the beginning of the Late Triassic to near the end of the Liassic. This same formation is visible exclusively in the Cutucú Mountain Range and is composed of a sequence of non-metamorphosed marine sediments such as gray siliceous limestone, calcareous sandstone (turbidite in parts) and black slate and volcano-sediments towards the upper part. There are correlations towards the north of Ecuador with the Sacha Formation of continental environment which forms with the Santiago Formation a syn-tectonic cycle recording the opening of a “Rift”.

The Tayos cave is formed in a set of limestone layers, interspersed with dolomites, argillites and sandstones. Due to the geodynamics, the layers have been lifted from the depths of the crust, outcropping today near the surface. Due to these tectonic movements, folds and geological faults were formed. Both structural processes can be observed in the cave where there is a slight dip (5-15º) in the western part of the cave and another more steeply inclined one (~70º) in the eastern part of the cavity, while rectangular dislocations of rocks and deposits expressed in fissures or vertical fractures are noted. The general direction of the cave with its passages is SW-NE and it has an extension of just under 5 km in total. The cave has a series of enormous chambers. The main entrance is a doline with a depth of about 70 meters, but there is a deeper doline where most of the unique Tayos birds are found in the western part of the main entrance. Next to the sinkholes are impressive sites of stalagmites and stalactites, waterfalls, an amphitheater, a dome and smooth, flat walls called the “Portal of Moricz”. The entire length of the known part of the cave is almost 5 km, while at least 3 km are still unmapped.

Figure 1. Resting spot within the “Cathedral” of the Tayos cave.

There are numerous myths about this emblematic Ecuadorian cave. In popular culture, these myths revolve around the arrival and existence of extraterrestrials and intraterrestrials, the supposed discovery of metal plates or books and various other treasures, such as golden statues, hieroglyphs and prehistoric antiquities unknown to mankind and much more. These tales originated primarily with Hungarian-Argentine Juan Moricz, the first speleologist who promoted the cave since 1969 and Erich von Däniken, a pseudoscientist and pseudohistorian. Erich von Däniken, known for his frauds, published in 1973 the book entitled “The Gold of the Gods” without ever visiting this site or Ecuador itself. In this book, which has sold millions of copies, it was claimed “A gigantic system of tunnels, thousands of miles long and built by unknown persons at an unknown date, lies hidden deep beneath the South American continent.” The Tayos cave is truly spectacular, apart from the lies and myths surrounding it. The formations of the geological deposits, the limestone structures in speleothems, stalagmites and stalactites as well as the endemic flora and fauna attracted by the surrounding forests make this site unique, and surely in the whole continent. The real treasures are the information that is yet to be discovered, such as what is recorded in paleontology, paleoclimatology, paleoceanography, bacteria, gases, minerals, animal behavior (Tayos birds, bats, rats, frogs, snakes etc.), entomological life, ethnology, archaeology alongside other natural and social sciences.

Figure 2. Left "Portal of Moricz; right "Skylight" doline, one of the two entrances of the Tayos cave.

Figure 3. Part of the Stalagmite-forest of the Tayos cave.

The Triple Volcano in the Galapagos

Volcanic caves are found on all islands of the Galapagos, which have been formed in almost all the same way with a few exceptions. Island caves are the product of low-viscosity and very fluid lava flows, sometimes with enormous proportions or volumes, which harden at their edges when in contact with air or water and thus allow the conservation of heat and fluidity in their interior. As the molten lava continues to flow and seeps beneath the crust it leaves behind a void in the flow, which is known as a lava tube or cave. Some lava tubes are only a few centimeters high while others are so large or high that many people can walk on or inside them simultaneously. Lava caves can be several kilometers long and partially flooded, others may be dry and some have sometimes collapsed. Most are very shallow, but some older tubes are partially buried by younger tubes and extend deep into the ground. A few exceptions of volcanic caves have been formed in very curious ways. In the midst of volcanic activity in a parasitic volcanic cone above the huge shield volcanoes, the explosions abruptly stop, and the volcano's conduit is left open. These caverns are characterized by their verticality and depth. These sites are excellent environments to study the interior of a frozen and preserved magma chamber of a volcano.

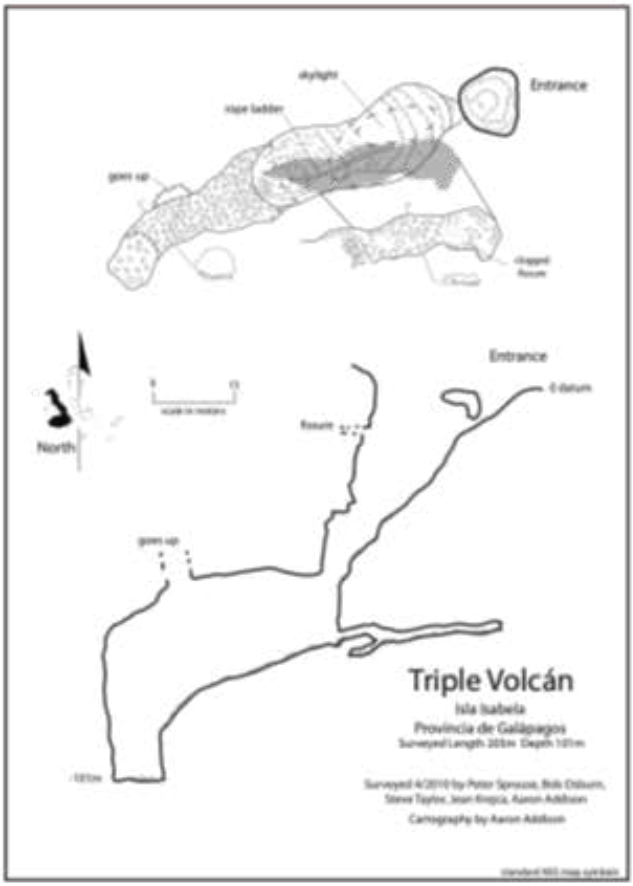

Figure 4. Map of the Triple Volcano.

Figure 5. Insight image of the Triple Volcano´s magma chamber

The Cave called “Triple Volcano” meets all of the above and is precisely the cave that represents a fossilized magma chamber with its intact conduct towards the surface. This cave is located on the southern flank of the Sierra Negra volcano on Isabela Island. Its maximum depth is 101 meters below the entrance (Addison, 2011; Addison *et al.*, 2013). The colors of the internal formations of this cave leave even speleologists with decades of experience with their mouths open. There is no color missing, a complete rainbow. These colors are represented by various crystallizations, mainly of zeolites, in the inner part of the magma chamber reflecting different volcanic processes during times of activity (Debut *et al.*, 2021). Furthermore, at the bottom of the cave there are other witnesses of the varied and complex past history of this underground site such as fossils, bacteria and insects, still unknown to the scientific world.

Conclusion

Both Ecuadorian caves, Tayos and Triple Volcano, have difficult access and entrances, but therefore these sites remained isolated from natural processes existing on their upper part and in general surroundings. However, both caves meet several criteria proposed by UNESCO to be considered candidates for the List of Natural World Heritage Sites. Therefore, both sites will be soon proposed, after few complementary studies, as the next Ecuadorian icons on the UNESCO List of World Heritage Sites.

Acknowledgements

The authors are grateful to different organizations that sponsored our research in various ways, The Galapagos National Park, the Army Special Forces, the Iwia School, the Ecuadorian Scientific Society of Speleology - ECUCAVE, the Military Geographic Institute, the Pan-American Center for Geographic Research - CEPEIGE, the National Speleological Society and the communities in eastern Ecuador the Cave Research Foundation and the many researchers with specialized skills needed to property document these world class resources.

BULLETIN OF THE GEOLOGICAL SOCIETY OF GREECE, SP. PUBL.

EXTENDED ABSTRACT 312

A review of calcareous nannofossil biostratigraphic studies in the Hellenic territory (Greece): the contribution of the Micropaleontology Collection of the Laboratory of Historical Geology and Biogeosciences (NKUA)

Triantaphyllou M.V.[1], Skampa E.[1], Dimou V.-G.[2]

(1) National and Kapodistrian University of Athens, Department of Geology and Geoenvironment, Athens, Greece, mtriant@geol.uoa.gr (2) Aristotle University of Thessaloniki, School of Geology, Thessaloniki, Greece

Introduction

The calcareous nannofossil biostratigraphy is widely based on the standard zonal schemes of Martini (1971), Okada and Bukry (1980), Bown (1998), Burnett (1998) and the updated schemes of e.g., Backman *et al.* (2012) and Agnini *et al.* (2017). In the marginal Mediterranean basin, the fragmentation of the geological record, together with the strong diachroneity of zonal boundary events and/or the absence or extreme rareness of primary marker species, does not allow easily the application of the standard nannofossil zonations. Therefore, regional zonal schemes were developed (e.g., Theodoridis, 1984; Rio *et al.*, 1990; Fornaciari & Rio 1996).

In this study, an extended dataset concerning the investigated locations of the Hellenic territory (alpine, flysch, mollasic and post-alpine deposits) and the available published calcareous nannofossil biostratigraphic results, has been constructed, aiming to standardize the available data and provide realistic biochronologic estimations, according to the magnetobiochronology of Berggren *et al.* (1995) and the more recent astrobiochronological approaches of e.g., Lourens *et al.* (2004), Raffi *et al.* (2006), Backman *et al.* (2012), Agnini *et al.* (2017). In addition, a series of new locations with their unpublished calcareous nannofossil biostratigraphic determinations (e.g., Triantaphyllou, 2017), are incorporated to the dataset, providing a useful framework for correlations in the eastern Mediterranean and beyond. The geographical distribution of all the available data is presented in a series of geological maps arranged per each nannofossil biozone.

A big part of the micropaleontological/geological material associated with the constructed calcareous nannofossil biostratigraphy dataset, is already incorporated into the Micropaleontology Collection at the Laboratory of Historical Geology and Biogeosciences (HG-BioGeoSci), National and Kapodistrian University of Athens (NKUA).

The curation of this Collection undergoes the auspices of the newly introduced international MSc Programme “Industrial and Environmental Applications in Micropaleontology” (IdEA-M, https://idea-m.com/) at the Department of Geology and Geoenvironment (NKUA) and the Interinstitutional MSc Programme “Paleontology-Geobiology” directed by the Aristotle University of Thessaloniki. Our aim is to create a free access database of all micropaleontological objects stored in the HG-BioGeoSci, not only for educational purposes but also benefiting all interested parties to visit and study the collections.

Materials and Methods

The calcareous nannofossils Collection concerns microscope slides, mounted SEM stubs and filtered water samples. The majority of the items comes from the Greek territory and the broader Mediterranean area as well as from other locations worldwide, including samples collected by the global deep-sea drilling programs (DSDP, ODP, IODP etc.).

Except for the microfossil content, the raw material comprising rock samples, marine core records, boreholes and drillings, surface sediments, sediment traps, as well as sample residues are also recorded in a digital database.

The database displays a 2-level classification where all different types of microfossils are documented, labeled with a unique Laboratory code and linked to all available data, i.e., lithology/material type, sampling date and methods, preparation date and analysis techniques, biozone/ biostratigraphic assignment, applied biozonal scheme, age, paleoenvironment type, owner, analyst, references list, repository and notes (e.g., field notes, photos, original drawings, derived publications etc.).

The nannofossil biostratigraphy has been accomplished through qualitative, semiquantitative and quantitative analyses.

Results and Conclusions

The presented calcareous nannofossil biostratigraphy dataset contributes to a better understanding of the spatiotemporal impact on calcareous nannofossil biostratigraphic assignments of the different geological-geotectonic origin deposits in the Hellenic territory and of the factors limiting the distribution and controlling the presence of the widely used nannofossil biostratigraphic indices (examples in Figures 1, 2).

The effort to synthesize and critically evaluate all available biostratigraphic data based on calcareous nannofossil analysis contributes to e.g., defining the age of alpine carbonates, the onset of clastic sedimentation in the various geotectonic units, the stratigraphic age of the different flysch and post-alpine deposits, etc.

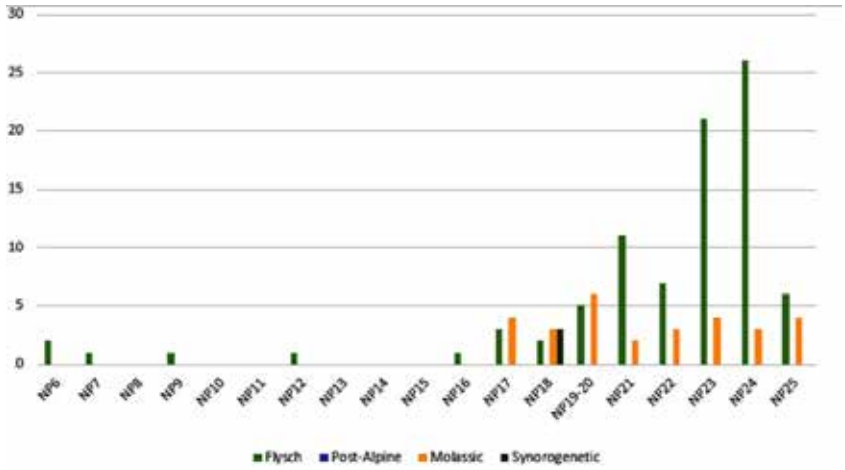

Figure 1. Example of the distribution of calcareous nannofossil Paleogene biozones in the Hellenic territory clastic deposits.

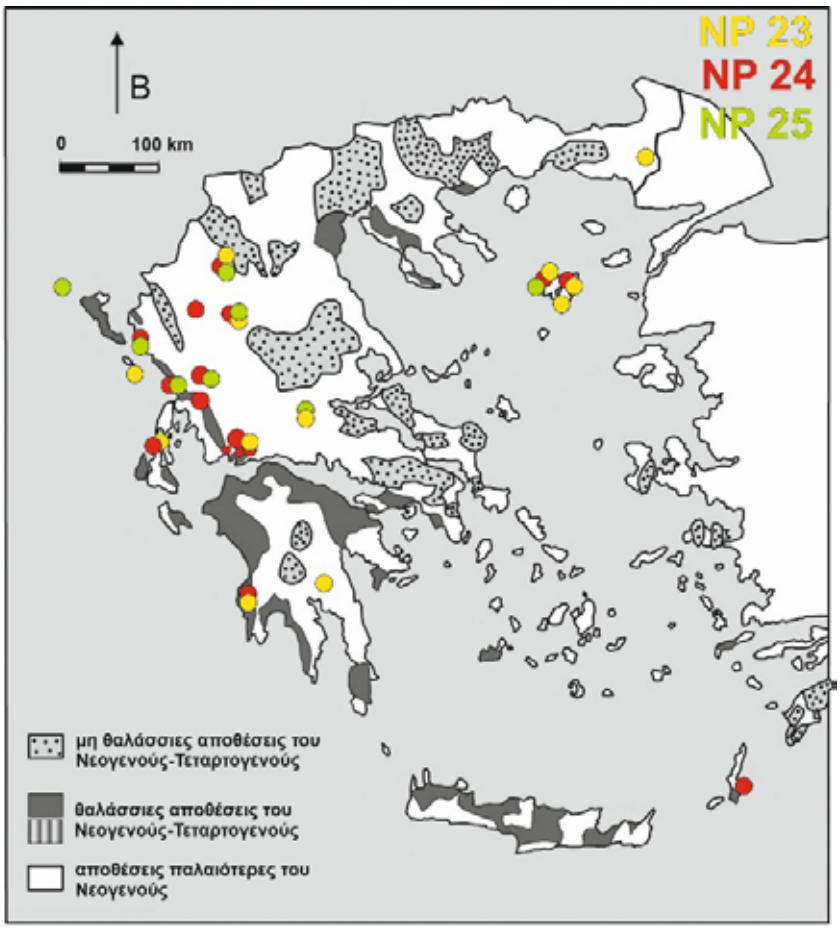

Figure 2. The presence of the Paleogene biozones NP23-NP25 in the clastic deposits.

More than 8.000 available calcareous nannoplankton preparations have been entered in the HG-BioGeoSci Micropaleontology Collection database, associated with more than 20.000 entries of sample residues and raw samples. The aforementioned material derived from more than 100 sites, has been introduced in the digital database and demonstrated in Figure 3. Most sites are distributed in the Mediterranean area; nevertheless, data from North and South Atlantic Ocean, Gulf of Mexico, Gulf of Aden, Laccadive Sea, etc. are also included, offering a worldwide record.

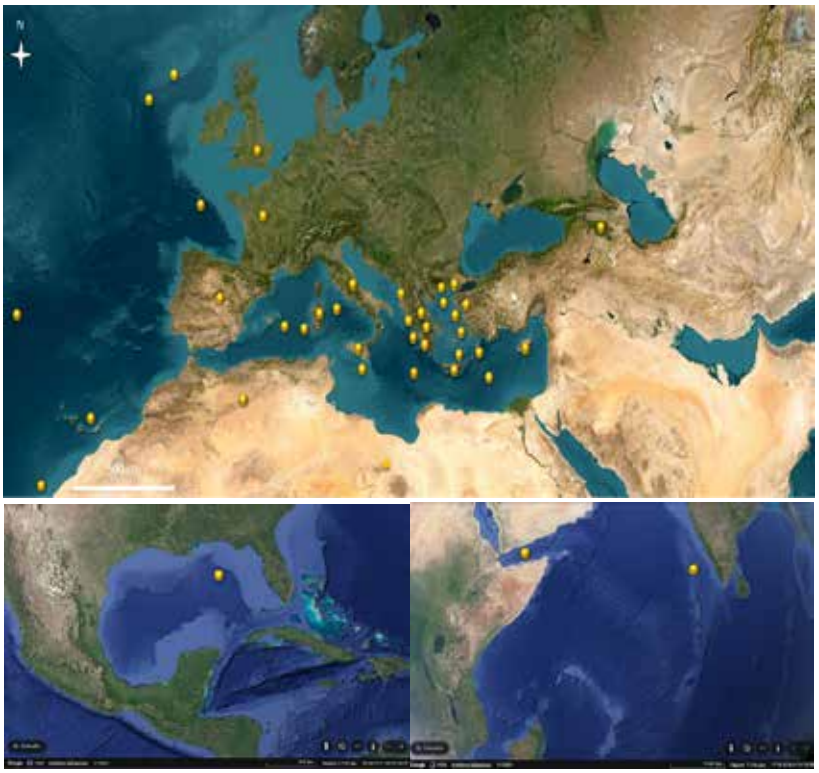

Figure 3. Overview map of the up-to-date calcareous nannofossil entities in the HG-BioGeoSci Micropaleontology Collection.

Up to now, the calcareous nannofossil HG-BioGeoSci Micropaleontology Collection (Figure 4) exhibits mostly Neogene (46%) entities, followed by Quaternary and Paleogene (18% and 17%, respectively). Modern coccolithophore records (water column filtered samples and sediment trap timeseries) are also well represented (13%).

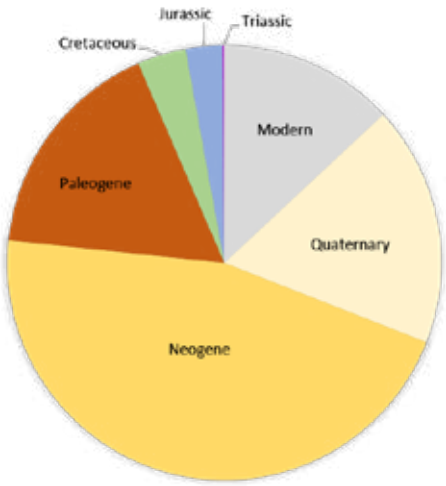

Figure 4. Pie chart showing the abundances of various time periods in respect of the up-to-date record of biostratigraphic entities.

The digitization, archiving and storage of calcareous nannofossil and coccolithophore dataset together with (paleo) environmental data are expected to allow us the understanding of long-term (paleo)ecosystem and ecological dynamics mainly in the Mediterranean area in comparison to the worldwide record. This information is crucial in predicting long-term human-induced environmental and climatic changes.

EXTENDED ABSTRACT 313

Assessing Future Climate Change Risk to Cultural Heritage of Greece: A Case Study of Mycenae and Delos

Tringa E.[1], Tolika K.[1]
(1) Department of Meteorology and Climatology, School of Geology, Aristotle University of Thessaloniki, Thessaloniki, 54124 Greece

Research Highlights

Assessing the risk of damage to cultural heritage due to climate change.
Future projections using the up-to-date regional climate model (RCM) RegCM4 for two Greek cultural heritage sites.

Introduction

Cultural heritage sites have historically been, and will continue to be, affected by environmental factors such as weathering processes. However, climate change presents significant new challenges, accelerating deterioration processes and amplifying the vulnerability of these non-renewable heritages. Changes in temperature, precipitation, air pollution, wind intensity, and the frequency and severity of extreme weather events—such as droughts, floods, and landslides—along with sea level rise (SLR) and the interaction between climate change and air pollution, have significant impacts on cultural heritage (Sesana et al. (2021)). These factors have been recognized by UNESCO as serious threats to cultural heritage (UNESCO World Heritage Centre, (2008)). Climate change can intensify physical, chemical, and biological mechanisms of degradation, affecting the structure and composition of materials. The destructive effects of climate change are particularly evident in regions like the Mediterranean, which include monuments that remain actively used long after their original construction. Outdoor cultural heritage, such as ancient Greek theaters, which form an integral part of Mediterranean culture, provides a prime example of how monuments are impacted by climate change and other contributing factors. These include the natural deterioration of materials over time, the increasing frequency and intensity of extreme weather events, and degradation caused by continued human use of the monuments and their surroundings. Researchers have recognized the risks posed by climate change to cultural heritage sites and have approached the issue in various ways. Ioannidis et al. (2024) studied the impacts of climate change on European cultural heritage sites from 1970 to 2020, highlighting the increased heat stress on elements made from stone and marble, thereby increasing the risk of damage. Kapsomenakis et al. (2023) evaluated the impacts of climate change on multiple UNESCO cultural and natural heritage sites in the Mediterranean, revealing that as global warming progresses, the risks to most of the sites studied intensify. In our previous work (Tringa and Tolika (2023)), we explored the impacts of climate change on Thessaloniki and Delphi, showing that the risk of damage to inorganic materials is expected to increase with temperature fluctuations. Despite the growing body of research on the effects of climate change on cultural heritage, the need for quantitative data and projections remains critical for developing effective adaptation and mitigation strategies, as emphasized by Bonazza and Sardella (2023).

Research aims

Awareness of the significant social and economic value of cultural monuments to the country, along with recognition of the potentially negative impacts of climate change on them, served as the motivation for this research. The aim of this work is to assess the future heritage microclimate risk due to climate change and to quantify the predicted risk of damage to the construction materials of monuments at two Greek cultural heritage sites. Future simulations will provide valuable insights into how climate change could affect the monuments of these sites, offering a basis for informed decision-making in the management and conservation of cultural heritage. This work will contribute to the development of adaptive strategies to safeguard cultural monuments, ensuring their resilience in the face of climate-related challenges.

Data and Methods

This work examines the impacts of climate change on cultural heritage at two Greek sites: Mycenae and Delos. Using the Heritage Outdoor Microclimate Risk (HMR_{out}) and Predicted Risk of Damage (PRD) indices, this study quantifies potential damage to inorganic materials due to long-term changes in temperature and relative humidity (RH). The analysis was carried out for three different time periods, the period 1980–2000 and the future periods 2039–2059 and 2079–2099. Climate projections are based on the up-to-date regional climate model RCM RegCM4 with the fine spatial resolution of 10x10km, providing detailed simulations of the climate parameters in Greece. The model's output is based on the updated "medium" emission scenario, Representative Concentration Pathway (RCP4.5).

Discussion

The results of this study indicate that climate change poses an increasing threat to the preservation of cultural heritage at both Mycenae and Delos. The long-term analysis, which covers both the present and future climate projections, highlights the potential for accelerated material degradation due to the combination of increased heat stress and relative humidity fluctuations. By using indices such as HMR_{out} and PRD, this study provides valuable insights into the potential future threats faced by the case study sites, offering a scientific basis for conservation efforts and the development of adaptive strategies. Furthermore, the high spatial resolution of the RegCM4 model enables more accurate projections of climate conditions at specific heritage sites, which is essential for developing targeted, site-specific conservation strategies. Finally, as climate change continues to affect both environmental and cultural sites, it is essential for decision-makers and heritage conservationists to incorporate climate change projections into their strategies.

Introduction

Mercury (Hg) is one of the most hazardous elements released into the atmosphere from both natural and human-made sources. It exists in three oxidation states: gaseous elemental mercury (GEM), monovalent mercury, and divalent mercury. Volcanic emissions represent a significant natural source of mercury to the environment and over the last 40 years several studies have been focused on estimating mercury fluxes (Varekamp & Buseck, 1986; Pyle & Mather, 2003; Nriagu & Becker, 2003). Understanding the pathways of mercury once it is released into the atmosphere is crucial, given its potential toxicity and long atmospheric residence time (approximately one year) that allows for efficient global distribution compared to many other volcanogenic elements. This research focuses on the biogeochemical study of mercury at Mt. Etna volcano, where both passive degassing and volcanic eruptions represent important sources of Hg input into the environment, with total annual fluxes between 2.1 to 27.3 t yr^{-1} (Bagnato *et al.*, 2007; Edwards *et al.*, 2021; Ferrara *et al.*, 2000; Ferrara & Maserti, 1990; Dedeurwaerder *et al.*, 1982; Buat-Ménard & Arnold, 1978). The specific objectives are: (i) to determine the concentrations of mercury in soils and interstitial gases within these soils; (ii) to characterize the microbiota associated with the mercury cycle in the soils; (iii) to quantify the mercury emissions from the volcano's peripheral sources; and (iv) to measure the atmospheric deposition fluxes of mercury. Our preliminary results focused on the gaseous elemental mercury concentrations both in free and in soil interstitial gases on Mt. Etna.

Methods

The levels of gaseous elemental mercury (GEM) were measured in real-time using the Lumex RA-915M, an atomic absorption spectrometer that utilizes the Zeeman effect and high-frequency modulation of light polarization (ZAAS-HFMLP). This instrument isolates spectral lines at a wavelength of 254 nm with the help of a permanent external magnetic field, using a mercury (Hg) lamp as the radiation source. It operates at a flow rate of 10 L min^{-1} and has a detection limit of 0.5 ng m^{-3}, with an accuracy of 20% for concentrations ranging from 2 to 50,000 ng m^{-3}. During several field campaigns, we measured GEM at different sites of Mt. Etna (Fig. 1) in atmosphere, in diffuse degassing areas and in the interstitial soil gases. To determine GEM in interstitial soil gases, gas samples were collected from the soil at a depth of approximately 50 cm using a rigid Teflon tube embedded in the ground, connected with a 100 mL syringe and then injected into the instrument's gas inlet (Tassi *et al.*, 2016). In case of free gases (fumaroles and bubbling pools), GEM was collected using a three-way valve connected to an inverted funnel placed inside the degassing pools.

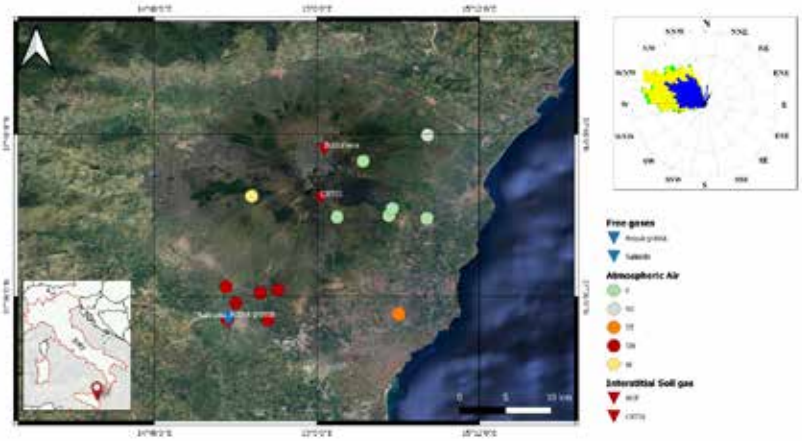

Figure 1. a: The study area; b: Wind rose diagram.

Results

Atmospheric gaseous elemental mercury (GEM) concentrations were measured at various locations around Mt. Etna (Fig. 1). The results revealed concentrations ranging from 0.5 to 5 ng m^{-3}. Our preliminary findings indicate that the median Hg concentration at sampling points in the east, northeast, west, southwest, and southeast sectors aligns with the global background level of 2 ng m^{-3} (Fig. 2a). Based on this data, it appears that the volcanic plume does not significantly deliver Hg at downwind sites, at least at ground level. In contrast, in some degassing areas on the volcano's flanks (e.g. low-temperature fumaroles or degassing bubbling pools) high Hg levels were measured, ranging from 2 to 200 ng m^{-3}. In particular, at the Aqua Grassa site GEM concentrations exceeded 1,000 ng m^{-3}, which is the WHO average annual concentration limit for mercury vapor inhalation (Fig. 2b).

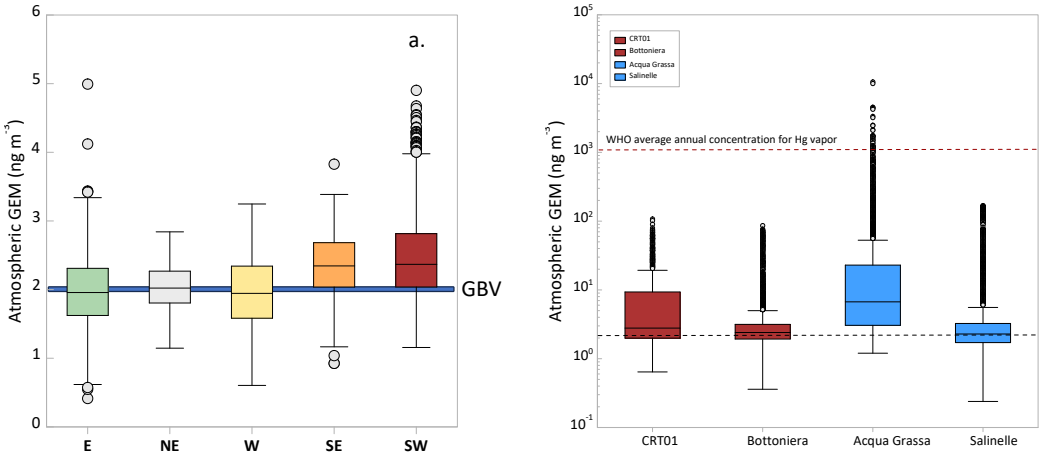

Figure 2- a. Box plot of GEM in atmospheric air; b. Box plot of GEM measured in the free gases and low-temperature fumaroles.

In addition to atmospheric GEM measurements, interstitial soil GEM concentrations were measured. GEM concentrations were recalculated considering the dimensions of the areas of the Hg-spikes in the instrumental output, with respect to the standard. The sampling points were located near low-temperature fumaroles, namely CRT1 and BOT sites, where soil temperature varied from 29.5 to 59 °C and from 12.5 to 90.2 °C, respectively. At the CRT01 site, the measured mercury (Hg) concentrations ranged from 146 to 9615 ng m^{-3}, indicating significant variations in Hg levels across the study area. Meanwhile, the BOT site showed a gaseous elemental mercury (GEM) concentration ranging from 114 to 3109 ng m^{-3}. The binary diagrams of Figure 3 demonstrated a strong correlation between GEM concentration and soil temperature at the BOT site (R^2 = 0.68). In contrast, no correlation was observed at the CRT01 site (R^2 = 0.05).

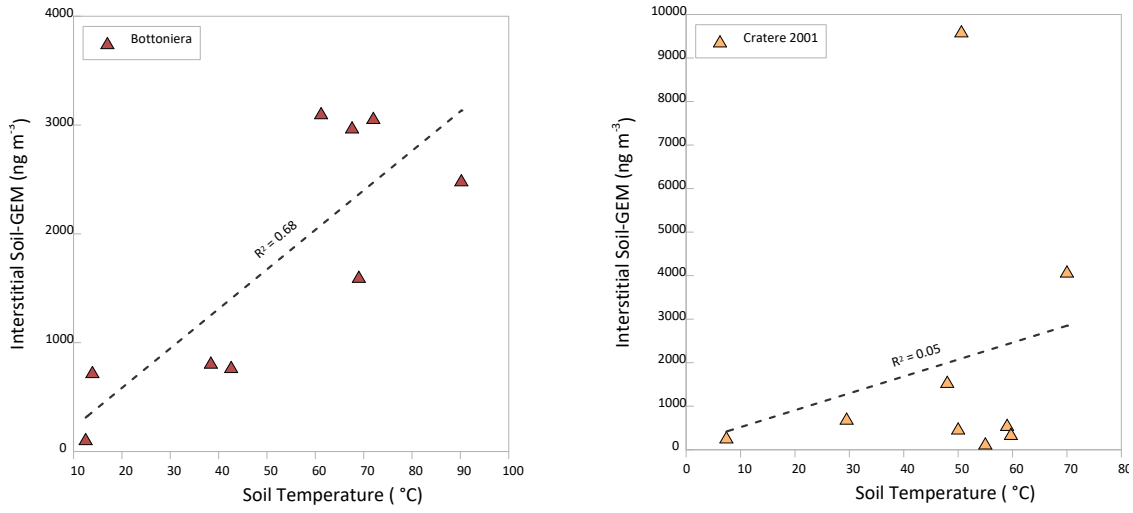

Figure 3. Binary diagram of Interstitial Soil-GEM *vs* Soil Temperature.

Conclusions

This study highlights that peripheral volcanic emissions significantly contribute to atmospheric mercury levels. Field measurements at Mt. Etna and its surrounding areas demonstrated substantial outgassing of mercury, with GEM concentrations far exceeding median global atmospheric levels. Free gas emissions (e.g. fumaroles, bubbling pools), as well as interstitial soil gases, can reach high concentrations of mercury, thus underscoring the importance of volcanic sources of mercury. Notably, GEM concentrations had a strong correlation with soil temperature at certain sites, like BOT, but not uniformly across all locations, such as CRT01. These preliminary findings emphasize the necessity of further research to better understand the biogeochemical cycles of mercury, especially regarding its peripheral emissions, and their broader environmental impact.

"Unfolding the Fold"- An Introduction to the Geology of Greece Through a Museum Kit by the Natural History Museum of Arsakeia Schools

Tripolitsiotou F[1], Argyraki A[2], Drinia H[2]

(1) Natural History Museum of Society for Promoting Education and Learning (Arsakeia Schools), Athens, Greece (2), Department of Geology and Geoenvironment, Athens, Greece

Abstract:

This study aims to highlight Natural History Museums as suitable educational spaces for teaching geosciences to High school students. Specifically, it presents the design and practical use of a museum kit inspired by the geology of Greece. Museum kits are innovative educational tools that combine experiential learning with environmental education. This study examines the design, development, and application of a museum kit that connects the exhibits of the Natural History Museum of Arsakeia Schools with the teaching of Geology-Geography, as outlined in the curriculum for 2nd and 3rd High School grades This educational tool focuses on familiarizing students with the geological history of Greece. It includes geological maps, rocks, minerals, fossils, and activities designed to help students understand the unique geotectonic structure of the region. The museum kit was piloted with 90 students, yielding highly positive results.

Keywords: Museum Kit, Natural History Museums, Geology of Greece, Teaching Geology

Introduction

The education of natural sciences takes place through various formal and informal approaches. Learning opportunities extend beyond the classroom and can be organized in other school spaces or even outside the school premises. One of the most significant educational spaces is the Natural History Museum (Kokkotas, 2004). Museums, in general, play an educational role by creating interactive materials where learning occurs through exhibits, collections, and specially designed educational programs (Tripolitsiotou, 2020). Educational programs are considered a modern approach to exploring the natural and cultural environment within museums (Kaloforidis, 2015). These programs align with the curricula of primary and secondary education, as defined by the Ministry of Education, and are adapted to meet the cognitive needs of each class and group visiting the museum (Tripolitsiotou, 2023). Active teaching methods are utilized to familiarize visitors with the museum space, turning their visit into both an educational and entertaining experience (Tziaferi, 2005).

Description of the museum kit

The Natural History Museum of Arsakeia Schools is located within the school complex of Arsakeia Schools in Psychiko, allowing students frequent access to this unique space and participation in museum-based educational interventions. The primary criterion for selecting the topic of this educational program was the experiential approach to the chapter on the geology of Greece, part of the Geology-Geography curriculum of High School.

The program was designed based on the principles of constructivist and mediated, inquiry-based learning. It follows the educational model of Allard & Boucher and Paquin and incorporates cooperative teaching methods. It primarily targets high school students, especially 2nd graders, without excluding other grade levels.

The materials included in the program are as follows:

- The printed Geological Map of Greece (Bornovas and Rondogianni-Tsiambaou, 1983) at scale 1:500000, published by the Institute of Geology and Mineral Exploration and printed in dimensions 200 x 140 cm.
- Interactive material simulating geological processes
- Authentic specimens of minerals and rocks characteristic of Greece's geological formations
- Fossils providing insights into the paleoenvironment of various regions
- A 6-meter-long geological time tape, an educational model designed by the Natural History Museum of Arsakeia Schools for teaching geological time
- Worksheets

The educational program was piloted with 90 2nd grade students over 2-3 teaching hours.

Initially, through an interactive presentation, students are introduced to the convergence of lithospheric plates, specifically the African plate and the Eurasian plate, and the results of this convergence (e.g., trench formation, orogenesis, and the creation of a volcanic arc).

Next, a brief description of the Tethys Ocean and the role of Alpine orogenesis in shaping the Greek region over

geological time is provided, based on the overall geodynamic and paleogeographic evolution of the Hellenides as described by Pananikolaou (2021). Examples include the formation of the Pindos mountain range, volcanic activity in the Rhodope region, the present-day volcanic arc, and the creation of the Ionian Islands. As noted by Papanikolaou (2021), explaining the Geology of Greece is a complex and rather challenging task, incorporating a Late Paleozoic—Early Cenozoic orogenic history of a Tethyan segment and an active subduction and orogenic arc in the Eastern Mediterranean. Thus, teaching by using typical "by the book" methodologies, combined with the limited prescribed time allowed in order to explain complex concepts and theories, becomes difficult for students and science teachers alike.
The aim of the program is to enable participants to understand, through cognitive, psychomotor, and emotional objectives, that:
a. The geological structure of Greece was not always as it is today over geological time.
b. The geological structure did not form simultaneously across its entire extent but rather evolved gradually over a vast timescale, requiring millions of years.
c. The current landscape is not final; the process is dynamic and continues to evolve over time.
d. There is a significant difference between geological and historical time.

Students explore the geological history of Greece through hands-on interaction with rocks and fossils found in the region. The activity begins with the printed geological map laid on the floor, where students gather to place labeled rock and fossil specimens according to their geographical origin. As they work, the characteristics and geological history of each specimen are explained. In the second part of the activity, students reconstruct the formation of the Hellenic orogen. Starting with the youngest specimens, they progressively "unfold" the tectonic structures as well as the geological timeline by placing the rocks and fossils on a 6-meter-long time tape arranged next to the map, corresponding to their age of formation.
By the end of the activity, students gain a deeper understanding of the spatial and temporal dimensions of the geological processes that have shaped Greece over time.

The evaluation was conducted using worksheets and questionnaires. The program's success inspired the idea of expanding it into a museum kit that could travel to schools nationwide. Museum kits are innovative tools in museum education, enabling knowledge dissemination in diverse cultural and educational settings. This broader reach enriches feedback and contributes to the continuous improvement of this educational material.

Conclusions
Museum educational programs and kits provide students with opportunities to actively participate, develop initiatives, and cultivate scientific processes and skills. Specifically, students:

- Engage with real objects
- Gain a better understanding of geological phenomena and their connection to the Greek environment
- Actively participate in discovering knowledge through pedagogically designed activities
- Learn about nature and its creations
- Develop critical thinking skills
- Practice scientific processes (observation, classification, recording, comparison, communication)

Moreover, the museum's role proves particularly significant in linking informal education with formal education by:

- Creating interactive educational materials
- Utilizing collections and exhibits in teaching
- Designing learning conditions through tailored educational programs and museum kits aligned with the national curriculum

This approach transforms curriculum content from mere information into knowledge through experiential learning, offering students the joy and satisfaction of participating in the educational process.

EXTENDED ABSTRACT 316

Exploring Urban Geotourism Through Geomythology: A Geotrail from Faliro Bay to Vouliagmeni Peninsula, Attiki Region, Greece

Tripolitsiotou F[1], Drinia H[1], Argyraki A[1]
(1) Department of Geology and Geoenvironment, Athens, Greece

Introduction

Urban geotourism is a growing field that focuses on the exploration and appreciation of geological features and geocultural heritage within urban environments. It bridges the natural and human-made worlds by highlighting the geological significance of urban landscapes while incorporating historical, cultural, and mythological narratives. As Del Lama (2018) defines, urban geotourism involves visiting sites within city boundaries that are connected to geological concepts and features, whether these are purely natural formations or modified by human intervention. Geotrails play a central role in this context by offering structured routes that connect points of geological, cultural, and historical interest.

On the other hand, geomythology, the study of how natural geological phenomena inspires myths and legends, provides a fascinating lens through which to explore the relationship between human culture and the Earth's dynamic processes. By examining the interplay of geological events and ancient narratives, geomythology offers insights into how early civilizations interpreted and mythologized their environments. In the context of urban geotourism, geomythology enriches the exploration of geosites by connecting scientific interpretations with cultural heritage.

The purpose of this study is to create a geotrail in order to promote awareness and appreciation of the geological and cultural heritage of the Attiki Region, highlighting the connections between natural processes and human history. It aims to present geological concepts in an accessible and engaging manner, fostering environmental awareness and encouraging sustainable tourism practices. The geotrail also offers an alternative perspective on Athens' urban and natural landscapes, combining geological diversity, historical narratives, and geomythological interpretations.

Study Area

Athens, the capital of Greece, is a city where history, culture, and geology converge in a unique urban landscape (Drinia et al., 2022). Nestled in the Attiki Region, Athens boasts a geological heritage shaped by millions of years of dynamic processes. The Attica Basin features a diverse lithology, including Pliocene marine deposits, Pleistocene clays, and rocks from the Alpine orogenic cycle, such as the famous marbles of Pendeli, used in ancient architecture. The study area extends along the southern coastline of the Attiki Region, from Faliro Bay to the peninsula of Vouliagmeni, covering approximately 20 kilometers. This coastal zone, situated southwest of Athens, serves as a natural outlet of the Attiki Basin into the Saronic Gulf. Rich in geological and cultural features, the area includes key sites such as the Ilissos River estuary, ancient ports, beach rock formations, and fossilized remains. The route traverses diverse lithologies and landscapes, from urbanized waterfronts to the striking natural beauty of Vouliagmeni, making it an ideal setting for exploring the interplay of geology, history, and urban development within the framework of urban geotourism. (fig.1)

Figure 1. Depiction of the geotrail with the selected geocities of the study area

Methodology

The development of this geotrail involved identifying and studying geological, cultural, and historical points of interest along the route. Specific attention was paid to sites with geomythological significance, where natural features and processes inspired ancient myths. Scientific literature, field observations, and geomorphological mapping were combined to document the area's geological formations and their interactions with cultural heritage.

The trail highlights nine key points of interest, beginning at the mouth of the Ilisos River and culminating at the Church of Saint Nicholas on the Vouliagmeni Peninsula. Along this route, sites were selected for their geological diversity, cultural relevance, and accessibility. These include areas that host ancient ports, beach rocks, ancient saline lakes (lagoons), fossils, and unique geomorphological features.

Results

The geotrail showcases the geological and cultural richness of the Faliro to Vouliagmeni route. The journey begins at Faliro Bay, specifically at the mouth of the Ilisos River, one of the few wetlands on the western coast of Attica. Although the Ilisos River has been largely transformed into an artificial structure, it remains a significant geosite, reflecting the region's dynamic interaction between natural and urban development.

Key points along the route include:

Trocadero (the small chapel of Saint George), Pani Hill (a geological and cultural landmark), Elliniko Beach (featuring beach rocks and other coastal formations), Voula Beach (known for its proximity to the Town Hall and fossilized

remains), Great Kavouri (a site of unique geological interest), Vouliagmeni Peninsula (the endpoint of the trail, where visitors encounter the Church of Saint Nicholas, constructed from local rocks and pebbles).
The lithology of the region reveals significant variations, including clays, silts, breccias, sandy marls, conglomerates, and cohesive breccio-conglomerates. These formations reflect the coastal depositional environment and offer a window into the paleoenvironment during the mythological period (Charalambakis, 1952; Papanikolaou et al., 2004). The geotrail provides visitors with a structured, immersive journey into the geological and cultural history of Attica, combining scientific insights with cultural narratives to foster a deeper appreciation of this unique urban landscape.

Discussion - Conclusion

The geotrail from Faliro Bay to Vouliagmeni Peninsula highlights the unique interplay of geology, culture, and urban development in the southern Attiki Region. By combining geomythological narratives with geological observations, the trail offers an innovative approach to urban geotourism that engages visitors in exploring the region's natural and cultural heritage. The study illustrates how geological features have influenced both the environment and human activity, shaping the myths, legends, and history of the area.
This geotrail serves multiple purposes: it fosters environmental awareness, promotes sustainable tourism, and showcases the scientific and cultural significance of geosites within urban settings. Additionally, it emphasizes the importance of integrating urban development with the preservation of natural and cultural resources. By connecting the scientific understanding of geological formations with the myths that arose from them, the geotrail bridges the gap between science and culture, offering a holistic perspective on the dynamic relationship between humans and their environment.
The creation of such trails not only enhances public appreciation of geology but also demonstrates the potential for urban geotourism to contribute to sustainable urban planning and development. Future initiatives could further expand on this approach by incorporating digital tools, guided tours, and community engagement to enhance the visitor experience while ensuring the long-term conservation of these valuable geosites**.**

EXTENDED ABSTRACT 317

Exploring Social Perceptions of Water Scarcity and Local Water Resource Management in Greece: Insights from a National Survey.

Troupakis A, Feloni E. , Kalogeropoulos K., Tsatsaris A.
Department of Surveying and Geoinformatics Engineering, University of West Attica, 28 Ag. Spiridonos, 12243 Egaleo, Athens, Greece; efeloni@uniwa.gr

Abstract

Water scarcity has emerged as a critical challenge in Greece, particularly following the extreme drought of summer 2024, which led to significant shortages in multiple regions. In response, a nationwide survey was conducted to examine public perceptions of water scarcity and local water resource management. The survey, structured into seven sections, explored awareness levels, personal conservation habits, policy perspectives, and regional disparities in water availability and governance.

Beyond assessing public opinion, this study investigates spatial patterns that may reveal connections between perceived water scarcity and local limitations in water resources or management strategies. Findings indicate notable regional variations in concern levels, conservation efforts, and trust in governmental responses. Notably, areas that experienced more severe shortages demonstrated heightened awareness and a stronger inclination toward water-saving behaviors. Additionally, a significant majority of respondents expressed the need for environmental education programs in schools, recognizing their potential to cultivate long-term sustainable practices.

By integrating public perceptions with spatial insights, this study provides valuable input for policymakers to develop targeted, region-specific strategies for sustainable water management. The findings underscore the necessity of both technical improvements in water governance and widespread educational initiatives to foster a culture of water conservation in Greece.

Keywords: Water scarcity, Greece, drought 2024, public perception, water management, spatial analysis, environmental education, conservation policies

Introduction

Community engagement plays a crucial role in shaping effective policies for sustainable water management, particularly in the face of increasing water scarcity. Public perception surveys serve as an essential tool in this process, enabling policymakers to assess awareness, attitudes, and behavioral patterns related to water resources, water use and management (Dolnicar et al., 2011; Willis et al., 2011; Fielding et al., 2012; Garcia-Cuerva et al., 2016). Understanding social perceptions not only facilitates informed decision-making but also enhances public trust and participation in conservation initiatives. Given the unprecedented drought conditions that affected Greece during the summer of 2024, leading to severe shortages in multiple regions (keeptalkinggreece.com), the necessity of examining public opinion on water scarcity has become more pressing than ever.

Water scarcity is a multidimensional issue influenced by climatic variability, infrastructure resilience, and governance strategies. While technical and economic interventions are critical in addressing supply challenges, social acceptance and engagement significantly impact the success of water conservation efforts. Previous studies have investigated public perceptions of water-related issues in various contexts, highlighting regional variations in awareness and acceptance of solutions. For instance, research conducted by Pathiranage et al. (2024) explored public attitudes toward water reuse in the Southeastern United States, demonstrating that public perception plays a key role in shaping water policies and acceptance of alternative water sources. Similarly, a growing body of literature underscores the importance of understanding regional and demographic variations in perceptions to design effective, localized interventions (e.g., Dolnicar et al., 2011; Willis et al., 2011; Fielding et al., 2012).

Building upon this foundation, the present study aims to provide a comprehensive analysis of public perceptions regarding water scarcity and local water resource management in Greece. Through a structured nationwide survey with 500 participants, the study examines levels of awareness, personal conservation behaviors, policy preferences, and spatial patterns in attitudes toward water governance. The findings offer valuable insights into the relationship between water scarcity experiences and public response, with implications for both short-term crisis management and long-term sustainability strategies, while the majority of participants believe that comprehensive educational initiatives are essential for fostering a culture of water conservation, as also evidenced by Heath and Gifford (2006).

Materials and Methods

A. Survey design

The survey was designed to assess public perceptions of water scarcity in Greece, particularly following the extreme drought of summer 2024. It was structured into seven sections, covering key aspects of awareness, attitudes, and potential solutions. The questionnaire included a mix of multiple-choice and open-ended questions to capture both quantitative and qualitative insights.

The first section gathered demographic data, including age, gender, education level, and geographic location, enabling spatial analysis of responses. Subsequent sections explored awareness levels, personal experiences with water shortages, and perceptions of the main causes of water scarcity. Respondents were also asked about their water conservation behaviors and their views on governmental measures to address the issue. A key objective of the survey was to identify regional patterns in perceptions and examine whether attitudes toward water management varied based on local water resource availability. Additionally, the survey assessed public support for various policy interventions, such as infrastructure investments, regulatory measures, and environmental education programs in schools. The structured yet flexible design allowed for a comprehensive understanding of public sentiment, providing valuable insights for policymakers seeking to implement targeted, region-specific water management strategies.

B. Platform

The survey was designed and implemented using the Microsoft Forms platform, a widely used digital tool for collecting and analyzing survey responses. Microsoft Forms ensures participant anonymity by allowing responses to be recorded without collecting personal identifiers, aligning with General Data Protection Regulation (GDPR) requirements. The platform provides secure data encryption and access controls, ensuring that responses remain confidential and are used solely for research purposes. By leveraging Microsoft Forms, the study adhered to ethical guidelines for data protection and privacy, maintaining participant trust while facilitating an efficient and compliant survey process. The questionnaire can be accessed in Greek through the link: https://bit.ly/42p4IDG.

Results

A. Participants

The survey on water scarcity in Greece gathered responses from a diverse group of participants across various demographic categories. The majority of respondents were between the ages of 25 and 54, representing a balanced mix of young professionals and middle-aged individuals. Gender distribution was relatively even, with a slight predominance of female participants. In terms of educational background, a significant portion held university degrees, reflecting a well-educated sample group. Geographically, responses were collected from multiple regions across Greece, with a notable concentration in urban centers such as Athens and Thessaloniki, but also including perspectives from rural areas affected by last summer's severe drought. This diverse representation provides valuable insights into public perceptions of water scarcity across different social and geographic contexts.

B. Overall perception

Public Awareness of Water Scarcity: The survey results indicate varying levels of public awareness regarding water scarcity in Greece. A significant portion of respondents, totaling 212 individuals, consider themselves "moderately informed" on the issue, while 140 participants stated they were "slightly informed." In contrast, only 116 respondents reported being "well-informed." These findings suggest that although some awareness exists, there remains a considerable knowledge gap among the public. This highlights the need for more effective awareness campaigns to enhance public understanding of water scarcity issues and their long-term consequences.

Perceived Causes of Water Scarcity: When asked about the primary causes of water scarcity, respondents identified several key factors. The most commonly cited reason was climate change, with 207 responses highlighting its impact on water availability. Additionally, 141 respondents attributed the problem to aging infrastructure and water network losses, emphasizing the role of outdated systems in exacerbating water shortages. Overconsumption of water resources was another major concern, noted by 107 participants. While fewer respondents pointed to water pollution as a significant factor, many acknowledged that multiple causes contribute to the issue. This underscores the complexity of water scarcity and the necessity of a holistic water management strategy that addresses both environmental and infrastructural challenges.

Perception of Water Scarcity as a Serious Issue: The vast majority of survey participants, perceive water scarcity as a very serious problem in Greece (Figure 1). This overwhelming consensus indicates widespread public concern, likely influenced by the extreme drought of summer 2024. The severity of recent water shortages appears to have heightened awareness of the issue, reinforcing the need for urgent and comprehensive policy responses to ensure sustainable water management.

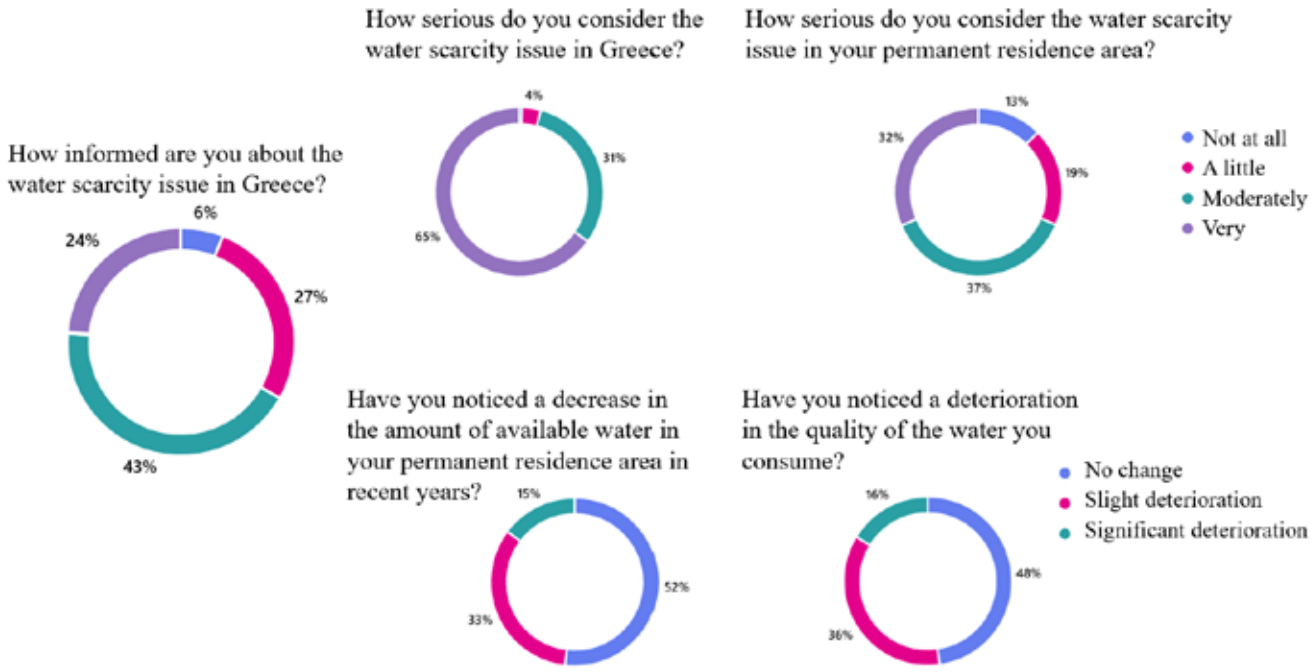

Figure 1. Aggregated responses to general questions about water scarcity

Policy Preferences for Addressing Water Scarcity: In terms of policy measures, respondents expressed strong preferences for actions that enhance water security. Among the most favored solutions were increased investment in water infrastructure, including supply and sewage systems, as well as the promotion of water-saving technologies. Many participants also supported the establishment of a central government authority dedicated to managing water resources. These responses indicate a clear recognition of the need for both governmental intervention and technological advancements in addressing the country's water challenges.

Preference for Water Conservation Measures: The survey also explored public attitudes toward water conservation strategies. A large number of respondents advocated for the mandatory implementation of water-saving technologies in buildings, recognizing their potential to reduce excessive water consumption. Similarly, there was strong support for initiatives promoting the recycling and reuse of water. These preferences align with the broader call for infrastructure investments and highlight a willingness among the public to embrace regulatory measures aimed at long-term water conservation.

Regional Disparities in Water Scarcity Perception: Geographic differences in the perception of water scarcity were also evident in the survey results. The majority of participants (329) reside in Attica, followed by Central Greece and the South Aegean. While national concern over water scarcity remains high, regions with historically strained water resources—such as island communities and agricultural areas—expressed greater dissatisfaction with current water management policies. This suggests that regional disparities must be taken into account when designing policies to address water scarcity, ensuring that the most affected areas receive targeted interventions.

Support for Environmental Education in Schools: One of the most notable findings of the survey is the strong public endorsement of environmental education programs in schools. A large majority of respondents emphasized the importance of integrating water conservation topics into the curriculum, believing that such initiatives could foster long-term behavioral changes. This suggests that beyond immediate policy interventions, efforts should also focus on educating future generations about sustainable water use. By embedding environmental awareness into school programs, policymakers can contribute to a more informed and proactive society in the years to come.

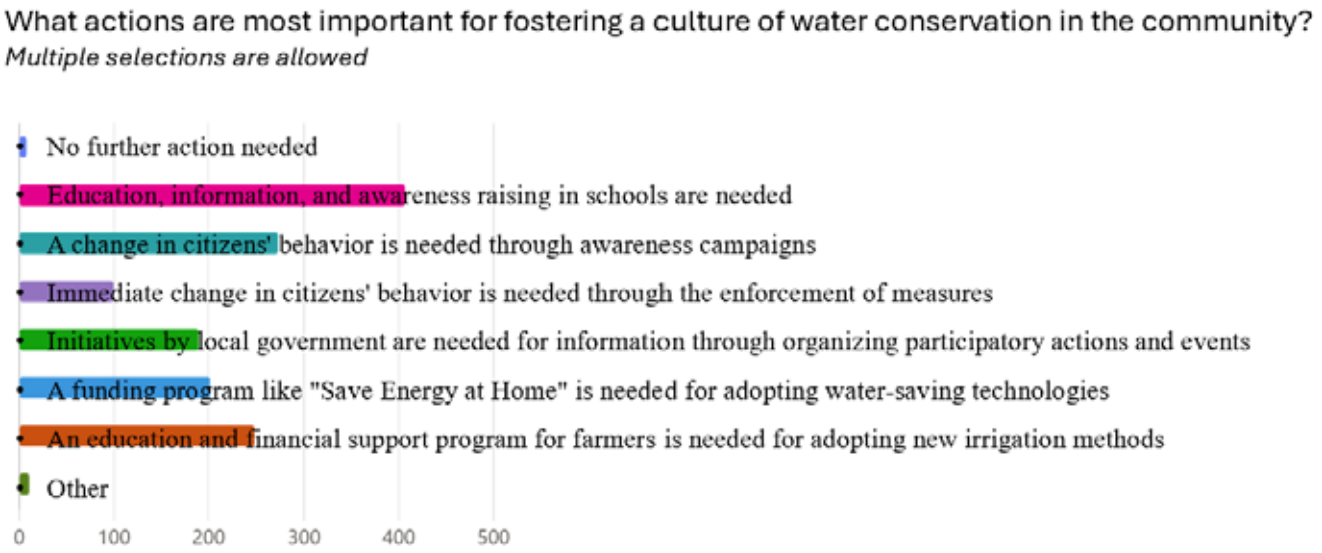

Figure 2. Question on actions that may help foster a culture of water conservation in the community

Concluding Remarks

In conclusion, the study highlights widespread public concern about water scarcity in Greece, particularly following the severe drought of 2024. The findings reveal that while many individuals are aware of the issue, there is still a significant knowledge gap, indicating the need for more effective awareness campaigns. Climate change, aging infrastructure, and overconsumption are commonly cited as the main causes of water shortages.

Furthermore, the study underscores the importance of regional strategies to address water scarcity, with areas facing more severe water shortages expressing greater dissatisfaction with current management efforts. There is strong public backing for government action, particularly in improving infrastructure and promoting water-saving technologies. Moreover, there is significant support for incorporating environmental education into school curricula to encourage long-term changes in water conservation behavior. These findings offer valuable guidance for creating targeted policies to achieve sustainable water management in Greece.

Introduction

Different types of Engineering Geology research works and studies have already become not only necessary but in fact obligatory steps for the permitting of new construction projects. Furthermore, it is recognized amongst related scientists that Engineering Geology can contribute to the rescuing and enhancing of even small-scale cultural works effectively. This article presents how the major findings of the geological – geotechnical engineering study of the ancient Antaeus Fountain environment can be used for the Fountain's protection and enhancement. The close co-operation among geologists and the other scientists involved like archaeologists constitutes key component for the successful implementation of the research results.

Background

The archaeological site of the Fountain is located at the Antaeus and Gennaios Kolokotronis streets' junction in the Amalia Merkouri Square in Ano Petralona. It was discovered by the archaeologist Olga Dakoura – Vogiatzoglou during excavations in July 1976 (Fig.1).

The Ano Petralona district is well known for its remarkable historical and archaeological character. Based on published documents (Kontopanagou & Spamoudi, 2013), this area was a ceramic craftsmen district characterized by the abundant presence of ceramic craftwork places in the years between the latter half of the 4th Century BC and the beginning of the 5th Century BC.

The study area is very close (less than 1km distance to the east and north east) to a number of limestone hills of high historical importance, linked to the social, political and religious setting of Ancient Athens. More specifically, these are the well-known Hill of the Nymphs (+105.38m), the Hill of the Pnyx (+104.67m) and the Hill of the Muses – Filopappou (+147.23m). Eastern to the above, one can see the sacred rock of Athens, the Acropolis (+159.56m), the most magnificent monument of Athens, the Parthenon, which is devoted to Athena, the patron goddess of the city (Fig.2).

Figure 1. Western view of the Antaeus Fountain, photo from the pavement of Gennaios Kolokotronis Street.

Figure 2. The Hillsides in the neighborhood of the study area (Extract from the 2016 Land Registry orthophoto map).

The three historic hills and the Sacred Rock of the Acropolis are a single, integral and living part of an important civilization that first laid its foundations, developed and spread to the ends of the Earth, around these rocky outcrops. Their historical relationship is more than obvious and self-evident, but this is also due to the specificity of the geological background of the Athens basin. The Parthenon was founded on the limestone rock of the Acropolis, the meetings of the Church of the Municipality were also held on the limestone rock of the hill of the Pnyx and the remains of the sanctuary of the Nymphs were found on the

top of the homonymous hill of limestone composition. The common geological history of the limestone outcrops begins in the Upper Cretaceous 100 million years ago, where the allochthonous series of Athens was tectonically emplaced on top of the autochthonous series of the Sub-Pelagonian zone. The allochthonous series consists mainly of limestones of the neritic and pelagic phase, in which clastic turbiditic formations are intercalated. The 'footprints' of this geotectonic unit are evident in a series of hilly rocky outcrops scattered throughout the Athens basin (Turkovounia, Lycabettus, Strefi Hill, Arditos Hill, etc.).
The immediate proximity of the district of Petralona with the hills upstream, as well as with the Sacred Rock of the Acropolis, make this district an active historical part of the civilization that developed during the ancient times in the area of Athens. This character has been preserved to this day in the specific district, under the concerted efforts of the State, the competent Ephorate of Antiquities and the residents, who are resisting the violent tourist homogenisation and commercialisation of their city.
The Fountain construction was placed at a strategic point between the Long Walls, perhaps outside the Western Gate of the Walls of Themistocles, where the Street of Koilis passed, and could be characterized as the "Fountain of Koilis" (Fig.1). It should be noted here that the fall in the water table of Athens during the 4th century BC and the need to find water at greater depths led to public concern for the provision of this precious commodity, with the construction of fountains. The office of 'curator of fountains' is mentioned, responsible for the supervision, proper operation and repair of fountains and pipelines. The Fountain probably forms part of this programme of public works in the second half of the 4th century BC (Kontopanagou & Spamoudi, 2013). Water entered the fountain's water collection tank through two pairs of holes formed in the natural rock (Fig.3). Then through a socket, where a marble vault had been carved, the hydria for water collection was placed (Fig.4).

Figure 3. Artificial holes, carved within the rock formation to feed the Fountain, through the main hydro-amalgamated surface conduit developed in a general N-S direction.

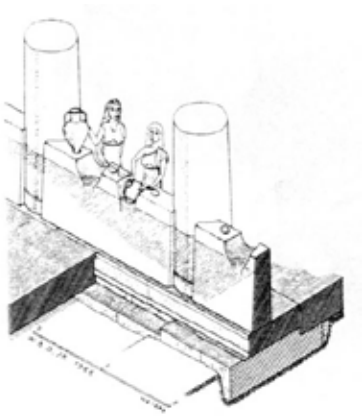

Figure 4. Schematic typical representation of groove for the reception of urn to a fountain.

As mentioned above, the geomorphology and geology of the area played an important role in the choice of the location of the Fountain, constituting a "capable and necessary condition" for its exploitation by the inhabitants of ancient Athens, where, with the use of the available mechanical means and the know-how of the time, it was transformed into a reservoir for water collection and distribution.
Specifically, in the case of the fountain in question, it is a partly natural semi-rocky - rocky cavity, in which weak soil zones are interspersed. In particular, this cavity is located in a brecciated limestone, which is mainly the natural roof of the Fountain. This limestone eventually and in the front part of the cavity develops into a calcareous breccia, which is directly related to the tectonic processes of the wider area. The opening of the enclosure (i.e. the chamber of the Fountain) is about 5-6m and bears in its front part, which is also the entrance, two natural pillars of the same calcareous breccia, thus forming three rudimentary arches, a wider one in the center and two smaller ones on either side of it (Fig.1).
The sophisticated location of the monument consists in the fact, that it is developed on the foothills of the limestone complex of hillsides (Hill of the Nymphs, Hill of the Pnyx and Hill of the Muses-Philopappou), constituting a natural recipient of small water tributaries which start from the upstream hills and pass through the location of the study area. These streams, may have been natural tributaries of the Ilissos River, according to historical maps (Curtius & Kaupert, 1903). Ilissos was the main source of the hydrographic network in the study area at the time, with its active bed located 400m south of the ancient Petralona Fountain, where a characteristic meandering development is observed. Today, the River Ilissos is mostly enclosed and flows for a large part underground, usually under main roads.

Objectives

The physical condition of the archaeological monument as a whole, is judged today as relatively moderate, considering also its age. Factors that contributed significantly to its preservation are the construction materials and the architectural design. Moreover, the continuous and intense urbanisation changed the hydrological regime with the gradual disappearance of natural streams and their conversion into underground rainwater pipes. This fact along with the particular geomorphological configuration of the Fountain (namely a cavity protected from the climatic conditions), indirectly acted as a brake on the deterioration of the Monument.

However, the passage of time, past and present man-made interventions, certain vandalism and the need for prevention to avoid future disasters from extreme weather events and potential geohazards, make it imperative to protect the Monument immediately. In particular, the objective of the Geological - Geotechnical Study performed included the following: a) the investigation of the geological - geotechnical conditions prevailing in the immediate area of the project; b) the detection of the paleogeographic evolution of the area; c) the determination of the seismic risk; d) the assessment of the physical and mechanical characteristics of the rock formations occurring in the environment of the Fountain; e) the collection and analysis of tectonic discontinuities in order to identify kinematically unstable surfaces; f) the classification of rock masses according to international standards and regulations. Summarizing, the accomplishment of the above investigations and studies was considered necessary in order to be able to propose and design the appropriate support measures in the area of the Fountain, with the aim of its conservation and enhancement.

Methods

Within this framework, extensive literature review was carried out regarding the climatic, geomorphological, geological-hydrogeological, tectonic and seismological conditions in the broader project area. Furthermore, this review was completed with fieldwork that was carried out in order to gain a more complete understanding of the geological-techno-geological conditions and to determine important geotechnical parameters.

During the geological mapping, the occurring alpine and meta-alpine geological formations and their geological boundaries were identified. Also, typical slopes and directions of the maximum slope of discontinuities (joints), as well as the erosion degree of the formations were recorded. The 1:75 scale geological map of the wider Fountain area (Fig.6), including a generated view and cross-sectional images of the narrow area (Fig.7 & 8) are given below.

During the fieldwork, the existence of a sparse network of tectonic discontinuities was recognised, which were recorded despite the small height of the shaped slope on the face of the monument (<3.0m), the intense weathering and erosion of the rocky ledges, the coating with artificial lime mortar of the entire interior of the cave and the base of the rocky pillars. The geometrical characteristics (dip/dip direction) of the three observed groups of tectonic disconuities, as well as those of the slope are J1: 03/087, J2: 75/260, J3: 35/178 and S: 88/220.

Subsequently, the existing technical-geological status of the formations that make up the archaeological site of Fountain was assessed and the rock mass classification was estimated using the international empirical classification system GSI. From a geotechnical point of view, the georesearch programme carried out - included:

- A series of measurements at selected locations using a Schmidt rebound hammer to determine the strength of the rock mass (non-destructive tests).
- The surface sampling of three (3) pieces of detached rock mass, for the formation of prismatic samples in a certified laboratory of soil mechanics - rock mechanics, in order to determine their physical and mechanical characteristics.
-

Results

The Petralona Fountain is part of an area with the lowest precipitation levels in Greece. However, due to the fact that the archaeological monument is a naturally formed cave with special morphological and tectonic characteristics and taking into account the existence of two different floor levels with an altitude difference of about 3.00m in the cave, it is considered possible that in the future a concentration of rainwater may be observed on the floor of the archaeological site, in extreme rainfall events. Based on the results of the geological mapping and the on-site macroscopic geological observations, the geological substratum in the immediate project area is composed of Quaternary formations (artificial deposits, backfill materials and alluvial deposits) and Upper Cretaceous formations (Breccia Limestone – Lim_{br}, Calcareous Breccia II - Br_{lim}II and Calcareous Breccia I - Br_{lim}I). The major findings for the formations in the Fountain environment are as follows:

- The backfill materials (loamy sand and gravel, crushed stone) come mainly from the roadbed support works on Antaiou Street. The formation in question is located on the northern flank of the fenced area of the archaeological site, with a maximum height of about 2.00m and a width of about 4.40m. A small-scale ground failure is evident, with a portion of the formation having slide across the floor of the Fountain construction. Contributing to this has been the limited presence of water, manifested in the form of moisture in the lower parts of the formation. The roof of the formation is underlain by the 7cm thick asphalt material of the road surface of Antaiou Street, which has collapsed in some parts. From a technical-geological point of view, this

formation consists of loosely unbound roadwork materials and is characterised by poor mechanical properties. Furthermore, it is an uneven formation and, in combination with its steep slope, it is generally considered to be prone to soil failure and erosion. The above is also evidenced by a small-scale flat ground slip observed within the archaeological site, a fact to which the weak hydrology found in the form of moisture in the lower parts of the formation has also contributed.

- Alluvial deposits (al): This formation may be of small thickness and consists of medium cohesive – cohesive dark brown clay and gravels. They entirely occupy the floor of the ancient Fountain, on which the marble slabs that formed the courtyard of the Fountain construction are placed. The deposits are covered by the characteristic low herbaceous vegetation (wild grass, periwinkle, etc.), which covers part of the floor. As known, alluvial deposits are the youngest geological formation, have poor mechanical characteristics and are susceptible to all types of soil failure and erosion. However, because of their position on the floor of the archaeological site and in small residual deposits in the upper part of the archaeological site, they do not affect the structure and stability of the monument.
- Breccia Limestone (Lim_{br}): It is a white to off-white, in places sub-ashy un-stratified limestone. It appears mildly karstified with superficial presence of small-scale cavities. Dark brown and reddish-brown marly intercalations were observed within the rock's mass. The formation occurs in the upper parts of the Fountain pillars, possibly occupying a large area of the cavity roof, as revealed in places where the Fountain internal construction mortar has deteriorated. The formation also occurs at the entrance to the archaeological site near the metal door, and in an adjacent south-eastern plot. In the parts of the cavity that have not been coated with mortar, there is a very sparse network of discontinuities. The formation presents a visible thickness ranging from 0.50-0.90m and is slightly weathered (degree of weathering: IB-II), while its susceptibility to erosion and all kinds of failures is estimated to be low. An isolated occurrence of potential failure of wedge-shaped detachment of significant volume was noticed in the cross-section of three (3) levels of tectonic discontinuities.
- Calcareous Breccia II (Br_{lim}II): It is an un-stratified calcareous gravel and nodules breccia with angular sub-white to sub-ash gravels Dmax≈7cm, bound together by a matrix of reddish-brown calcareous-marly material. The presence of soil zones, strongly weathered (pulverized) within this formation, suggests the potential existence of tectonism. The formation has a thickness ranging from 0.20-1.00m. It is located in the central parts of the pillars, part of the cave roof and in the northern part of the site. The formation is highly inhomogeneous and due to the presence of fragmented zones it exhibits poor to moderate cohesiveness and appears moderately to highly weathered (degree of weathering: III-IV). Unstable conditions are expected in its contacts with the neighbor formations, revealed in the form of soil and/or rock slides and the presence of natural gaps.
- Calcareous Breccia I (Br_{lim}I): It is an un-stratified formation, with maximum visible thickness of about 0.70m, mainly found at the base of the fountain pillars and at the edges of the Backfill Materials (M.M.M.) on the north side. It consists of ash-white-coloured angular gravels (Dmax≈15cm) and pebbles, bound by a matrix of reddish-brown calcareous marly material. There were not noticed any discontinuities in the formation, which represents moderately to well-connected materials with satisfactory mechanical behavior and appears slight to moderate weathering (degree of weathering: II-III). Though it should be noted that even if the formation is relatively homogeneous and shows partial susceptibility to erosion and all kinds of failures, in the event of heavy rainfall and seismic loading, its mechanical behaviour may be impaired.

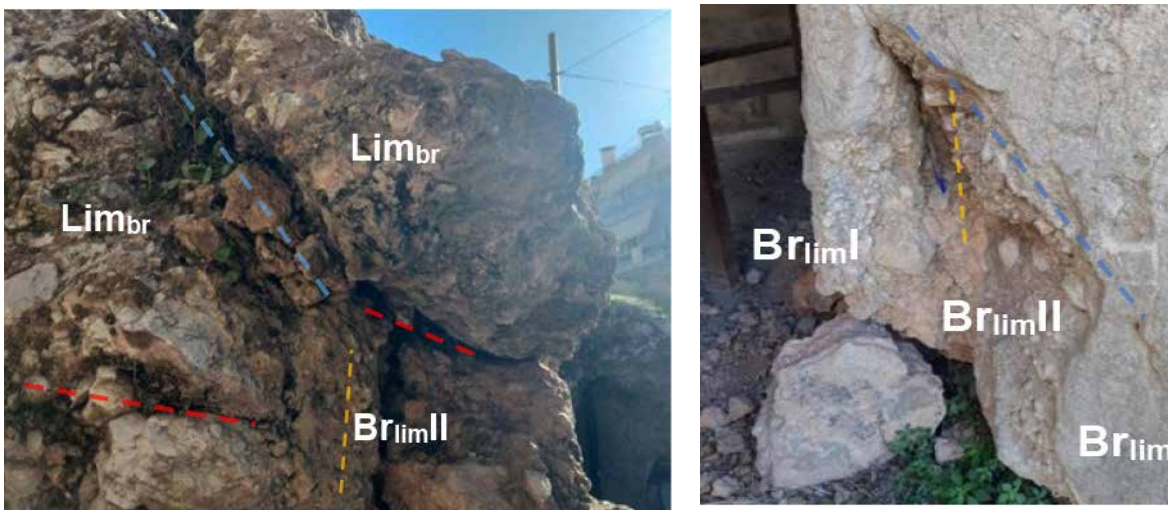

Fig. 5. On the left: Precarious equilibrium conditions in overhanging fractures of the Lim_{br} Limestone and the Br_{lim}II Calcareous Breccia on the northern pillar, due to the cross-sectional plane of tectonic discontinuities. On the Right: Detachment of rock fragment from the base of the southern pillar - creation of a local undercrop. The failure occurred at the contact of the Calcareous Breccia II (Br_{lim}II) and the Calcareous Breccia I (Br_{lim}I), along discontinuities J2 and J3.

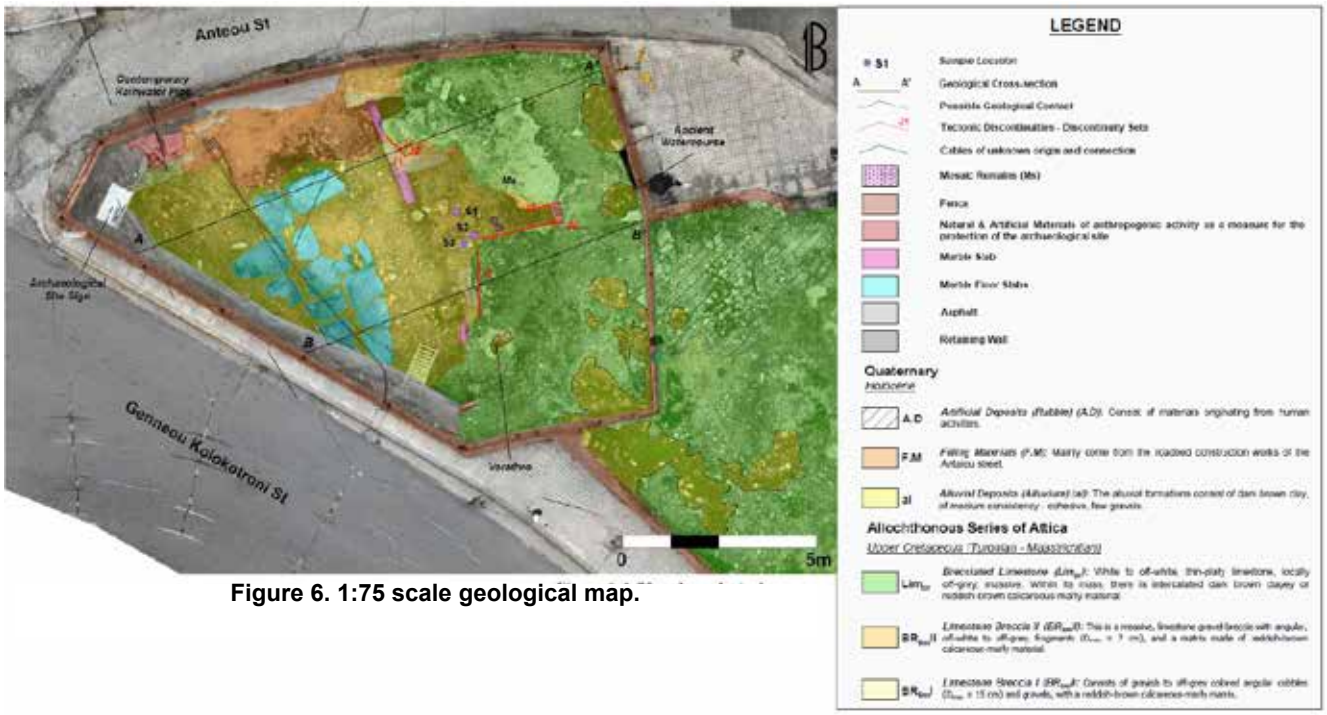

Figure 6. 1:75 scale geological map.

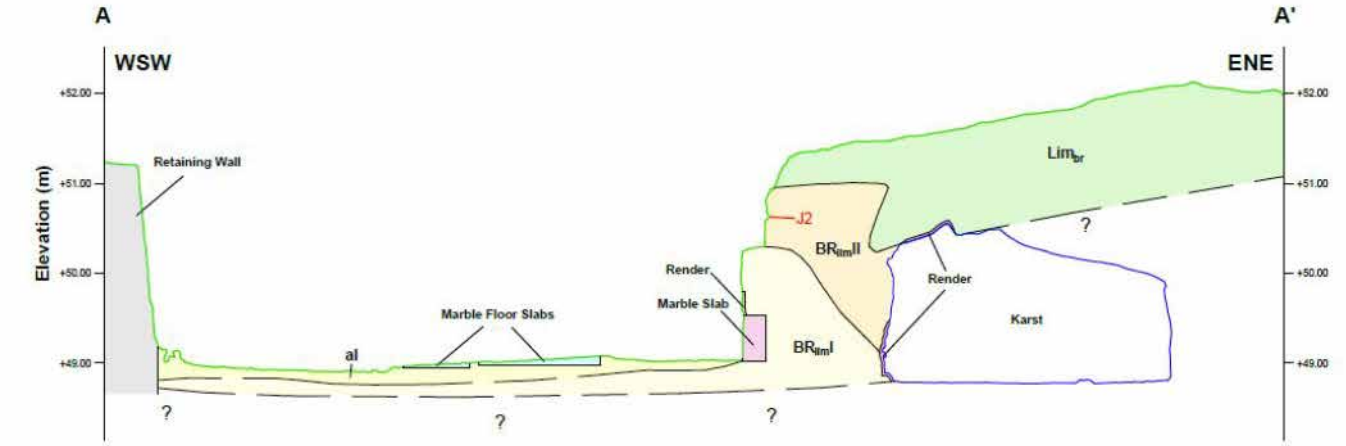

Figure 8. Output image following the geological mapping (cross-section).

Conclusions

The city of Athens is one of the driest places in Greece and the streams and rivers that cross it are of short length and

have a strong seasonal flow. The anxiety and care of the ancient inhabitants of the city for the provision, management and distribution of water is strongly reflected in a series of works that dominated the city (aqueducts, baths, fountains, wells, reservoirs, rainwater and sewage pipes).

The fact that concentration of considerable amounts of rainwater may be observed on the floor of the archaeological site during extreme rainfall phenomena, combined with the fact that no flood forecasting works (overflow) are provisioned leads to the conclusion that measures may be required for the management of rainwater in order to protect the Monument from future flooding phenomena. It is also proposed to consider the necessity of erecting a metal roof to in order to protect the Fountain from rainwater.

In case of intense rainfall and/or possible seismic loading, the technical-geological characteristics of the loose formations (backfill materials) that occur in the environment of the Fountain may be degraded. It is therefore estimated that some type of intervention should be needed in the future, in order to stabilise these formations.

Precaution stabilization measures are proposed to be taken (e.g. wire rope fencing, either filling of the discontinuities or scaling by simple mechanical means) regarding the northern pillar of the Fountain, where a wedge-shaped detachment of a significant volume of the Breccia Limestone (Lim_{br}) limestone was noticed in the cross-section of three (3) levels of tectonic discontinuities.

In the event of heavy rainfall and seismic loading, the mechanical behaviour both of the Breccia Limestone (Lim_{br}) and the Calcareous Breccia II (Br_{lim}II) formations may be impaired. It is underlined that the latter is found in the central parts of the pillars, in part of the roof of the cave and in the northern part of the fountain's plot creating precarious conditions for the integrity of the Monument. As far as the Calcareous Breccia I (Br_{lim}I) is concerned, which is mainly found at the base of the Fountain pillars and at the edges of the Backfill Materials (M.E.) on the north side, it has satisfactory mechanical behaviour.

Finally, in the context of the present investigation, the rock failures noticed or/and the potential rock slides due to unstable conditions found along specific tectonic discontinuities, should be taken into account for the design and planning of retaining works and roof support of the Fountain rock environment and construction correspondingly (Fig.5).

Introduction

Coastal regions located above subduction zones are useful to understanding the complex tectonic processes occurring at convergent plate boundaries. They are particularly significant when they contain geomorphic markers, which offer information into the deformation of the upper plate. Such markers enable researchers to quantify tectonic activity, making these areas a focus of scientific investigation (e.g., Lajoie, 1986; Marquardt et al., 2004; Pedoja et al., 2011).

Palaeoshoreline markers—including beachrocks, marine notches, benches, marine terraces, and palaeostrandlines—serve as indicators of past shoreline positions and are essential tools for assessing long-term tectonic movements, particularly in terms of rock uplift rates and tilting patterns in tectonically active regions. By providing a record of crustal deformation over geological timescales, these features allow researchers to reconstruct the interaction between tectonics, sea-level changes, and coastal processes (Merritts and Bull, 1989; Mouslopoulou et al., 2015).

Among these indicators, marine terraces are particularly noteworthy. Marine terraces form in areas where tectonic uplift elevates former coastal platforms above sea level. They generally consist of two distinct elements: an abrasion platform, a relatively flat surface that slopes seaward, shaped by wave action; and an inland-facing sea cliff, which forms at a stable angle of repose due to coastal erosion. The junction between the flat palaeoplatform and the inland palaeocliff is called the palaeoshoreline angle, or the inner edge of the platform. This angle is often preserved as a wave-cut notch, providing a direct indicator of the sea level at the time of terrace formation (Burbank and Anderson, 2007).

The palaeoshoreline angle is of particular importance because it closely approximates the elevation of the sea level during its formation, typically corresponding to periods of highstand when sea levels were stable. As a result, it serves as a critical palaeo-horizontal marker that allows researchers to analyze tectonic tilting and to map vertical movement of the Earth's crust. These analyses can help to identify tectonic activity over extended timeframes (Lajoie, 1986; Scott and Pinter, 2003).

In Greece, marine terraces provide compelling evidence of tectonic uplift and are widely observed along the southern coastline of the Gulf of Corinth (the Corinth Rift) and throughout the forearc of the Hellenic Subduction Zone. This includes areas such as the south- and southwestern Peloponnese and the islands of Cephalonia, Kythera, Crete, Karpathos, and Rhodes. (Armijo et al., 1996; Gaki-Papanastassiou et al., 2011; Strobl et al., 2014; Karymbalis et al., 2013;2022; Tsanakas et al., 2022).

The aim of this study is to identify and map the uplifted marine terraces along the western and eastern coasts of the Laconic peninsula, SE Peloponnese, through digital elevation model analysis utilizing GIS techniques and extensive field work.

Study area

The study area is located along the western and eastern coasts of the Laconic Peninsula (Fig. 1a). The alpine rocks of the study area belong to two tectonic units (Fig. 1b). The lower one is the high-pressure metamorphic unit called Phyllites-Quartzites (PQ) Unit while the upper one is the non-metamorphic Tripolis Unit (Lekkas et al., 1997; I.G.M.E, 1999). The PQ Unit consists of mica schists and quartzites and have suffered at least four deformation phases. The upper Tripolis Unit consists of a volcanosedimentary sequence of Permio-Triassic age (Tyros Beds) followed by a thick carbonate sequence of limestones and dolomites of Mesozoic to Lower Tertiary age (Lekkas et al., 1997; I.G.M.E, 1999). The Pelagonian unit crops out in a very small part and consists of limestones (mainly biosparites) of the Upper Cretaceous age (I.G.M.E, 1999). The occurrence of Pliocene-Pleistocene sedimentary sequences of marine origin up to ~180 m above present-day sea level is the most evident consequence of the widespread Quaternary uplift due to the proximity to the Hellenic Subduction Zone. Pliocene formations are composed of marine deposits occasionaly including gypsum layers and Pleistocene formations consist of marine deposits mainly marls, clays, sands and conglomerates (I.G.M.E, 1999). The Holocene deposits consist of talus cones, scree and unconsolidated alluvial deposits.

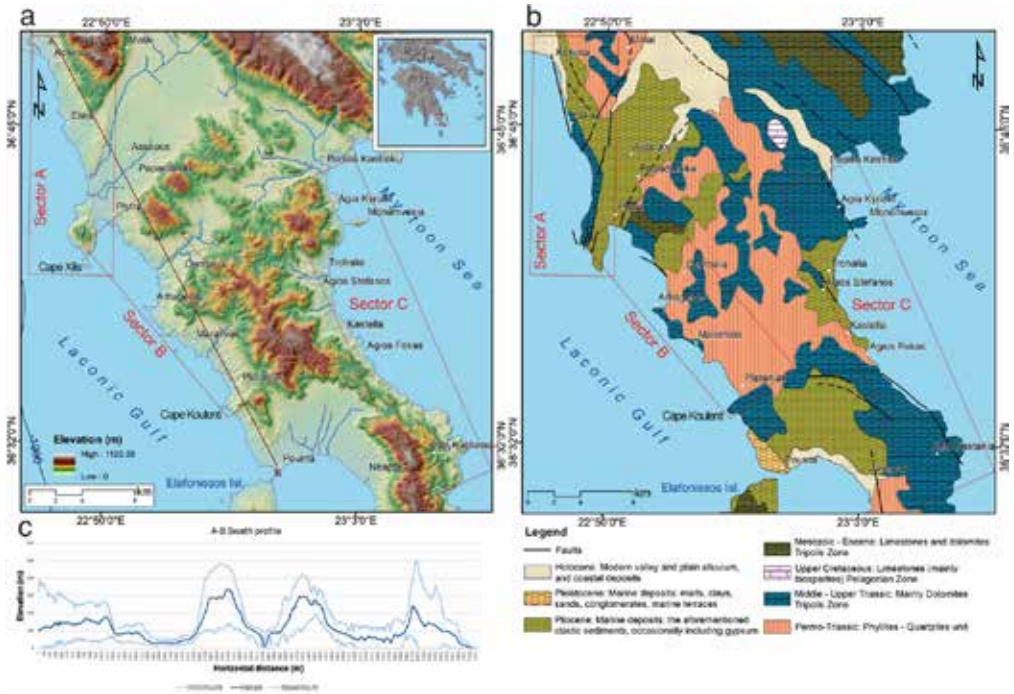

Figure 1. a) Map showing the Laconic Peninsula's location in Greece, the three study sectors, and the region's topography based on a digital elevation model (DEM). b) Geological map of the study area (IGME, 1999). c) Swat Profile along A-B line.

The study area is tectonically very active since it is situated approximately 60-80 km E-NE of the Hellenic subduction zone where the African tectonic plate is subducting beneath the Eurasian plate at a rate of ~36 mm a^{-1} (Reilinger et al., 2006). The Hellenic subduction zone is the largest and most seismically active subduction zone in the Mediterranean as revealed by earthquakes, seismic tomography and seismic reflection data (e.g. Wortel and Spakman, 2000). Rates of crustal motion offshore the Peloponnese and the Island of Crete, estimated from GPS measurements, are up to ~40 mm a^{-1} (Kahle et al., 2000). It is obvious that the geodynamic processes in the study area are also related to the active convergent plate boundary hence it provides a first-order example of actively deforming continental crust situated in the forearc of a subduction zone.

Specific focus was given in three sectors within the Laconic Peninsula (Fig. 1a). Sectors A and B are situated on the western coast of the Maleas Peninsula (eastern Laconic Gulf), between Kokinia and Cape Xilis and between Plytra and Cape Koulenti respectively. The bathymetry of the Laconic gulf shows an asymmetric basin, elongated in the N-S direction with the axis of the basin running close to the eastern coastline (Papanikolaou et al, 2001). The asymmetry is marked by the difference in the slope morphology, which shows abrupt slopes along the eastern margin as opposed to more gentle slopes along the western margin of the gulf (Papanikolaou et al, 2001). The basin is bounded by N-S marginal normal faults which control the geometry of the basin by producing subsidence (of more than 1000 m) (Papanikolaou et al, 2001) at its central part and uplift at the margins.

Sector C is located on the eastern part of the Laconic Peninsula, between Paralia Kastraki and Kato Kastania. The coastal morphology of sector C is steep enough due to recent fault activity (Lapas et al, 2011).

Data and methods

The detailed mapping of the distinct marine terrace surfaces and their inner edges has been carried out using both Geographic Information System (GIS) analyses and field techniques (Tsanakas et al., 2019). Data for the GIS analyses included a 5m cell size DEM obtained from National Cadastre & Mapping Agency S.A., the geological maps of the study area, at 1:50,000 scale, published by the Institute of Geology and Mineral Exploration of Greece, and the neotectonic map of Gythio, Neapolis and Elafonisos (Scale 1:100.000) published by the Earthquake Planning and Protection Organization and the European Center on Prevention and Forecasting of Earthquakes.

For the delineation and mapping of the marine terraces and their corresponding inner edges, a Red Relied Image Map was produced. This method is based on multi-layered topographic information computed from three - dimensional data (DEM). The basic concept is the multiplication of three element layers, topographic slope, positive and negative openness (Chiba et al., 2008). Positive and negative openness were defined by (Yokoyama et al., 2002). Negative openness represents concavities of surfaces and takes higher values on landforms such as valleys, gorges, or the inside parts of craters (Figure 2a). On the other hand, positive openness represents convexities and is ideal for mapping crests, ridges, scarps etc (Figure 2b). In this way the Red Relief Image Map can visualize not only topographic slopes, but also concavities and convexities at the same time.

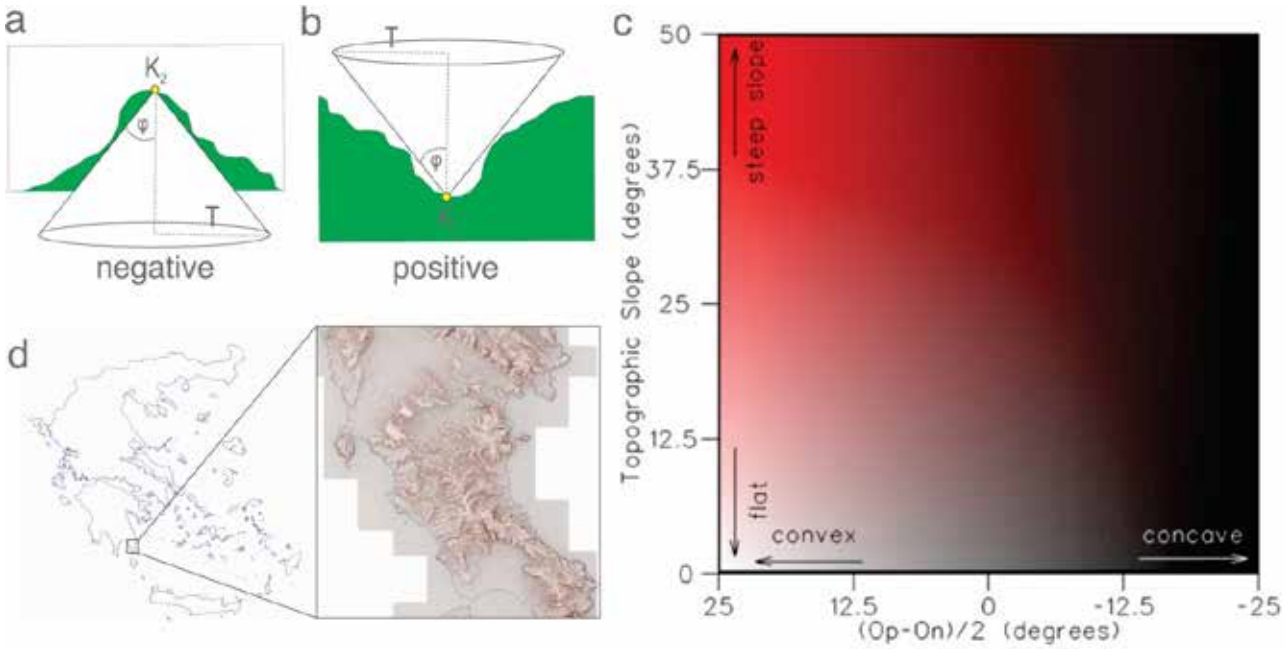

Figure 2. Conceptual diagram of positive openness (a) and negative openness (b), modified by (Yokoyama et al., 2002). c) Colour diagram of RRIM. Topographic slope is showed as chroma value of red (y axis) and (Op-On)/2 is showed as brightness (x axis) (Chiba et al., 2008). d) Red Relief Image Map (RRIM) of part of the Laconic Peninsula. The visualization emphasizes topographic details such as ridges, valleys, and escarpments and flat surfaces.

The generation of the RRIM is based primarily on the calculation of the Ridge and Valley Index (RVi) (Chiba et al., 2008) as shown below:

$$RVi = \frac{Op-On}{2} \quad (i)$$

where Op is the positive openness and On is the negative openness as defined by Yokoyama et al, (2002). The RVi overcomes the dependency on incident light direction, unlike shaded relief images, while capturing both convexity and concavity. It assigns high values to convex features and low values to concave ones. In RRIM, this information is displayed using a grayscale layer for topographic expression and a red layer for slope (Figure 2c).

The derivative mentioned above, along with imagery from Google Earth and UAVs, was visually analyzed and interpreted to create an initial morphographic sketch of the study area, highlighting marine terrace surfaces and their inner edges. Comprehensive fieldwork was essential for validating this preliminary sketch and producing the final map of the uplifted marine terraces.

The field survey primarily focused on examining the spatial distribution of the uplifted terraces and verifying the accuracy of inner edge elevations at specific points. Field validation was crucial for refining and confirming the maps and sketches derived from the DEM analysis, as well as the Google Earth and UAV imagery interpretation. The entire study area was thoroughly examined to verify most of the uplifted marine terraces identified during the earlier stages. A handheld Topcon GMS-2 differential GPS (DGPS) was used to record precise waypoints marking the locations of inner edges, which correspond to former shorelines. During the post-field mapping phase, the collected GPS data was integrated into the existing GIS database. A comparison of field-based observations and remote sensing data was conducted to validate the preliminary marine terrace map and facilitate the creation of final maps.

The resulting maps illustrate a sequence of well-defined marine terrace surfaces, categorized based on the elevation ranges of their inner edges.

Results

The GIS procedures combined with field survey identified sequences of uplifted marine terraces in sectors A and B along the western coast of the Laconic peninsula and in sector C along the eastern coast (Fig. 3).

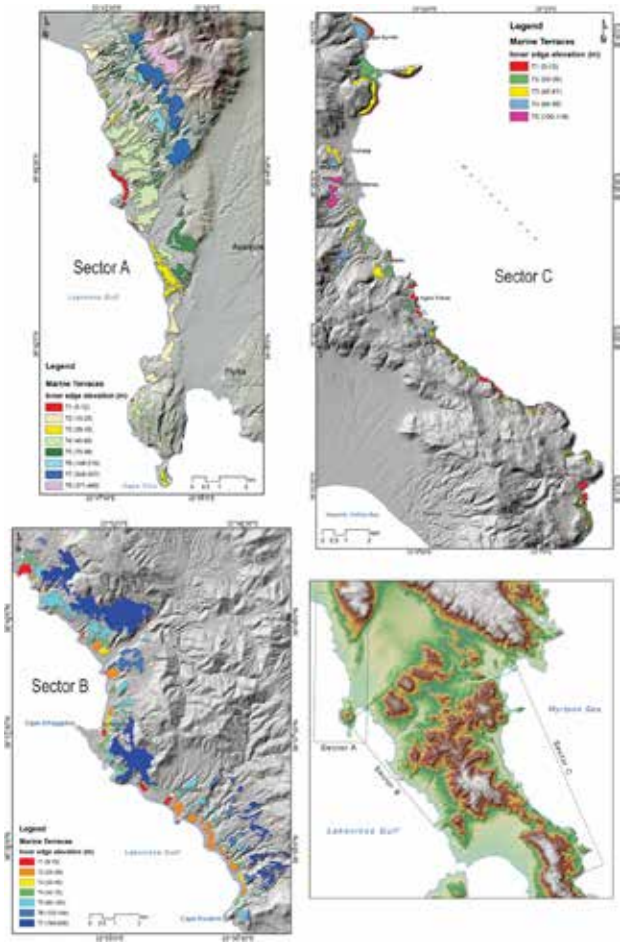

Figure 3. Map of the uplifted marine terraces in sectors A, B and C in the Laconic Peninsula.

Sector A

A sequence of eight uplifted marine terraces has been identified and mapped in sector A, between Kokkinia and Cape Xilis (Fig 3a). In most locations, these terraces are characterized by well-preserved wave-cut surfaces interrupted by landward palaeocliffs. The inner edge elevations range from 5 to 12 m above sea level for the lowest terrace and from 371 to 460 m above sea level for the highest one. Terraces T_1, T_2, T_3, T_4, T_5, and T_6 are primarily cut into Mesozoic-Eocene limestones and dolomites of the Tripolis Zone, as well as Middle to Upper Triassic dolomites of the same geotectonic zone. The highest terraces, T_7 and T_8, are cut into Permo-Triassic phyllites and quartzites. In some locations, the T_2 and T_4 terraces are overlain by well-cemented sediments, forming a prominent cap-rock. Terraces T_2, T_4, T_5, T_6, T7, and T_8 can be traced across a large part of sector A but are not laterally continuous due to intense fluvial incision. The T_1 terrace has been identified mainly in the Elaia area.

Sector B

In sector B, located between Plytra and Cape Koulenti (Fig. 3b), a sequence of seven uplifted marine terraces has been identified and mapped. Compared to those in sector A, these terraces are less well-preserved. Their elevations range from 9 to 15 m above sea level asl for the lowest terrace and from 160 to 200 m asl for the highest one. The terraces have been incised into Mesozoic-Eocene limestones and dolomites and Middle to Upper Triassic dolomites of the Tripolis Zone, as well as into Permo-Triassic phyllites and quartzites. The extensive fluvial incision within this sector has disrupted their lateral continuity. Terraces T_1 and T_3 are highly fragmented, with only isolated remnants preserved in a few locations. In contrast, Terrace T_5 exhibits more extensive preservation and can be traced at multiple sites across sector B. The most prominent feature is Terrace T_7, which appears particularly extensive in the central and northern portions of the sector. Its relatively broad morphology suggests it may represent a well-developed rasa surface, indicative of prolonged erosional processes and subsequent tectonic uplift.

Sector C

In the eastern part of the Laconic peninsula (sector C), a well-preserved sequence of five uplifted marine terraces has been identified, forming a distinct flight of emerged abrasion platforms (Fig 3c). These terraces exhibit inner edges ranging from 5 to 15 m above sea level for the lowest terrace (T_1), up to 100 to 118 m asl for the highest terrace (T_5). The terraces are primarily

carved into Mesozoic-Eocene limestones and dolomites, Middle to Upper Triassic dolomites of the Tripolis Zone, and Permo-Triassic phyllites and quartzites. Compared to sectors A and B, the terraces in sector C exhibit greater lateral continuity. This continuity is likely attributed to the reduced density of drainage networks and the smaller size of drainage basins in this area, resulting in minimal fluvial incision and better terrace preservation.

Discussion

The study of marine terraces in the Laconic Peninsula provides information into the tectonic and geomorphological evolution of the region during the Late Pleistocene. Our findings, supported also by previous research, suggest that the broader area has experienced tectonic uplift during the late Pleistocene, likely driven by its proximity to the Hellenic subduction zone.

Marine terrace analysis revealed notable spatial variations between sectors A, B, and C, which can be attributed to tectonic deformation and differential uplift rates. In sector A, eight distinct marine terraces were identified, and they were found at higher elevations compared to the seven terraces in sector B. This pattern can be explained by the presence of the Molai normal fault, which separates the two sectors (Fig 1b). Sector A is situated on the footwall of this fault, resulting in a higher degree of uplift compared to sector B, which lies on the hanging wall.The vertical displacement of marine terraces between sectors A and B further supports the tectonic influence of the Molai fault. The lack of consistent terrace elevations between these sectors further enhances the role of fault-related deformation in shaping the landscape.

The T_1 marine terrace in sector B can be traced in the broader area of Neapolis, Profitis Ilias, and Agia Marina (Kelletat et al., 1976; Tsartsidou et al., 2002; Karymbalis et al., 2022). Previous research by Karymbalis et al (2022) linked this terrace to Marine Isotope Stage (MIS) 5a. The dating conducted in this study in the nearby Neapoli Bay region provided an uplift rate of 0.36 ± 0.11 mm a□¹ over the last 215 ± 5.5 ka. Given the geomorphological similarities, it is reasonable to apply this uplift rate to sector B. However, this uplift rate is unlikely to be uniform across the entire Laconic Peninsula due to the presence of local faults, which create differential uplift patterns between sectors A and B. The localized tectonic deformation necessitates caution when extrapolating uplift rates across different sectors. Absolute dating of terraces in both sectors A and B is necessary to accurately correlate terraces between these sectors and to draw conclusions regarding the activity of the faults.

Sector C displayed significantly fewer marine terraces (five) and at much lower elevations compared to sectors A and B. This sector is situated farther from the influence of the Hellenic subduction zone, resulting in reduced tectonic activity and a correspondingly lower rate of uplift.

Conclusions

The distribution and elevation of marine terraces across the Laconic Peninsula are clear indicators of differential tectonic uplift driven by proximity to the Hellenic subduction zone and the influence of local faults. The higher number and elevation of terraces in sector A compared to sector B reflect the footwall-hanging wall relationship imposed by the Molai normal fault, while the reduced number and elevation of terraces in sector C suggest the diminishing tectonic influence with distance from the subduction zone. These findings contribute to a better comprehension of the tectonic evolution of the Laconic Peninsula and emphasize the need for localized geomorphological assessments when interpreting uplift rates and landscape development. Further detailed geochronological studies are recommended to refine the age constraints of the marine terraces and improve our understanding of tectonic activity in the region.

Introduction / Background

Satellite data may have a decisive contribution to the preliminary exploration of geothermal fields, enabling large-scale investigations of target areas in a cost-effective manner, while providing access to otherwise inaccessible locations (Abubakar et al., 2017; Silvestri et al., 2020). The use of satellite data in hydrology is increasing due to the availability of high-resolution data for monitoring parameters such as soil moisture, precipitation, evapotranspiration, irrigation water use, and reservoir water volumes. Soil moisture data is also employed in slope stability, flooding, and landslides investigation (Brocca et al., 2023). Satellite-based detection of thermal anomalies in geothermal regions has been explored in previous studies (Silvestri et al., 2020). Different categories of satellite data can be applied in geothermal research, including thermal data to identify water discharges, tectonic data to assess structural features, and land cover data for land-use analysis.

The Thermal Infrared Remote Sensing (TIRS) method, registers electromagnetic radiation based on surface temperatures. Thermal infrared radiation penetrates the Earth's atmosphere efficiently in two wavelength ranges, 3.5–5 μm and 8.0–14.0 μm, enabling thermal imaging acquisition during both day and night. This data is primarily used to map thermal anomalies and detect submarine thermal water discharges in offshore areas (Abubakar et al., 2017; Meijerink et al., 2007). Thermal and quantitative variations of the water draining into the sea can complicate the detection of thermal discharges. Evapotranspiration can also be estimated by combining thermal and meteorological data.

Satellite data can also be used for tectonic analysis in geothermal fields, facilitating the detection of thermal fluid pathways across fault structures in reservoir rocks. The use of data from Synthetic Aperture Radar (SAR) and other remote sensing techniques, enables the investigation of the subsurface dynamics in geothermal fields and the characterization of structural discontinuities (Abubakar et al., 2017; Ali et al., 2016; Saepuloh et al., 2015). Satellite data are useful for mapping tectonic structures, providing critical insights into the geological framework and the evolution of geothermal areas. These datasets serve as a valuable tool for assessing the impact of tectonic activity in the study area (Silvestri et al., 2020)for example, following the evolution of thermal anomalies, which may represent a modification of the current state of the geothermal field and a possible hazard for both the population and industrial assets. Here, we show the results obtained in three field campaigns during which the simultaneous acquisition of Landsat 8 satellite and UAV (FlyBit octocopter, IDS, Rome, Italy.

Although land cover is not directly related to geothermal processes, satellite-derived land use data can be a valuable support for preliminary studies on geothermal fields. Such information could help in identifying surface features that indicate ongoing geothermal activity, such as altered vegetation of arid land, as well as in assessing accessibility for future field work and infrastructure development. The data from the Sentinel-2 satellite offers significant advantages for land use monitoring, as it has a high spatial and temporal resolutions of 10 meters and revisiting capability of 5 days, and also includes red-edge bands. The integration of Sentinel-2 data with other remote sensing datasets offers enhanced analysis of land cover mapping and provides valuable observations in the development of crops, forests and urban areas. Satellite data for land use are also used to monitor water resources and natural hazards. Sentinel-2 data monitoring capability can be reduced due to cloud cover, but shows high compatibility with other satellite data, such as Landsat thermal imagery, which helps to mitigate the effects of cloud interference (Phiri et al., 2020).

This study emphasizes the crucial contribution of remote sensing in geothermal field research by providing valuable insights in advance of field research. It provides recommendations on how satellite data can be used in geothermal studies and serves as a methodology that can be applied in future research in geothermal regions. Using the geothermal field of the Methana peninsula as a case study, we present here a methodology that integrates different satellite data from multiple satellite systems and demonstrate its applicability to other geothermal systems.

Geological setting

The geological structure of Argolis, encompassing the Methana peninsula, is complex and remains partially interpreted. The region (Photiades & Deligiannakis, 2022; Suesskoch et al., 1974) includes three main geological units: (a) Post-Alpine Formations comprising Quaternary alluvial deposits, colluvial sediments, debris cones, and Pliocene-Pleistocene conglomerates, marls, and sandstones of the Porto Heli-Kranidi Unit; (b) Post-Alpine Volcanic Formations of Methana-Poros, dated to the Middle-Upper

Pleistocene; and (c) Alpine Formations, subdivided into the Didyma Unit (Sub-Pelagonian) with schists, sandstones, cherts, ophiolites, and limestones, and the Complex Upper Tectonic Unit of Southern Argolis, including the Adheres flysch, Cretaceous carbonates, and ultrabasic serpentinites. The Methana peninsula (Fig. 1) is predominantly volcanic, with Cretaceous limestones and conglomeratic formations exposed at its southern tip, and alluvial deposits and debris cones observed in coastal areas and stream channels. The peninsula's volcanic rocks include: a) Loose Reworked Volcanic Materials characterized by poor stratification, b) Pyroclastic deposits identified in the Kameno Vouno complex and Paleokastro dome, consisting primarily by black tuffs with scoria layers and xenoliths of metamorphosed limestones. c) Breccias that represent dome collapse and pyroclastic flows. d) Dacites (SiO_2: 63–70%) structured in domes and lava flows with zoned plagioclase, hornblende, orthopyroxene, and biotite. Quartz and magnetite are common, with signs of magmatic corrosion. e) Andesites that are subdivided into: Basaltic Andesites (SiO_2: 52–56%) with porphyritic textures, zoned plagioclase, pyroxenes, magnetite, and sporadic olivine and hornblende; and andesites (SiO_2: 56–63%) with similar textures, abundant hornblende, dispersed biotite, magnetite, and quartz with reaction rims. Regarding the tectonic regime according to Tzanis et al., (2018, 2020), the ascent of magmatic material that fuels volcanic eruptions in the broader Methana region occurs through major fault structures mapped in the area. These fault and fracture zones are oriented along NW-SE, NE-SW, and WNW-ESE directions. Radiometric K-Ar dating places volcanic activity between 0.75 and 0.32 Ma. The youngest volcanic dome dates to 258 BC in the Kameni area, while the last recorded eruption occurred in AD 1700 at the submarine "Pausanias" volcano, north-northwest of Kameni. Detailed documentation of the latter was provided by Foutrakis and Anastasakis, (2018).

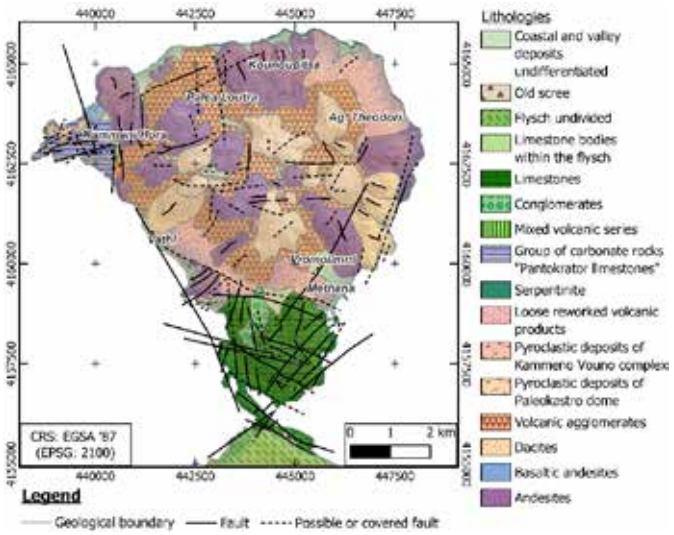

Figure 1. Geological map of Methana.

Methodology

The first step of the study was to digitize the geological map of the Methana peninsula using to identify the geological factors that influence groundwater circulation. This process was implemented using the Quantum GIS (QGIS) software and was based on the geological sheet provided by the Hellenic Authority for Geological and Mineral Exploration (EAGME), illustrating the geological formations and fault structures and the onshore tectonic discontinuities in the study area mapped by Tzanis et al., (2020) (Fig. 1). The satellite data analysis is implemented according to the following six consecutive phases: a) collection and evaluation of available data, b) field survey to address gaps, including periodical water level measurements, c) establishment of GIS-linked databases, d) testing aquifer responses to scenarios of the future plans, e) implementation of a remote sensing technique to refine the geological map and create a lineaments map, and f) employment of satellite images to identify land cover / agricultural practices and generate a regional land-use map.

For the purposes of this study, satellite data were acquired from the Sentinel 2 and Landsat 9 satellites. To ensure the acquisition of high-quality data, cloud coverage threshold was adjusted to 10–20% during data selection, allowing an uninterrupted view of the peninsula and its surrounding area. These datasets provide critical information on thermal discharges, land cover, and fault structures. Digital Elevation Model (DEM) derived from the Hellenic National Cadastral authority was employed to analyze key hydrological and topographical parameters within the study area. It was utilized to delineate flow paths, watershed boundaries, and drainage basins. Furthermore, DEM enabled the estimation of stream order, elevation changes, slope, and upstream and downstream flow distances, providing insights into the geomorphological characteristics of the region. The collected data were synthesized and subsequently processed using the Quantum GIS (QGIS) and Datum Workstation software programs.

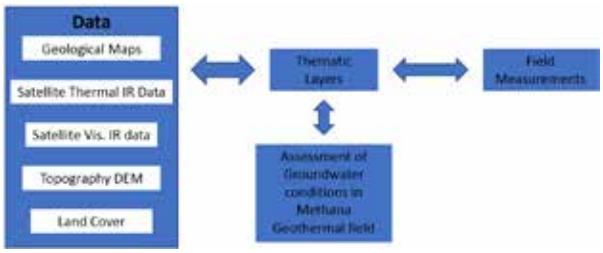

Figure 2: Methodology flow chart for satellite data analysis in geothermal field assessment.

Figure 2 presents the flow chart that describes the methodology followed in the terms of the present research, aiming in the deployment of satellite data in the examination of geothermal fields. Every step of the flow chart is serving a specific purpose. The next step in the process involved the analysis of Thermal Infrared Sensor (TIRS) data from the Landsat satellite to generate a map of surface coastal water outflows, enabling the identification and visualization of areas with elevated groundwater discharge potential. The detection of thermal discharges was initiated with the creation of a buffer zone, enabling the selection of the desired portion of each satellite image. This buffer zone was defined to extend 2 km from the coastline, directed outward toward the sea. The selected satellite images were acquired from the Bands 10 and 11 of Landsat 9. Subsequently, the parts of the satellite images within the buffer zone were extracted and the geospatial analysis was performed using Datum Workstation.
In the following phase, satellite images were employed to illustrate geological features, such as lithological units, tectonic discontinuities, lineaments, and land cover on a map. This analysis provides valuable insights into the factors that affect the overall conditions of groundwater. All thematic maps were validated through field confirmation, including in situ measurements in water samples.

Results and Discussion

The analysis of the acquired remote sensing data resulted in the generation of detailed images of the Methana peninsula that illustrate several key geophysical and environmental phenomena. Some of these images depict the thermal discharges from geothermal waters into the surrounding sea, offering insight into the heat exchange processes occurring at the coastline. Data revealing mineral degradation processes resulting from the flow of hydrothermal fluids through rock formations was also acquired. This information was utilized to identify alterations in the surface materials. Land uses were also depicted using satellite records, providing a comprehensive view of the spatial distribution of vegetation across the peninsula.
Thermal satellite data from Landsat 9 provide significant insights into the water discharges of the Methana peninsula, during the summer (Fig. 3a) and winter (Figs. 3b and 3c) periods. Surface runoff was computed using a 5-meter spatial resolution DEM, producing the hydrographic network of the study area, also illustrated in Figure 3. Stream classification was based on the Strahler system. During the summer period (Fig. 3a), thermal discharges from the peninsula to the sea are undetectable due to high seawater temperatures, obscuring the required thermal differentiation for their identification. In winter (Figs. 3b and 3c), thermal discharges are clearly revealed, marked with yellow circles, particularly in the southeastern part of the peninsula, as well as in the northern region. These areas correspond to the well-known thermal springs of Methana's baths, Agios Nikolaos and Pausanias. Field measurements confirmed the presence of thermal discharges, recording temperatures in thermal waters up to 35.7°C and a maximum electrical conductivity of 62,354 mS/cm (Tsekoura, 2024). It is observed that several higher-order Strahler branches of the Strahler classification converge in the areas with thermal discharges (N and SE), enhancing water flow from the peninsula to the sea.

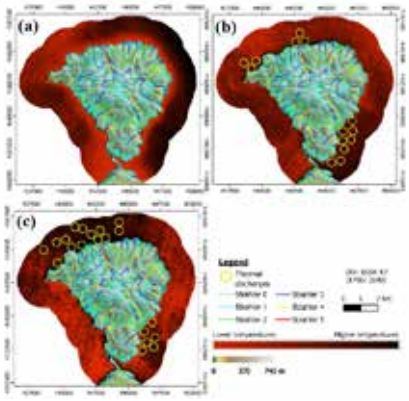

Figure 3. Digital Elevation map of Methana featuring the submarine thermal discharges in the summer and winter periods, based on thermal satellite records from Landsat 9 on (a) 25/07/2024, (b) 09/11/2022 and (c) 04/01/2023. The hydrographic network is displayed with Strahler stream order system.

Figure 4 was generated based on satellite data and highlights tectonic structures and mineral alteration zones in the Methana peninsula. The combination of geological and remote sensing data reveals the relationship between the tectonic evolution of the region and oxidation processes caused by the hydrothermal fluid flow within the volcanic and carbonate rocks of Methana. The bands utilized for the development of Figure 4 represent hydroxyl-bearing minerals (red) that are considered indicators of geothermal activity, along with iron oxides (green) that indicate oxidation processes and ferrous iron oxides (blue) that can be linked in specific mineral compositions. In this case, andesites and dacites (lithologies δα, α1 and α2) appear mineralogically differentiated, as indicated by their blue and green colors. A particularly characteristic occurrence of andesites is present in the NW part of the region, probably due to their elevated content in iron oxides. At this site, the volcanic rocks are originating from the most recent volcanic activity on the peninsula, which took place approximately 2,200 years ago, during historic times (D'Alessandro et al., 2017; Dotsika et al., 2010; Tzanis et al., 2020).

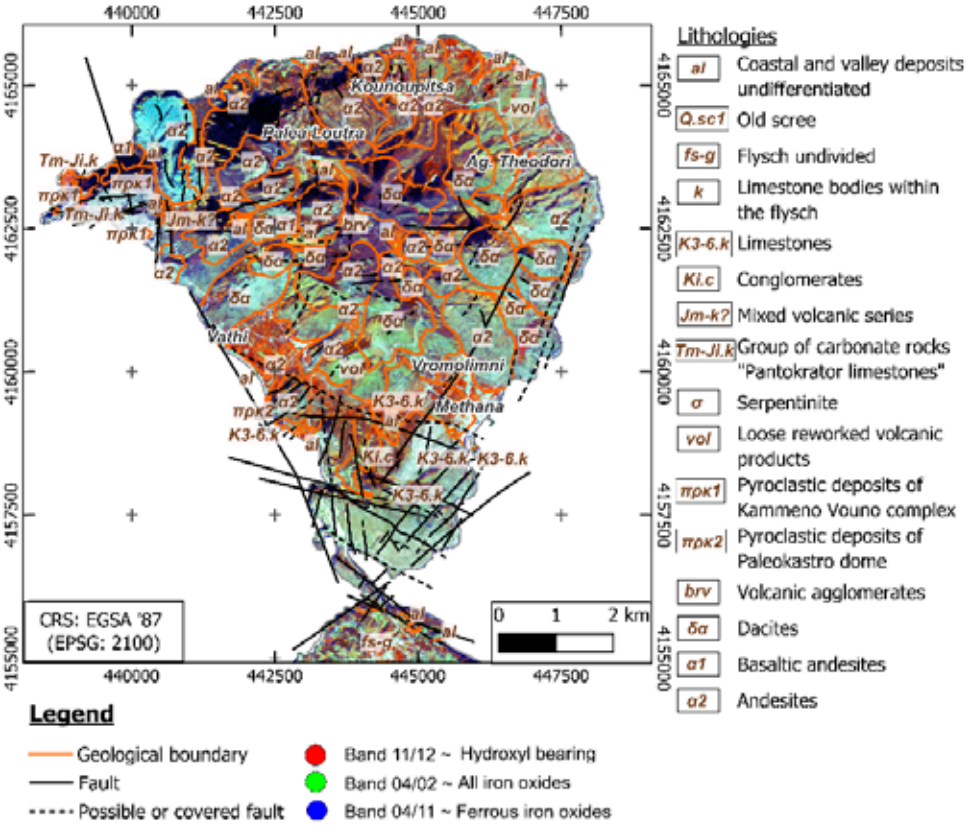

Figure 4. Geological map of Methana with tectonic elements and alteration zones using satellite-derived band combinations.

Figure 5 was generated using data from Sentinel-2 Bands 2, 3, and 4, providing a true-color visualization of vegetation and rock formations for enhanced readability. Digital optimization improved clarity and ensured a realistic representation of surface features. Visual processing of the satellite data revealed previously unmapped tectonic discontinuities, highlighted as dashed orange lines. The overlay of fault systems of Methana indicates terrain morphology and facilitates the identification of vegetation disruptions linked to fault activity, particularly in the W-E oriented faults in the southern region. The concurrent presentation of thermal discharges creates a synthetic visual presentation of the interaction between tectonic discontinuities and hydrothermal fluid flow on the peninsula.

The analysis of tectonic discontinuities in Methana (Fig. 5) provides insights into the region's volcanic evolution and geothermal potential. Faults alignment around the central and northwestern regions indicates a radial flow of andesitic and dacitic lavas toward the coast (Megalovasilis, 2014). In contrast, the southeastern fault systems are more linear and attributed to regional tectonic stress rather than volcanic activity. Identifying tectonic discontinuities, including potential covered faults, is crucial for assessing both seismic risks and their impact on the geothermal system. Furthermore, the development of the fracture network in a geothermal field is essential for identifying potential conduits for hydrothermal fluids. In this context, the NW-SE oriented possible faults of Methana should be mentioned, which appear to extend along the terrestrial corridor between the thermal discharges, linking the Pausanias hot spring in the north with the Agios Nikolaos and Methana hot springs in the southeastern part of the peninsula. Such insights are particularly valuable for the potential exploitation of geothermal resources.

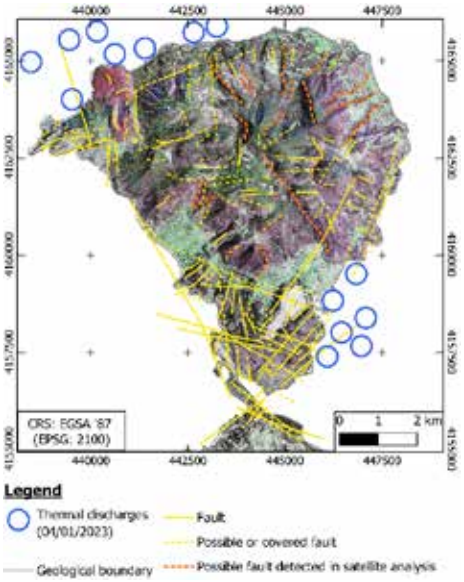

Figure 5. Digitally enhanced Sentinel-2 image in natural colors (RGB: 4/3/2), featuring the landscape of Methana, tectonic discontinuities and thermal discharges.

The Normalized Difference Vegetation Index (NDVI) and classified land cover map of Methana were created based on Sentinel 2 data (Fig. 6). Combining these maps provides a comprehensive view of the regional land use. The Corine land cover classification aligns closely with the NDVI values scaled to 100, confirming the extent of agricultural land and uncultivated areas. Forested areas and natural grasslands dominate the central, northern and NW parts of the peninsula. Agricultural zones, including olive groves and vineyards are more prominent in the NE and the southern areas. Higher NDVI values correspond well with the cultivated lands from the Corine map, whereas low NDVI values are associated with urban zones and barren lands, where the majority of volcanic rocks is located.

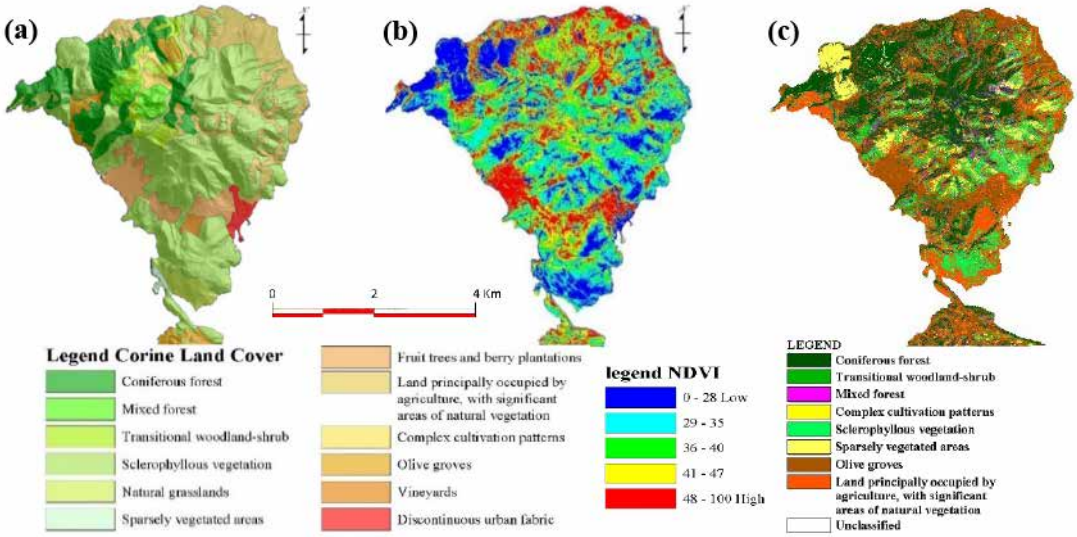

Figure 6. Land uses using Sentinel 2 data - L2A 19/01/2025, (a) Corine land cover map, (b) Map of the NDVI of bands 8 and 4 at 10 m resolution, (c) Land cover classification using Mahalanobis distance classifier bands 2 to 8 at 10 m resolution.

Conclusions

The conducted study revealed the potential of satellite imagery in the preliminary exploration of active geothermal fields, which also enables access in inaccessible areas. The methodology that is presented can be adapted to any active geothermal field,

providing valuable information regarding its potential. The identification of thermal discharges is among the primary benefits, for coastal geothermal systems, since it enables the detection of hot springs. It allows the early detection of geothermal resources, attracting potential investing interest for the exploitation of the geothermal resources of the region. The integration of geological information, including lithologies and fault systems, along with the spatial visualization of chemical components associated with hydrothermal discharges, facilitates the recognition of geological formations impacted by hydrothermal fluids within the study area. This approach improves the detection of fluid flowing paths within the reservoir rocks and surrounding formations. The utilization of digitally enhanced natural color maps generated from remotely sensed data may also enable the detection of non-mapped tectonic discontinuities, along with the identification of alterations in the local vegetation. Evaluating the land uses is equally important, since it provides valuable insights on the distribution of cultivated and arid areas. Land cover analysis is especially beneficial in order to evaluate the optimal method of utilizing geothermal energy to fulfill the existing needs of the region and support its further development. The use of remotely sensed data in the initial stages of evaluating and exploring active geothermal fields offers significant benefits. However, it is important to note that the analysis of satellite images can provide valuable insights, without fully substituting in-situ investigations of geothermal fields. Satellite analysis is subject to crucial limitations, the most significant of which include cloud coverage, which may hinder the acquisition of high-quality data, and spatial resolution constraints, which may prevent the detection of finer geological features. The presented approach requires limited financial resources and time, consisting an efficient and cost-effective methodology for utilizing satellite imagery as an initial step in the investigation of geothermal fields.

EXTENDED ABSTRACT 321

The influence of mineralogy on the non-dilatant friction angle of rock fractures

Tsikrikis A.[1], Marinos V.[2], Papaliangas T.[3]
(1) Aristotle University, Department of Geology, Thessaloniki, Greece, tsikrika@geo.auth.gr
(2) National Technical University, Department of Civil Engineering, Athens, Greece
(3) International Hellenic University, Department of Environmental Engineering, Thessaloniki, Greece.

Research Highlights

Laboratory results of direct shear tests on fresh tension-induced fractures of natural rocks are presented. The results indicate a clear influence of mineralogy on the non-dilatant sliding friction angle, with the values that correspond to fractures in carbonate rocks being distinctly higher than those of silicate ones.

Background

The shear strength of rock joints controls the mechanical behaviour of rock masses. The main factors affecting the shear strength of an unfilled joint are the mineral composition, the magnitude of the normal stress on the joint, the roughness and size of the joint, the degree of weathering, the joint wall strength, moisture and water pressure (Kulatilake, 1995).

The shear strength of a rock surface arises from three sources (e.g. Paterson and Wong 2005): (1) shearing of welded contacts and plastic flow (basic friction), (2) riding over topographic highs (dilation) and (3) local brittle fracture (asperity failure). At low normal stresses the asperity failure component can be ignored (Olsson and Barton 2001; Barton *et al*. 2023). In these cases, such as in slope stability problems, the other two shear strength components (basic friction and dilation) can be determined separately from direct shear tests, also referred to as sliding friction tests (Muralha *et al*. 2014). The dilation can be directly measured from normal and shear displacement diagrams and the sliding friction angle is determined easily and reliably, under conditions of non-dilatant shearing (i.e. dilation is zero) as the difference between the peak friction angle and the dilation angle (Hencher and Richards 1989, 2015).

Objectives

The objective of this laboratory-based study is (a) to examine the effect of mineralogy on the sliding friction angle of essentially flat surfaces with their natural texture retained and (b) to demonstrate that the shear strength of a rock joint can be considered to consist of two components: the first component is due to dilation (dilatant component), which depends on surface roughness, and the second is due to the frictional properties of the rock surface (non-dilatant component).

Methods

Blocks from ten rock types (six silicates and four carbonates) with porosities ranging from 0.15% to 4.29%, including three igneous (diorite, granodiorite and metadolerite), four metamorphic (amphibolite and 3 types of marble) and three sedimentary (2 types of sandstone and one limestone), were collected from natural outcrops, stone and marble quarries and tested in the laboratory. The samples of nine of the investigated rocks were collected from quarries and natural exposures in Greece. The tenth rock was Carrara marble from Italy, which was selected as a standard calcite rock material often used for laboratory tests. The petrophysical properties and the modal analysis of the ten rocks used in the study are depicted in Table 1.

The specimens used in the direct shear tests were rough artificial tension joints, created by inducing bending fractures in rectangular prismatic blocks. The rectangular shear surfaces of these specimens had average dimensions of 120 ± 16 mm in length and 80 ± 11 mm in width.

The tests were conducted using a custom-designed direct shear testing apparatus capable of accommodating samples of varying sizes and shapes and applying both shear and normal loads up to 100 kN. Shear forces were applied using a mechanical gear-driven actuator without closed-loop control, while a hydraulic actuator, connected to a constant-pressure pump, was used to maintain constant the selected normal load.

Shear displacement was monitored with a 25 mm linear variable differential transducer (LVDT) attached to the movable lower shear box, while dilation was measured using two additional 25 mm LVDTs positioned symmetrically, 1 cm from the edges of the specimen's upper half. The LVDTs offered an accuracy of 0.01 mm.

Table 1. Petrophysical properties and the modal analysis of the investigated rocks (Tsikrikis *et al*., 2024)

a/a	Rock name	Mean grain diameter (μm)	Dry density (kg/m³)	Open porosity (%)	Modal Analysis (%)
1	Rhodope Sandstone 1 (RS1)	134	2517	3.88	Q 56, K 18, Pl 22, M 4
2	Rhodope Sandstone 2 (RS2)	411	2513	4.29	Q 67, K 14, Pl 14, M 3, Kaol 2

9	Sithonia Granodiorite (SG)	1072	2621	1.79	Q 30, K 11, Pl 36, Bt 21, Chl 1, C 1
10	Mikrokleisoura Metadolerite (MD)	62	2761	1.13	Q 10, Pl 45, Chl 20, Op 20, Am 5

Q: Quartz, K: K-Felspar, M: Muscovite, Bt: Biotite, Pl: Plagioclase, Kaol: Kaolinite, Am: Amphibole, Chl: Chlorite, C: Calcite, Op: Opaque mineral, Do: Dolomite

All tests were performed under constant normal load (CNL) conditions, with normal stresses ranging from 5 kPa to 2.0 MPa. The multistage shear testing method was employed, with the joint repositioned to its original position before each shear stage, as described by Muralha *et al*. (2014). Repositioning during multi-stage tests significantly enhances accuracy compared to procedures without repositioning (MacDonald *et al.,* 2023).

Normal and shear stresses were computed by dividing the respective forces by the nominal area of the sample. The total relative shear displacement during testing was at least 5% of the specimen's length. Special care was taken to accurately record the normal displacement, which was subsequently used to calculate the dilation angle. This dilation angle enabled the separation of the total shear strength into two components: the geometric contribution due to dilation and the sliding frictional (non-dilatant) contribution.

The procedure followed for the determination of the non-dilatant friction angle from direct shear tests with detailed records of stress and dilation is described by Hencher and Richards (1989, 2015). The method is based on the assumption that shearing of a dilating joint (Figure 1i) is equivalent to a shear movement along an inclined plane (Figure 1ii), with a slope angle equal to the instantaneous dilation angle and involves resolving stresses with respect to the actual plane of sliding using the following equations:

$$\tau_i = (\tau\cos\psi - \sigma_n\sin\psi)\cos\psi \quad (1)$$

$$\sigma_i = (\sigma_n\cos\psi + \tau\sin\psi)\cos\psi \quad (2)$$

where
τ is the measured shear stress,
σ_n is the measured normal stress,
τ_i is the shear stress along the actual plane of sliding
σ_i is the normal stress along the actual plane of sliding and
ψ is the instantaneous dilation angle
An indicative diagram of measured and non-dilatant stresses is shown in Figure 1 (iii).

The direct shear test results were analyzed using the non-linear peak shear strength criterion for rock joints proposed by Papaliangas *et al.* (1995), which uses the non-dilatant friction angle as the basic frictional parameter. The criterion is described by equations (3) and (4):

$$\tau_p = \sigma_n\tan(\varphi_{nd} + \psi) \quad (3)$$

$$\tan\psi = \tan\psi_o(\log_{10}\frac{\sigma_{nt}}{\sigma_n})/(\log_{10}\frac{\sigma_{nt}}{\sigma_{no}}) \quad (4)$$

where
τ_p is the peak shear stress
σ_n is the normal stress

φ_{nd} is the sliding friction angle of a frictional, non-dilatant rock surface with zero tensile strength and cohesion
ψ is the dilation angle at the instant of peak shear strength, under effective normal stress σ_n
ψ_o is the peak dilation angle under a normal stress σ_{no} which causes negligible asperity deformation and
σ_{nt} is the transitional effective normal stress under which the normal dilation is completely suppressed.

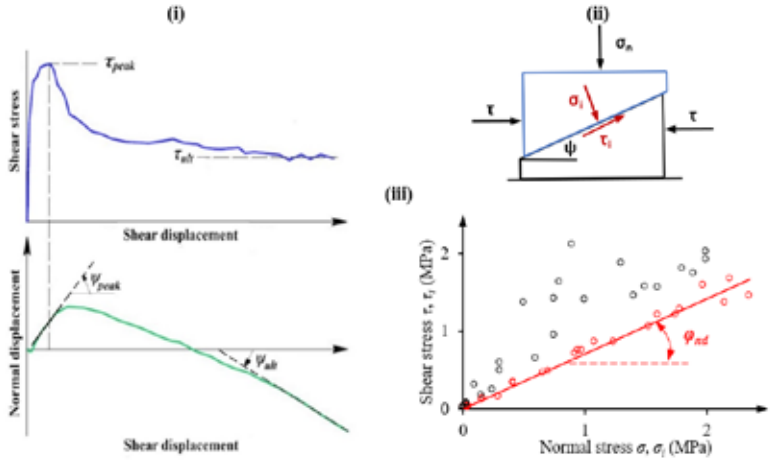

Figure 1. (i) Representative plots from a rock joint shear test conducted under constant normal stress conditions, following the ISRM recommended methodology.
(ii) Decomposition of applied stresses (σ_n, τ) into components acting on the sliding plane (σ_i, τ_i).
(iii) Peak shear stress (black) and non-dilatant shear stress (red) recorded during the tests (Tsikrikis *et al.*, 2024).

It is noted that both the sliding friction angle φ_{nd} and the maximum surface angle ψ_o (a three-dimensional roughness parameter) have clear physical meanings and are easily measurable in the laboratory.
When determined from direct shear tests of natural surfaces, the effect of various surface conditions like weathering, alteration, surface coating etc. is incorporated in the value of φ_{nd}.

Results

A total of 42 fresh, tension-induced joint specimens with prismatic geometry were prepared and subjected to direct shears testing, yielding 286 individual shear runs. The non-dilatant friction angle, a key parameter in the non-linear peak shear strength criterion proposed by Papaliangas *et al.* (1995), was employed to interpret the results, that are shown in Figure 2 for silicate rock samples and Figure 3 for carbonate ones.
For each pair of measured shear (τ) and normal (σ) stresses, the corresponding shear and normal stresses on the sliding plane (τ_i and σ_i) were calculated using the instantaneous dilation angle ψ. These stresses (τ_i and σ_i) represent conditions where shearing occurs without dilation along a naturally textured surface. In essence, they reflect stress states during non-dilatant shearing, where dilation is absent, and the granular texture of the surface exhibits no macroscopic roughness that could induce interlocking or dilation during sliding.
The non-dilatant friction angle (φ_{nd}) was derived from the slope of the regression line in the τ_i versus σ_i plot, as depicted in red in Figures 2 and 3. Peak shear strength envelopes, including an upper and lower bound, were fitted to the data using Papaliangas' criterion (Papaliangas *et al.*, 1995). The parameters φ_{nd}, ψ_o, and σ_{nt} are provided in the respective graphs.
The non-dilatant friction angles of the ten investigated rocks ranged from 32.7° to 40.2°, revealing a clear distinction between carbonate rocks (range 34.1°–40.2°) and silicate rocks (range 32.7°–36.3°). When categorized by origin (igneous, metamorphic and sedimentary) and mineralogy (silicates and carbonates), the following five subgroups emerged with the indicated values of φ_{nd}:
Igneous rocks:
Silicate (SG, TDR): 32.8º – 34.6º
Sedimentary rocks:
a. Silicate (RS1, RS2): 35.3º – 35.6º
b. Carbonate (GL): 34.1º
Metamorphic rocks:
a. Silicate (MD, TA): 32.7º–36.3º

b. Carbonate (TM, TKM, CM): 39.3º – 40.2º

The values of φ_{nd} correspond to the sliding friction angle of essentially flat surfaces with their natural texture retained and may be different (usually higher) from those of the corresponding values of saw-cut surfaces, that is attributed to the removal of the original rock texture caused by saw-cutting.

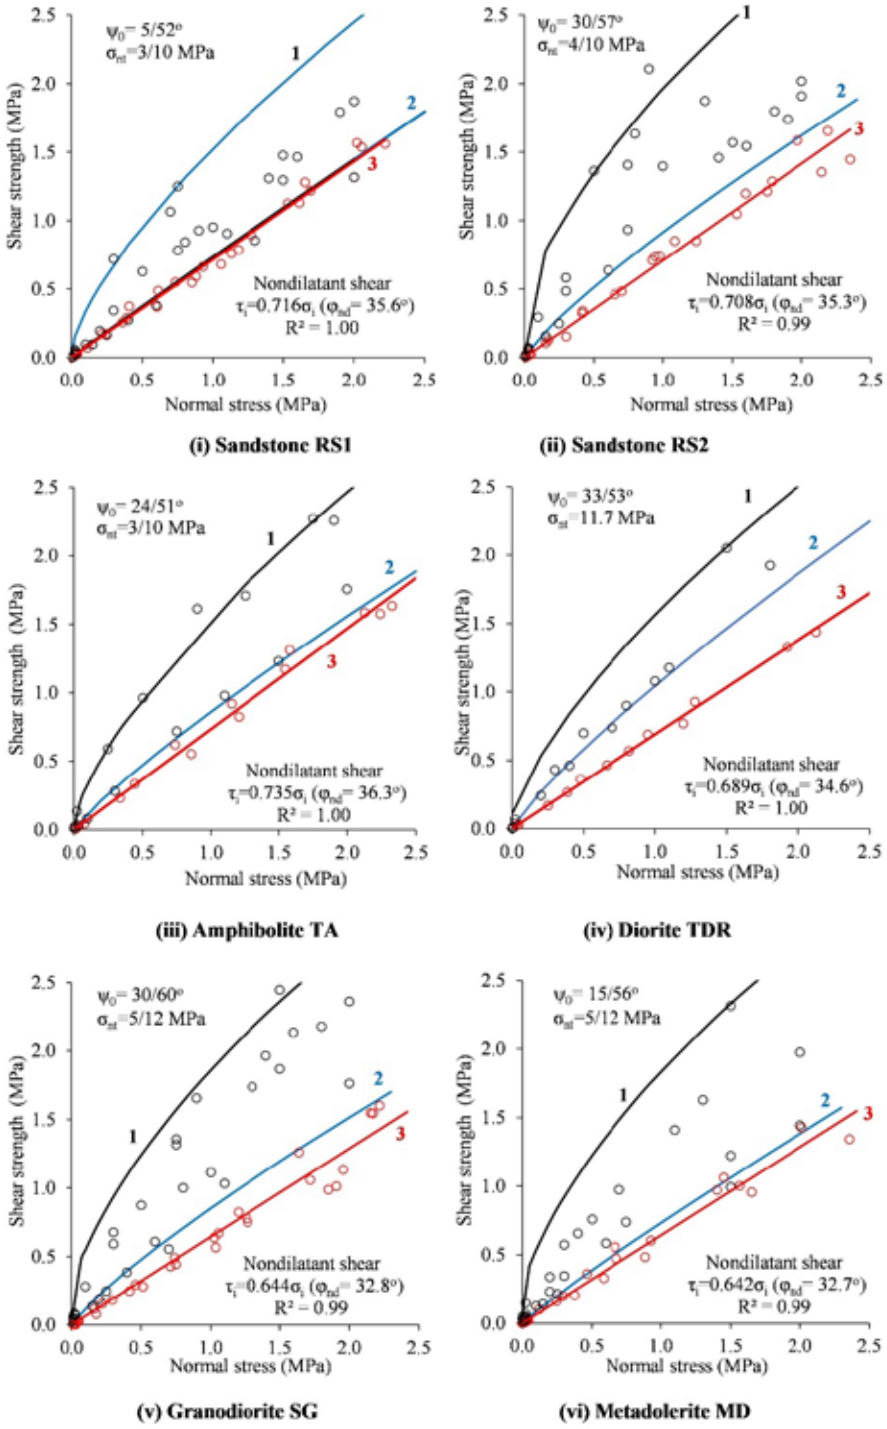

Figure 2. Fitted peak shear strength envelopes and the non-dilatant shear strength best-fit line for silicate rock induced tension joints. Curve 1 (black) and Curve 2 (blue) correspond to the upper and lower bounds of peak shear strength, respectively, as predicted by Papaliangas' criterion, with the parameters φ_{nd}, ψ_o, and σ_{nt} displayed on the diagram. Line 3 (red) denotes the non-dilatant shear strength (Tsikrikis *et al.*, 2024).

According to our results, the sliding friction angles for the studied rocks, are lower than those predicted from Byerlee's (1978) friction law $\tau = 0.85\sigma_n$ that provides an upper bound of our obtained values.
From the experimental results shown in Figures 2 and 3 it becomes evident that despite variations in peak shear strength across the tested rock types, the individual best-fit regression lines between normal stress and non-dilatant shear strength were well-defined. These linear relationships held consistently across the applied normal stress range (0–2 MPa), irrespective of mineralogy, grain size, porosity and joint surface roughness. This consistency highlights that non-dilatant shear strength is fundamentally frictional, as it is proportional to the applied normal stress.

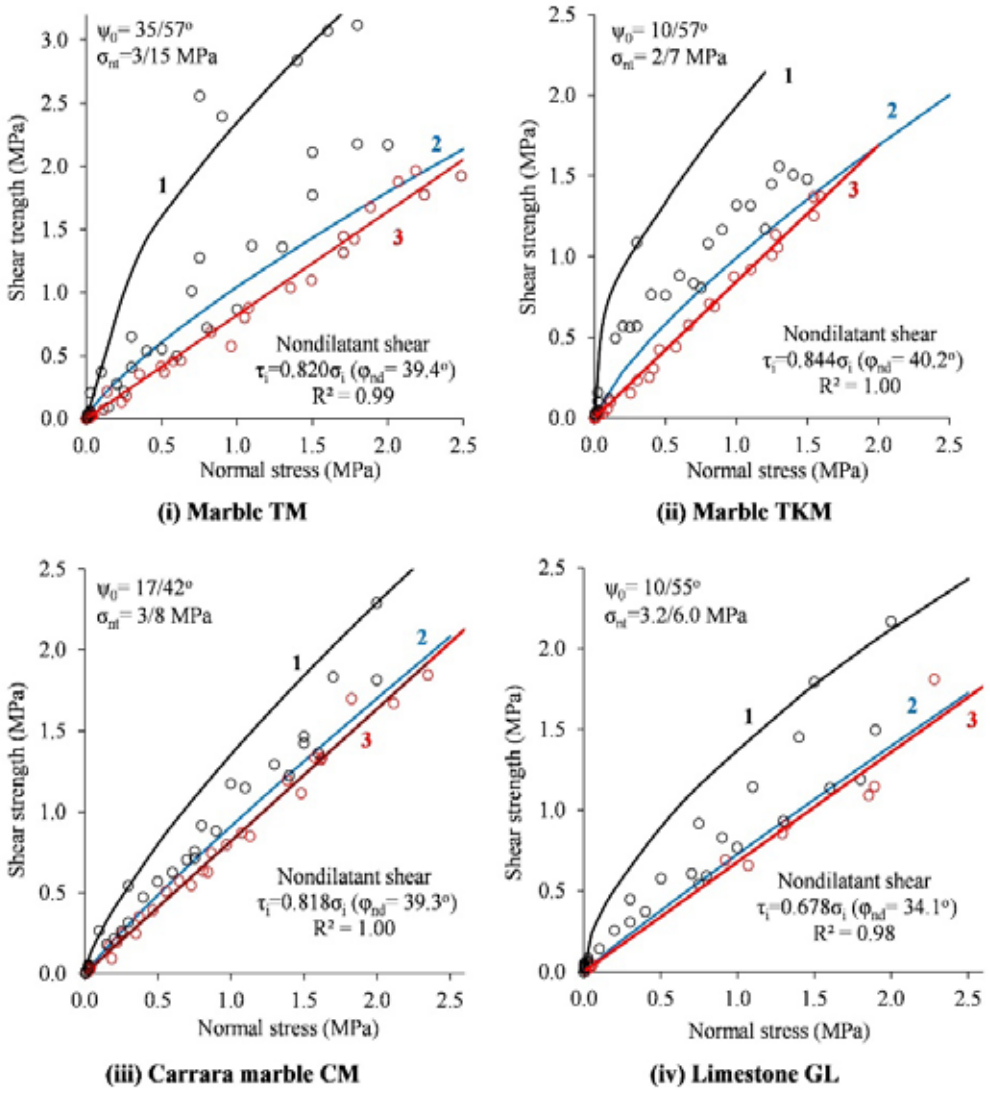

Figure 3. Fitted envelopes representing the peak shear strength and the non-dilatant shear strength best-fit line for carbonate rock induced tension joints tested in direct shear. Notations and methodology are consistent with Figure 2 (Tsikrikis *et al.*, 2024).

Accordingly, the shear strength can be divided into two components: a) a dilatant component, attributed to surface dilation, b) a non-dilatant component, stemming from the frictional properties of the rock surface.
Since the non-dilatant friction angle is derived from direct shear tests on natural surfaces, it inherently accounts for various surface conditions, including weathering, alterations and coatings. Importantly, both the sliding friction angle (φ_{nd}) of a naturally textured surface and the maximum surface angle (ψ_o), a three-dimensional roughness parameter, have clear physical significance and are easily measurable in the laboratory.

Conclusions

In this paper, several fresh induced tension fractures with different surface roughness from ten rock types (six silicates and four carbonates) tested dry in direct shear. The main conclusions resulted from 286 peak shear strength (τ_p) - normal stress (σ_n) - peak dilation angle (ψ) data sets are:

1) Although variations were observed in the peak shear strength across joints from the ten rock types tested, the sliding friction shear strength determined under conditions of non-dilatant shearing of each rock type was found to be proportional to the applied normal stress. This indicates that it is fundamentally frictional in nature. This proportionality holds across the applied normal stress range (0–2 MPa), regardless of mineralogy, grain size, or surface roughness. Consequently, the shear strength can be divided into two components: (a) a sliding friction component (non-dilatant component), and (b) a dilation component.
2) The values of the non-dilatant sliding friction angle φ_{nd} ranged from 32.7° to 40.2°, with weaker and more ductile carbonate rocks showing distinctly higher values (34.1°–40.2°) compared to the stronger and more brittle silicate rocks (32.7°–36.3°).

EXTENDED ABSTRACT 322

Exploring Participant Experiences in a Geoconservation Program in Apano Meria, Syros island, Greece

Tsipra Th.[1], Drinia H.[1]

(1) National and Kapodistrian University of Athens, Department of Geology and Paleontology, Panepistimiopolis 15784, Athens, Greece, ttsipra@geol.uoa.gr; cntrinia@geol.uoa.gr

Introduction

The purpose of this paper is to highlight the benefits the public gains from educational programs centered on the geocultural wealth of Greece. For this purpose, the study focuses on Apano Meria in Syros Island, South Aegean Sea, presenting an educational program designed to raise awareness about geoheritage and geoenvironmental awareness (Figure 1). Syros Island, with its remarkable petrological and tectonic history, provides an ideal backdrop for such an initiative. Its unparalleled preservation of mineral parageneses and tectonic structures—arising from a geotectonic environment associated with subduction—offers invaluable insights into the processes and evolution of our planet. These unique geological features have made Syros a global attraction for research geologists and an exemplary site for geoconservation and geoeducational efforts.

Learning in informal educational settings, such as field trips to geosites, museums, or natural parks, has proven to be one of the most effective methods of integrating theory with practice. Outdoor environments not only enhance children's ability to perceive and focus on natural phenomena but also provide a naturalistic, experiential approach to scientific learning. Wells (2000) emphasizes that daily exposure to natural settings significantly improves this process. In Syros, the exceptional and well-preserved rock formations offer an ideal environment for structured outdoor learning, allowing participants to engage directly with geological phenomena and processes.

The proposed educational program aligns with the island's candidacy for inclusion in the UNESCO Global Geoparks Network, as suggested by Drinia et al. (2021) and Tsipra and Drinia (2022). It underscores the island's potential as a platform for raising awareness about geoheritage and fostering sustainable behaviors through hands-on, outdoor learning experiences. This paper evaluates participants' experiences with the program to explore its educational value and effectiveness in promoting geoconservation and environmental awareness.

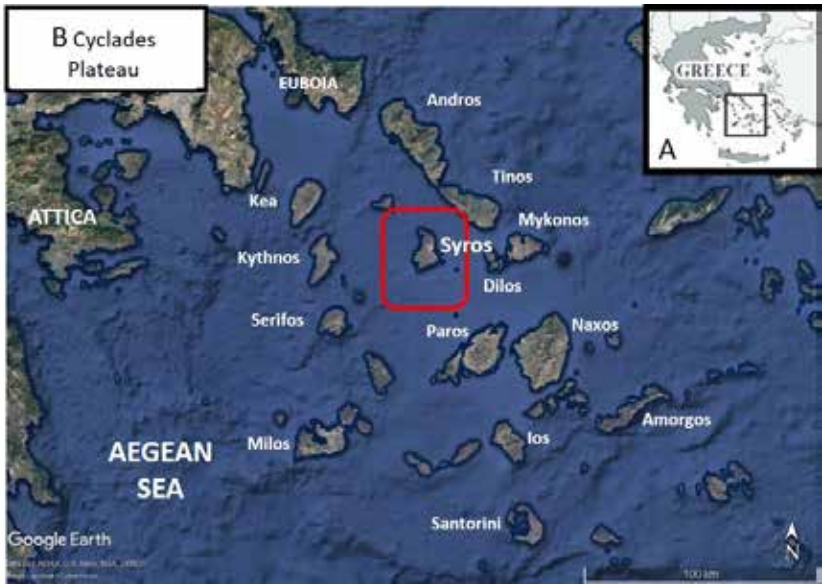

Figure 1. A. Sketch map of Greece indicating the location of Cyclades Plateau, B. Satellite photo of the Cyclades plateau, indicating the location of Syros island.

Methodology

The educational program is inspired by the geological evidence of the Apano Meria region in Syros. It introduces participants to the unique mineral rocks of the area in an engaging and enjoyable manner, while emphasizing the cultural and environmental significance of Geoparks. Designed according to principles of "learning by doing" and

teamwork, the program is structured based on Bloom's taxonomy (knowledge, comprehension, application, analysis, synthesis, and evaluation). A mystery game format resembling a treasure hunt forms the core of the program. Participants collaborate to follow clues, solve problems, and discover a "blue diamond," providing insights into geological processes and the formation of the island's unique rock formations. Creative activities were also integrated to help participants understand the historical formation of rocks and their connections to geocultural heritage.

The program has been tailored to different audiences and implemented in various settings. For postgraduate students, it was delivered as part of the "Museum Studies" program at the University of Athens during the "Museum Education" course. This included lectures on ecomuseums and a mini-workshop addressing age-group characteristics in educational planning. The program was also implemented with primary and secondary school students at the Aerolithos eclogite site on Syros Island (Figure 2). For public engagement, it featured an interactive exhibit at the Athens Science Festival, including augmented reality videos showcasing the geological and cultural heritage of Syros.

The evaluation process involved collecting qualitative and quantitative feedback through surveys. Thematic coding and word cloud visualizations highlighted recurring themes, while pie charts and graphs summarized satisfaction levels, willingness to reengage, and demographic information.

Figure 2. Eclogitic monolith locally known as "aerolithos", in Apano Meria, north Syros island

Results

Participants identified key elements of the program that resonated with them, including the significance of the geological area and natural heritage. Enjoyable aspects included walking routes, nature immersion, team activities, and problem-solving exercises. Challenges revolved around physical exertion, puzzle-solving, and environmental conditions, but most participants expressed no desire for significant changes. Emotional responses to the program were overwhelmingly positive, with terms such as "happy," "good," and "relaxed". A majority of participants (57) indicated they would participate in a similar program, emphasizing its perceived value. Demographically, the group was almost evenly split between female (34) and male (31) participants, with one individual identifying as a non-binary gender.

Discussion - Conclusions

The findings underline the program's success in creating an engaging and educational experience that highlights the importance of geoconservation. The interactive and nature-focused activities fostered positive emotions and a sense of community among participants. The challenges reported were minor and did not significantly detract from participants' overall enjoyment. The high percentage of participants willing to re-engage in similar programs demonstrates the potential for such initiatives to build long-term interest in geodiversity and sustainability. These insights provide a foundation for refining future programs, ensuring they remain inclusive, accessible, and impactful for diverse audiences...

Introduction

Western Greece (Fig. 1), a tectonically active region, is marking a North to South shift between collision to subduction, driven by the interaction between the Apulian platform, the oceanic subduction beneath the central and south Ionian Sea, and surrounding micro-blocks on the overriding plate. This region exhibits complex fault interactions and significant seismicity due to broader active faulting and the convergence of the Nubian and Eurasian plates (Perouse et al. 2012; Pearce et al. 2012). The area's tectonics are dominated by the Cephalonia Transform Fault Zone (CTF), a series of right-lateral fault segments, which mediates the transition from continental collision in the north to oceanic subduction in the south (Louvari et al., 1999; Ganas et al., 2016). This study leverages geodetic data (GNSS observations) to develop an elastic block model that elucidates fault geometries, block rotations, and slip rates, improving understanding of seismic hazards and regional deformation.

Study Area and Tectonic Setting

Western Greece encompasses the Ionian Islands, the western Peloponnese, and mainland areas such as Epirus and Aitoloakarnania. The CTF delineates a significant tectonic boundary between the Apulian-Ionian block and northwestern Greece (Briole et al., 2021; Vassilakis et al., 2011; Perouse et al., 2017). In addition, extensional grabens, including the Gulf of Amvrakikos (GoA Fig. 1), Gulf of Patras (GoP), and Gulf of Corinth (GoC), mark Plio-Quaternary active fault systems linked to slab retreat. Strike-slip faulting along two major continental faults is taking place along the Katouna-Stamna Fault (KSF) and the Movri Fault Zone (MFZ) which is located in the northwestern Peloponnese (Perouse et al., 2017; Gallovic et al., 2009; Ganas et al., 2009).

Methodology

Using geodetic data from 92 published GNSS stations spanning Greece and southern Italy, this study applies an elastic block model to analyze horizontal velocity fields (Hollenstein et al., 2008, Briole et al., 2021, Serpelloni et al., 2022). The model estimates block rotations, fault slip rates, and strain accumulation, integrating seismic, geological, and geodetic data. Euler poles and velocity residuals were employed to validate fault activity and block boundaries. Key fault segments and their kinematics were characterized based on observed velocity gradients and published geological and seismological data.

Model Results and Block Kinematics

The best-fitting model identifies five major tectonic blocks in Western Greece (Fig. 1b):

1. **Apulian Block (APUL):** Encompasses the central Ionian Sea and parts of the Italian peninsula.
2. **Ionian-Akarnania Block (IAB):** Bounded by the CTF, GoA graben, and Katouna-Stamna Fault (KSF).
3. **Central Greece Block (CGRE):** Defined by faults along the GoC and GoP.
4. **Peloponnese Block (PELOP):** Southern boundary influenced by the Movri Fault Zone (MFZ) and offshore structures.
5. **South Aitolia Block (SAB):** Proposed as a micro-block between the GoT and GoP.

Key Findings:

1. **Cephalonia Transform Fault (CTF):**
   - The CTF exhibits a right-lateral strike-slip motion (~16 mm/yr) with a reverse component (~5 mm/yr). The fault's slip rates align with previous studies, confirming its role as a boundary accommodating significant crustal deformation.
2. **Extensional Grabens:**
   - The GoA shows rapid extension (~10 mm/yr), with indications of left-lateral shear consistent with the KSF's westward continuation. The GoC and GoP are characterized by northward and southward fault-dipping systems.

3. **Katouna-Stamna Fault (KSF):**
   - This NW-SE striking fault displays left-lateral slip (~12 mm/yr) with low locking depths, suggesting aseismic creep along segments.
4. **Movri Fault Zone (MFZ):**
   - The MFZ demonstrates right-lateral motion (~8 mm/yr) with a possible tensional component. It likely contributes to the southern boundary of the IAB.
5. **Triple Junctions:**
   - Two triple junctions were identified -one near the western GoC (Rio area) and another near the GoA (offshore Preveza)- and define zones of complex deformation and intense seismicity. The GoP is a site of interaction between strike-slip and extensional faults.

Validation and Model Performance

The model achieves a high data variance reduction (99.4%) and a weighted root mean square error (wrms) of 0.94 mm/yr. Residual analysis highlights minor localized mismatches in areas with complex secondary faults or diffuse deformation zones. Slip vectors from earthquake focal mechanisms align well with predicted fault motions (see Fig. 1a), validating the model's accuracy.

Conclusions

This study underscores the utility of elastic block modeling in delineating the kinematics of fault systems and tectonic blocks using tectonic velocities from high-quality GNSS data. Western Greece's tectonics are dominated by crustal block interactions of the overriding Aegean plate along major faults such as the CTF, KSF, and MFZ, as well as active grabens. The findings include new data on fault slip rates and locking depths and highlight critical areas for seismic hazard assessment, such as the GoA and GoP, where significant strain accumulation and potential fault creep are observed. Further integration of subduction processes and secondary faults into models could refine predictions of regional seismic risks.

Introduction

Shell middens are anthropogenic deposits containing significant amounts of shell material (Campbell, 2005). They form in areas where human communities - whether hunter-gatherers, horticulturalists, agriculturalists or industrial societies - intensively harvest shellfish, extract and process the meat for consumption, or repurpose the shells as raw materials. The resulting shell debris accumulates at habitation or processing sites, where shells dominate the matrix. Shell middens are believed to have formed rapidly, with shell deposition rates exceeding those of sediments (Marean, 2014).

Shell middens are widespread in coastal regions worldwide, spanning environments from subarctic to tropical zones (Stratham, 1892, Álvarez *et al.*, 2011, Rabett *et al.*, 2011, Cardoso, 2015). Coastal shell middens can be found as exposed layers of shell in dunes, cliff faces, coastal scrub, and wetlands or as scattered shell deposits on eroded surfaces. These middens may consist of a single, thin layer or develop into thick, stratified deposits with multiple layers. Their size varies greatly ranging from small shell concentrations just a few meters across to extensive formations covering many hundreds of meters.

Research on shell midden began in the 1800s and gained significant momentum in the late 19th and early 20th centuries (Rick, 2024). The study of these deposits has been crucial in archaeological research, providing valuable insights into the relationship between humans and aquatic habitats, and revealing the significance of marine environments in human evolution and ecology (Wurz *et al.*, 2022, Rick, 2024).

Shell middens are among the most prominent archaeological sites along the entire coast of South Africa (Jerardino, 2010). The Stone Age shell middens of South Africa offer the richest and longest record of coastal adaptations, while shell middens of Early Iron Age are a critical archive for understanding past human activities in the region. However, the eastern Indian Ocean coast in South Africa has received less attention than the south coast, despite clear evidence of sustained coastal resource use there as well (Will *et al.*, 2022).

In this study, we present the results of optically stimulated luminescence (OSL) dating of five sediment samples collected from sand layers developed below and above a coastal shell midden outcrop approximately 80 m from the shore at Umhlanga Rocks on the Natal north coast.

Previous excavations from the nearby sites of Emberton Way and Umhlanga Rocks (Davies & MacDonald, 1978) revealed approximately 1.5 m of stratified sands containing ceramics, stone artifacts, shells and shell fragments. It is currently impossible to assess the original extent of the midden layer due to extensive disturbance in the surrounding area, primarily caused by urban development, one of the major causes of midden damage worldwide (Ceci, 1984). The midden must have been extensive, as in 1974 it was recorded as being 19 m long and 2 m thick at its deepest exposure with compacted *Perna perna* (brown mussel) layers, hearths and numerous ashy layers.

Study Area

The study area is located on the east coast of South Africa, along the north coast of KwaZulu Natal (north coast) (Figure 1). Along most of the KwaZulu-Natal coastline, a series of large, coast-parallel dune complexes, mainly of Cenozoic age, occur. The site of the stratigraphic section studied on the southern end of the Ohlanga Estuary, approximately 20 km north-northeast of Durban (Figure 1). The 2.3 m thick stratigraphic section is located about 80 m from the present-day shoreline and is part of the face of a low foredune cliff. The bulk of the studied deposit appears to remain undisturbed, despite evidence of large-scale disturbances to the immediate surroundings of the midden and the uppermost surface of the foredune cliff face.

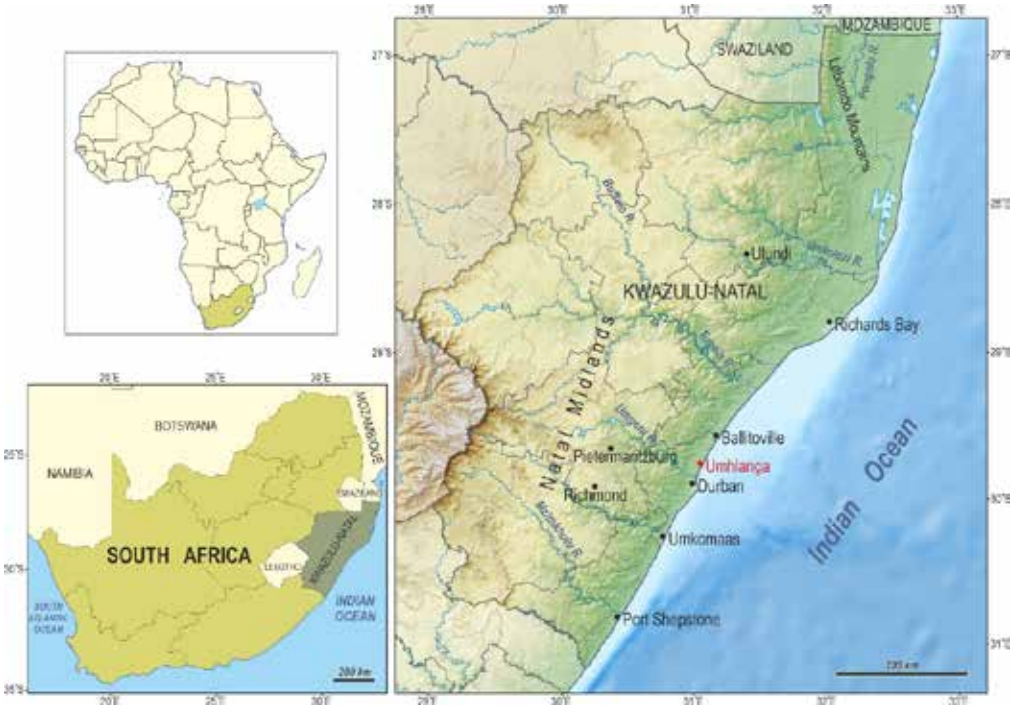

Figure 1. A relief map showing the location of Umhlanga in KwaZulu Natal, South Africa.

Methodology

The stratigraphy of the sediment layers in the section containing the shell midden were identified and described in detail. To achieve this, the face of the low dune cliff was carefully excavated and cleaned (Figure 2). The chronostratigraphy of the section was established using five samples collected from selected sedimentary layers below and above the shell midden layer, dated through OSL.

Figure 2. Photographs of the stratigraphic units exposed in the coastal natural outcrop at Umhlanga Rocks, Natal north coast, South Africa, along with the locations of luminescence sampling points.

OSL sample preparation was conducted in the Physical Geography laboratory of Harokopio University of Athens, Greece, while the OSL signal measurements were performed at the Nuclear Physics laboratory of the University of Ioannina, Greece.

Quartz grains (150-250 μm) were extracted through wet sieving and acid treatment (HCl, H_2O_2, HF), under subdued red-light conditions. The purity of the quartz extract was verified using the OSL-IR depletion ratio (Duller, 2003). The Single-Aliquot Regenerative-dose (SAR) protocol of Murray and Wintle (2000), was used to determine all equivalent doses (De).

All measurements were performed on an automated Risø TL/OSL-DA-20 reader equipped with a $^{90}Sr/^{90}Y$ beta radiation source. Quartz OSL signals were obtained by stimulating with blue LEDs (470 nm, ~47 mW/cm^2) and the signals were detected using a 7 mm Hoya U-340 optical filter. Environmental dose rates were calculated from radionuclide concentrations measured by high-resolution gamma spectrometry, applying the conversion factors of Liritzis *et al*. (2013).

Results

The stratigraphy of the site revealed deposits approximately 2.3 m thick (Figure 3), with six distinct layers identified and described:

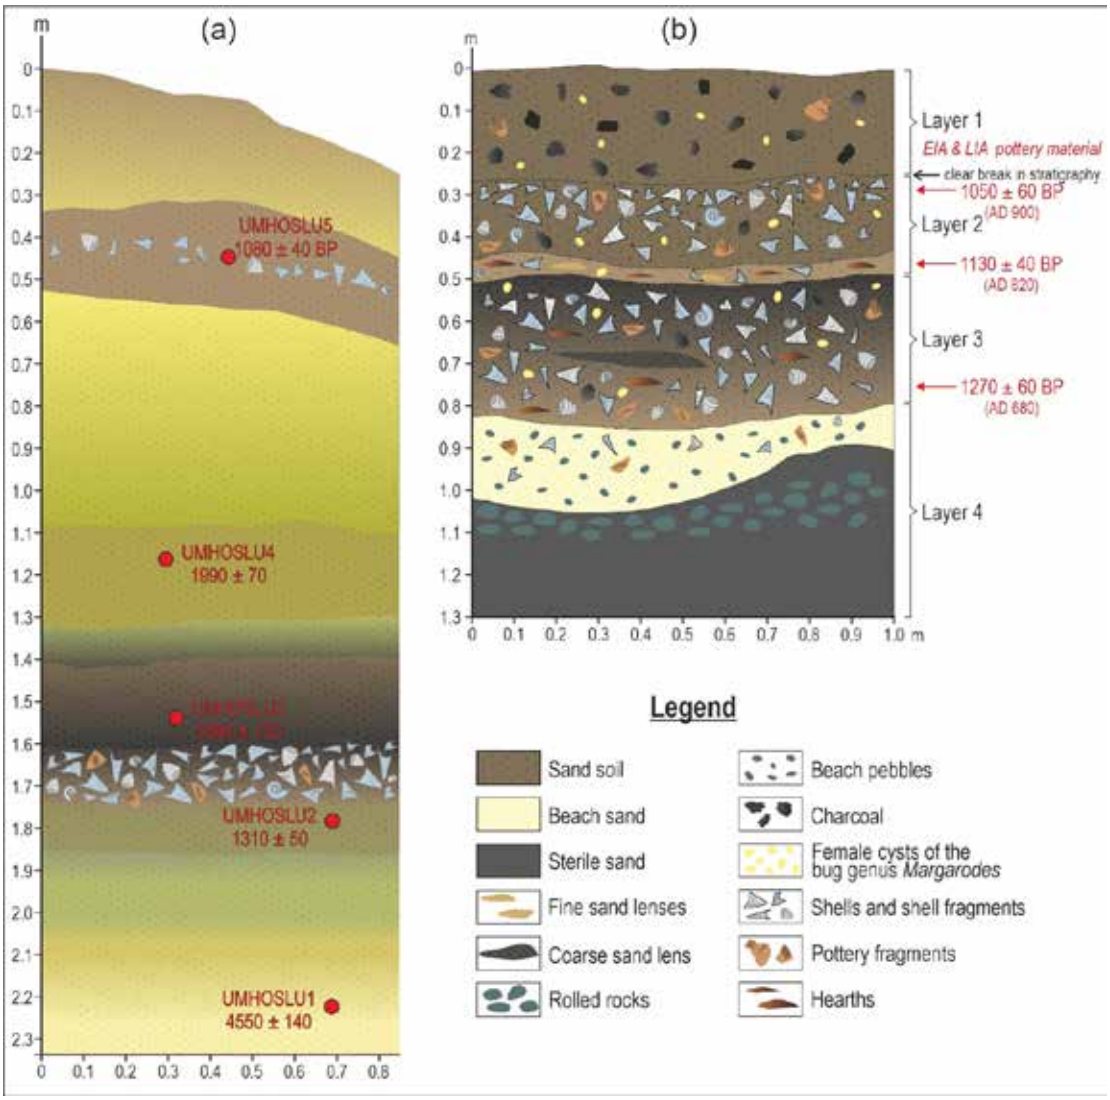

Figure 3. (a) Simplified stratigraphy exposed in the coastal natural outcrop located at Umhlanga Rocks, Natal north coast, South Africa. OSL sample points are shown and their corresponding OSL ages are provided. The stratigraphy revealed deposits up to 2.3 m deep, with six distinct layers identified and described. (b) Simplified stratigraphic log from a previous excavation at Emberton Way, Natal north coast (modified from Horwitz *et al*., 1991). The obtained radiocarbon ages are also provided. EIA: Early Iron Age, LIA: Late Iron Age.

The uppermost layer (Layer 1) is approximately 30 cm thick and consists of light brown, well-sorted sandy soil with root remnants. The sand appears to originate from the most recently active dune adjacent to the beach. Beneath it lies Layer 2, which is 18 cm thick and composed of brown sandy soil rich in humic material, with occasionally fragmented shell. The interface between Layers 1 and 2 is marked by a break in stratigraphy. A sample (UMHOSLU5) for OSL dating was collected from the middle of this layer. Layer 3, which underlies Layer 2, is 85 cm thick and incorporates three stratigraphic features. It consists of aeolian sands that range in color from olive green to dark green. A distinct stratigraphic break separates Layers 2 and 3. A sample (UMHOSLU4) for OSL dating was taken from the lower part of this layer. Layer 4, which is 20 cm thick, comprises dark brown, well-sorted sandy soil that becomes slightly lighter towards the upper contact. This layer is the upper part of the shell midden. A sample (UMHOSLU3) for OSL dating was collected near the contact between this sandy soil layer and the underlying shell midden. Layer 5 is the main shell midden, with a thickness of 12 cm. It is dark in color, likely due to a higher soil fraction, and contains a dense concentration of mollusk shells (including a variety of closely packed shells). Pottery sherds were also scattered throughout the layer. The lowermost layer, Layer 6, is 60 cm thick and composed of aeolian, well-sorted sandy sediments. The sediment color transitions from dark green at the top to light yellow at the base. Two samples (UMHOSLU2 and UMHOSLU1) for OSL dating were collected from the upper and the lower part of this layer, respectively (Figure 3).

The environmental dose rates calculated from radionuclide concentrations measured using high-resolution gamma spectrometry are presented in Table 1. A typical dose-response curve for sample UMHOSLU2, along with a natural OSL signal decay curve, is illustrated in Figure 4. The decay curve indicates that the signal is dominated by the fast component. The results of the preheat plateau test conducted at different preheat temperatures are displayed in Figure 5. Based on these results, a preheat temperature of 240 °C for 10s was selected for all subsequent measurements. Furthermore, a dose recovery test was performed on all samples. Statistical analysis of the doses recovered yielded a mean and standard deviation of 1.01 ± 0.06 relative to the given laboratory dose, confirming the suitability of the chosen SAR protocol for these samples. The De estimates and the corresponding ages are summarized in Table 1.

Table 1. Sample information and a summary of dosimetry and equivalent doses (De) measurements. Quartz OSL ages were calculated using the Central Age Model (CAM).

No	Sample ID	Water content (%)	Total dose rate (Gy/ka)	n	CAM De (Gy)	CAM age (ka)
1	UMHOSLU1	2.6	1.15±0.02	23	5.25±0.12	4.55±0.14
2	UMHOSLU2	3.4	4.58±0.06	23	6.01±0.2	1.31±0.05
3	UMHOSLU3	3.9	2.83±0.04	23	11.28±0.39	3.99±0.15
4	UMHOSLU4	4.1	3.56±0.05	23	7.08±0.23	1.99±0.07
5	UMHOSLU5	3.4	4.44±0.06	23	4.81±0.17	1.08±0.04

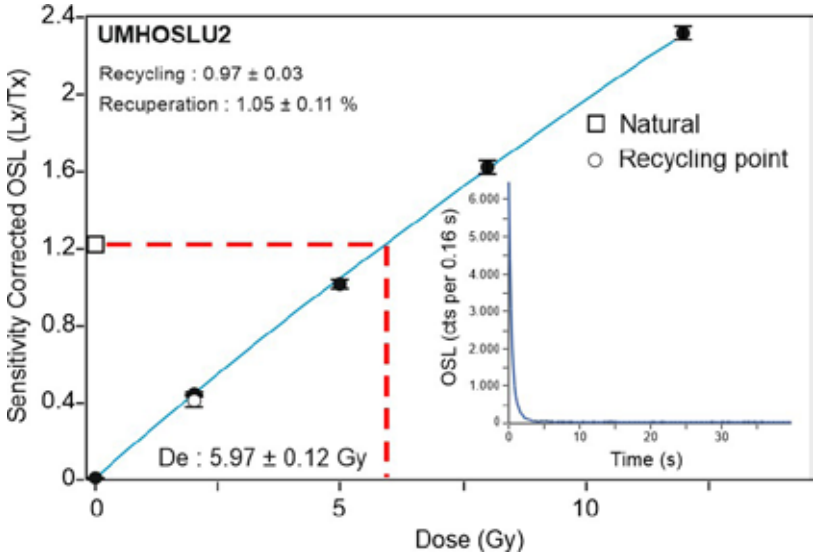

Figure 4. Typical dose-response curve with the natural OSL signal decay curve shown as an inset for sample UMHOSLU2.

The OSL age results for the collected samples, derived using the central age model, range from 4.55±0.14 ka to 1.08±0.04 ka, and are in stratigraphic order, with one exception. A comparison of the estimated OSL ages with radiocarbon dating results obtained from charcoal samples during a previous shell midden excavation at Emberton Way (Horwitz *et al*., 1991), approximately 20 km north-northeast of the stratigraphic section site studied here, reveals agreement between the OSL ages and the independent radiocarbon age controls. The archaeological findings from the excavation of the Emberton Way shell midden suggest a connection between large beachfront shell midden deposits and substantial inland village sites during the Msuluzi-Ntshekane period. Named after key archaeological sites, such as Msuluzi and Ntshekane, this period spans the 7th to 9th centuries AD and represents cultural phases within the Early Iron Age in South Africa (Whitelaw, 2019). This era is marked by the emergence of settled agricultural communities, the introduction of metallurgy, and significant cultural transformations.

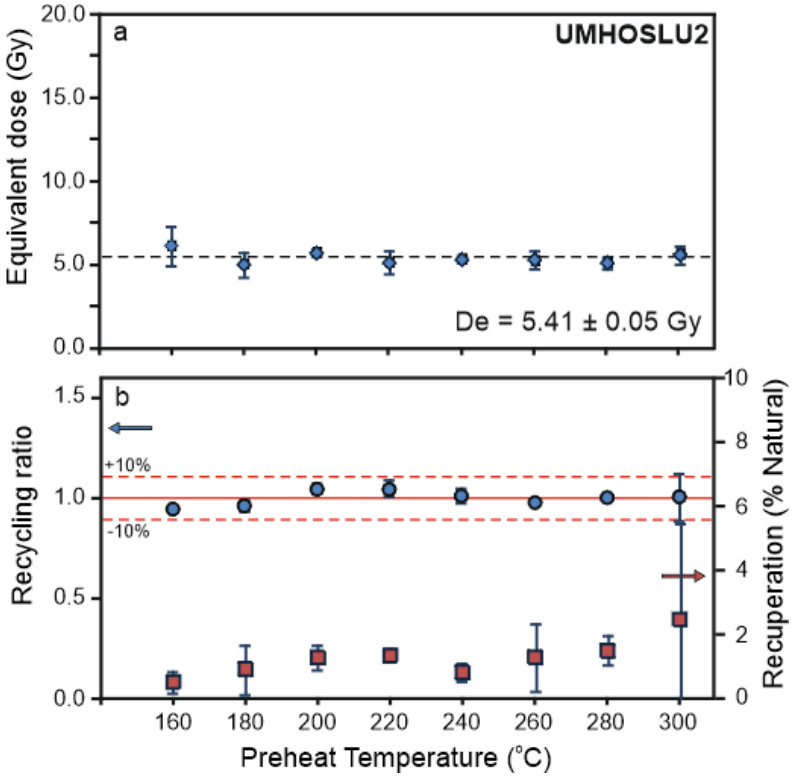

Figure 5. Preheat plateau test results show no dependence of the equivalent dose (a), recycling ratio and recuperation (b) on preheat temperature for sample UMHOSLU2. The cut heat temperature was 160°C, and the test dose was 2 Gy. Each point represents the average results from three aliquots.

Concluding Remarks

This study led to the following conclusions:

- The OSL dating of sedimentary layers within the stratigraphic section yielded ages ranging from 4.55±0.14 ka to 1.08±0.04 ka. With one notable exception, these results exhibit a coherent stratigraphic progression and demonstrate strong concordance with independent chronological benchmarks established through radiocarbon dating of Emberton Way site samples, as documented by Howitz *et al.* (1991).
- This study is the first to demonstrate that OSL dating using quartz has significant potential in this region. It proves to be a reliable method for establishing precise chronologies for coastal sediments along the Natal north coast.
- Findings from the archaeological excavation of the Emberton Way midden, located near the stratigraphic section studied here, suggest a connection between large beachfront shell midden deposits and substantial inland village sites during the Msuluzi-Ntshekane period.
- The limited range of resources exploited from the middens, as documented by previous researchers (Howitz *et al*., 1991), along with the distinctive Early Iron Age (dating from around AD 200 to AD 900) ceramics, strongly supports an agriculturist attribution for these sites. This evidence contradicts the earlier hypothesis of residual hunter-gatherer origin.

Introduction

The Chelmos-Vouraikos UNESCO Global Geopark has continued to demonstrate its unwavering commitment to conservation, education, and community engagement through a series of impactful actions during 2024. These initiatives highlight the Geopark's dedication to preserving natural and cultural heritage, while fostering sustainable development in close collaboration with local communities, national organizations, and international stakeholders.

Engaging with Society

Throughout the year, the Geopark got actively engaged with society through various events and initiatives that bridged cultural, environmental, and recreational themes. The organization of the 5th UNESCO Global Geoparks Conference of Greece and Cyprus, in Kalavryta, by Chelmos-Vouraikos Geopark, provided an international platform to showcase the Geopark's efforts in conservation and sustainable tourism. Publications such as the new geodiversity and plant guides and leaflets about freshwater fish fauna and the endemic plants of the geopark have been produced and distributed to educate visitors about the region's unique biodiversity (fig.1). Additionally, the new Geopark's Information Center (fig.2), which serves as a hub for visitor orientation and education, commenced its operation last year, offering an enhanced experience for visitors to learn about the area's natural and cultural heritage.

Promoting Sustainable Tourism and Regional Identity

Events like Oinoxeneia highlighted local gastronomy and traditions, fostering a deeper connection between the Geopark and its communities. Digital and physical tools, including info kiosks and a dedicated Geopark mobile application, enhanced visitor experiences and accessibility. Recreational activities such as the 44th Annual Vouraikos Gorge Crossing, the 1st Helmos Enduro 2024, and the 2nd Helmos Mountain Festival (fig.3), which took place in the past year, were organized by local entities within the Geopark, such as the Kalavryta Mountaineering Club and the Kalavryta Ski Center. These events were always accompanied by collaboration and parallel actions from the Chelmos-Vouraikos Geopark, emphasizing the strong partnership in promoting sustainable tourism and outdoor recreation within the region. Cultural collaborations, including the Ziria Festival and TEDx Patras, which were organized outside the Geopark, further underscored the Geopark's role in promoting regional identity. Despite being external events, these initiatives involved collaboration with the Chelmos-Vouraikos Geopark, highlighting its active role in supporting and enhancing regional cultural efforts. Additionally, the annual meeting of Trekking Hellas Achaia emphasized sustainable trekking practices and eco-tourism, while the participation of handball federation athletes in the Vouraikos Gorge connected sports with natural heritage under the organization of Chelmos- Vouraikos Geopark. The Aigio Mountaineering Club hosted a symposium entitled "On the Mountain's Paths," featuring a presentation on "Biodiversity Conservation: Linking with Mountaineering," which was delivered by staff members of the Chelmos-Vouraikos Geopark. This presentation highlighted the Geopark's efforts in promoting the connection between mountaineering and biodiversity conservation. Historical significance was also honored through the event commemorating the 20-year anniversary of the Holocaust Museum. This two-day event, organized by the Kalavryta Holocaust Museum, featured a presentation on the protected area, and participants of the seminar were given a guided tour of the Geopark's Information Center. These activities further highlighted the importance of conservation and the Geopark's role in preserving the region's natural and cultural heritage, reinforcing the ongoing collaboration between the Geopark and the Museum. This partnership has been strengthened through joint initiatives, such as the seminar on climate change co-organized the previous year as part of the International Museum Day celebrations. Environment Day this year was celebrated in three distinct ways: with a hike on Mount Panachaiko, a volunteer cleanup of Kastria stream, and a planting initiative with students from the Special School of Kalavryta. These activities highlighted the community's commitment to environmental stewardship and provided an opportunity for collaboration

with local schools and organizations.

Inspiring Education and Academic Research

Educational activities with schools and universities played a pivotal role in inspiring the next generation and supporting academic research. Collaborative efforts with the Special School of Kalavryta under the GRECABAT program integrated hands-on activities that connected biodiversity with education. On International Mountain Day, a presentation and interactive games at Diakopto Primary School raised awareness about mountain ecosystems. At Arsakeio School of Patras, a presentation titled “Natural Disasters and UNESCO Global Geoparks” emphasized the role of Geoparks in disaster risk reduction. Activities at Rodea Camp included an informational session and guided hike, fostering environmental awareness among participants. The European Bird Day celebration at Lake Doxa highlighted the importance of avian biodiversity and was celebrated in collaboration with the Primary, Secondary, and High School of Kleitoria. The event featured birdwatching activities and games, providing students with a hands-on learning experience about local wildlife and the significance of bird conservation. Field trips with Harokopio University provided students with the opportunity to conduct research in Vouraikos Gorge, focusing on topics such as fluvial geomorphology, ecosystem services and environmental cartography. The Geopark also welcomed annual visits from international researchers studying glacial formations, showcasing its global scientific relevance.

Advancing Research and Conservation Management

Research and management activities within the Geopark have been equally robust, aiming to enhance conservation and sustainable development. Efforts to protect rare and endemic species were supported through the establishment of micro-reserves. Biodiversity studies focusing on otters, dormice, and ichthyofauna enriched the understanding of local ecosystems. A monitoring station in Vouraikos River provides essential data for conservation strategies by measuring parameters such as water temperature, water level, conductivity, pH, dissolved oxygen, and turbidity. This data plays a crucial role in the proper management of the Vouraikos River, ensuring the health of the ecosystem and supporting sustainable tourism development through informed decision-making. The renowned Cave of the Lakes was the subject of a comprehensive management study to protect its geological and ecological features. Additionally, the development of a quality label study aligned local products and services with sustainable practices. The conservation program for *Silene conglomeratica*, a critically endangered endemic species within the Chelmos-Vouraikos UNESCO Global Geopark, highlights the essential link between geodiversity and biodiversity. Moreover, a carrying capacity study for Mount Helmos is currently underway, emphasizing the importance of regulating visitor numbers to balance tourism promotion with the preservation of the area’s natural environment.

Conclusions

Through these comprehensive actions, the Chelmos-Vouraikos UNESCO Global Geopark continues to exemplify its role as a leading stakeholder in conservation, education, and community collaboration. These efforts contribute significantly to the global mission of UNESCO Global Geoparks, ensuring a sustainable future for the region’s natural and cultural heritage.

EXTENDED ABSTRACT 326

Deep sea agglutinated foraminifera from the surface sediments of NE Mediterranean Sea

Tsourou Th.[1], Markoglou E.A. [1,2], Danelian T. [3], Parinos C [4], Gogou A.[4], Triantaphyllou M.V.[1]

(1) National and Kapodistrian University of Athens, Department of Geology and Geoenvironment, Athens, Greece, ttsourou@geol.uoa.gr, (2) University of Thessaloniki, Department of Geology and Palaeontology, Faculty of Geology, Thessaloniki Greece, (3) Universite de Lille, CNRS, UMR 8198- Unite Evo-Eco-Paleo, Lille, France, (4) Hellenic Centre for Marine Research, Institute of Oceanography, Attiki, Greece

The purpose of this study is to record and present the deep sea benthic foraminiferal assemblages, focusing on the agglutinated forms, retrieved from the surface sediments of the central and southern Aegean Sea and the NW Levantine Basin (Figure 1a). There are several previous studies about agglutinated foraminifera from the broader area mainly from Marmara Sea (e.g., Frontalini et al., 2011; Chatelet et al., 2013) and Saros Bay (NE Aegean; e.g., Frontalini et al., 2014; 2018), referring mostly to shallower regimes.

The southern Aegean is connected to the Levantine Basin and the Ionian Sea through the eastern (Kassos) and western (Antikithira-Kithira) Cretan Straits, respectively. The various subbasin gyre patterns namely the Cretan Cyclonic Gyre, the West Cretan Anticyclone, the Myrtoan West Cretan Cyclone, and the Pelops Gyre affect the circulation of the area (Theocharis et al., 1999). Additionally, the surface water circulation is influenced by the presence of low-salinity Modified Atlantic Waters (MAW), which primarily enter the Cretan Sea through the Antikithira Strait and occasionally through the Kassos Strait. Warm and saline Levantine Waters (LW) enter the Aegean through the eastern Cretan Straits and travel north along the eastern Aegean Sea (Zervakis et al., 2005).

Micropaleontological analysis was performed in eight surface sediments samples. The samples were recovered with a box corer during R/V Aegaeo MSFD cruise in March 2019, from relatively shallow to bathyal environments from 8 sampling stations (Figure 1b). In particular, the three shallower stations are located in the Cyclades plateau (2MSFD11), the broader area of Myrtoan Basin (2MSFD8) and the central-eastern Aegean (2MSFD12), while the deeper stations are located in the Cretan Sea (2MSFD9 and 2MSFD10) and off Crete and Rhodes islands towards the Levantine (2MSFD5, 2MSFD6 and 2MSFD7). The position and depth distribution of the sampling stations is presented in Figure 1b. The collected sediment was stored in an ethanol-Rose Benghal mixture. In the laboratory the samples were carefully wet sieved through 63 μm and 125 μm sieves, oven dried at 50°C, and the sediment fraction >125 μm was examined for the micropaleontological content.

Figure 1. a. Location map of the study area. b. The study area and the sampling stations during R/V Aegaeo MSFD cruise in March 2019.

The biogenic content of the analyzed samples consisted mainly of pteropods planktonic and benthic foraminifera, as well as rare ostracods and otoliths. Benthic foraminiferal assemblages presented the higher diversity and abundance among all the other groups of benthic organisms and their assemblages were composed of calcareous (hyaline) and agglutinated taxa. Calcareous foraminifera and agglutinated foraminifera present an inversely proportional relation with agglutinated foraminifera being more abundant in the samples from the lower bathyal stations.

The agglutinated foraminiferal assemblages demonstrate higher diversity in the samples from the shallower basins (e.g., stations 8, 11, 12), which decreases towards the deep lower bathyal environments (e.g., stations 9, 10). This pattern is in accordance with other studies such as the one of Hyams-Kaphzan et al. (2018) from the Levantine basin. A total of 13 genera and 15 species of agglutinated foraminifera have been so far identified. Their assemblages were composed mainly of arborescent/tubular taxa and globular forms. The most common taxon is the arborescent/tubular species *Saccorhiza ramosa* (Brady, 1879) which is the present in all the samples and displays the higher participation rates (11-84% of the agglutinated fauna). Its wall is made of mineral grains, coccoliths and sponge spicules, while in certain samples spumellarian radiolaria and pteropods are also incorporated in the test structure (Figure 2). Other common arborescent/tubular species are *Rhabdamminella cylindrica* (Brady, 1882) (present in stations 5, 8, 9, 10, 11; 0.2-12.5%); *Rhizammina algaeformis*, Brady, 1879 (present in stations 5, 6, 9, 10, 11; 1-26%), being coarsely agglutinated, beside inorganic grains, with planktonic foraminifera, radiolaria and pteropods and *Psammosiphonella* spp. (present in stations 5, 6, 8, 9, 10 11, 12; 0.44-63%). The most abundant globular taxon is *Glomospira* spp. (present in stations 5, 6, 7, 9, 10; 1-57%). Other taxa with scarce presence in the studied samples are *Psammosphaera fusca* Schulze, 1875 and species of *Bathysiphon*, *Marsipella*, *Hyperammina*, *Reophax*, *Cribrostomoides*, *Ammoscalaria* and *Ammodiscus*.

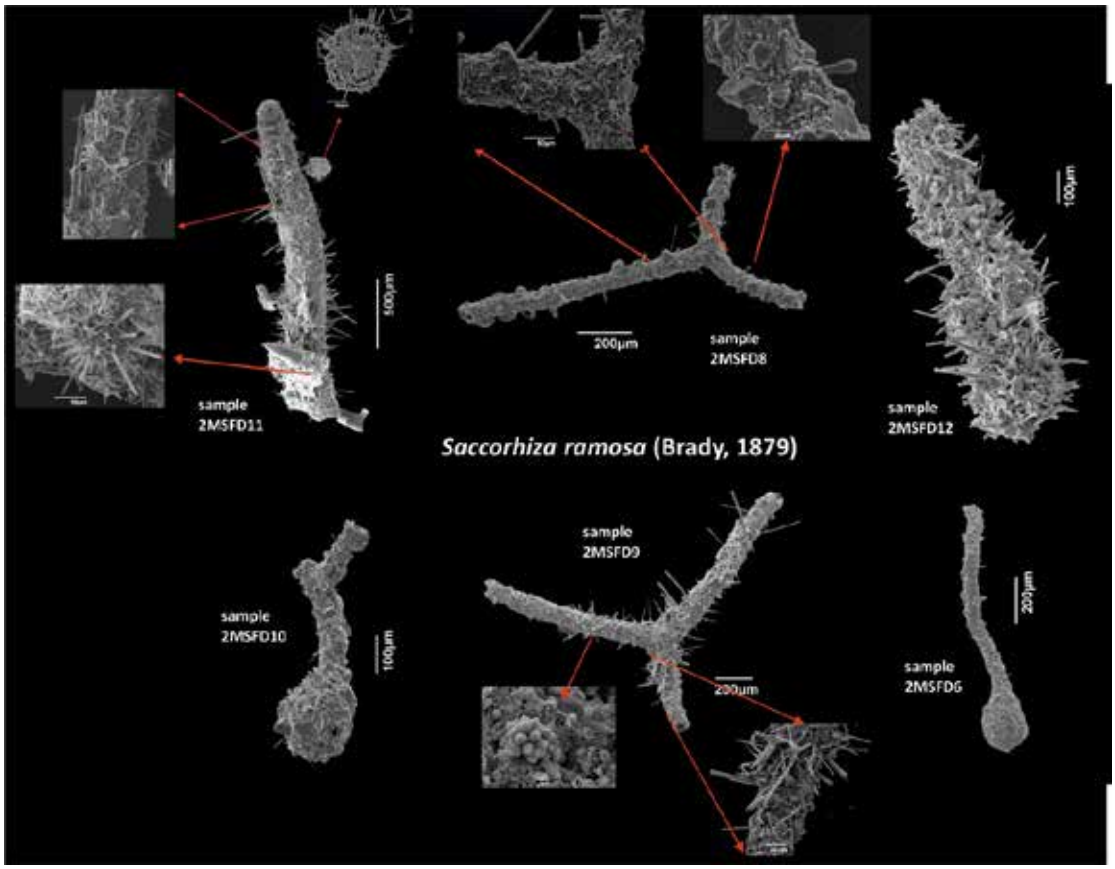

Figure 2. a. The most abundant species of agglutinated foraminifera in the studied samples and details of the test with several different biogenic particles.

The arborescent/tubular taxa *S. ramosa, R. cylindrica, R. algaeformis, Bathysiphon*, *Hyperammina, Psammosiphonella, Marsipella* belong to Morphogroup 1 (M1) of Kaminski and Gradstein (2005) and they are epifaunal forms, suspension feeders, preferring quite, bathyal-abyssal, oligotrophic environments. Generally, all the identified taxa, besides *Reophax* (infaunal, deposit feeders, preferring increased organic matter flux), are considered epifaunal forms indicating oligotrophic conditions (Kaminski and Gradstein, 2005). Especially *S. ramosa* seems to have developed the skill to survive for long time without food, benefiting from episodic sedimentation events e.g. in canyon environments (Koho et al., 2007). *Reophax* is present in all the samples from the shallower stations (8, 11, 12), demonstrating its higher participation rates (4-9.2%). Overall, the composition of the assemblages in the study area is in accordance with the oligotrophic character of the South Aegean Sea and eastern Mediterranean.

EXTENDED ABSTRACT 327

Stratigraphic assignment of the Mesozoic shallow carbonate succession of Epos Mountain, Chios Island, Greece

Tsourou Th.[1], Sakoulas N.[1], Paraskevopoulou A. [1], Perraki I.[1], Triantaphyllou M.V.[1]
(1) National and Kapodistrian University of Athens, Department of Geology and Geoenvironment, Athens, Greece, ttsourou@geol.uoa.gr

According to Besenecker *et al.* (1968;1971) the geology of Chios comprises, in general, two tectonostratigraphic units: the lower, Autochthonous Unit overthrusted by the upper, Allochthonous Unit. The Autochthonous Unit consists of a Paleozoic chaotic flysch type complex, including four olisthostromes of Permian age (Papanikolaou and Sideris 1983), which is transgressed by a Triassic basal conglomerate and an overlying carbonate succession of Triassic to Early Jurassic age (Figure 1b). This carbonate sequence corresponds to the internal platform of the "Sub-Pelagonian" Unit (Papanikolaou, 2021), in other words the easternmost part of the Pelagonian domain (e.g., Jacobshagen, 1986; Meinhold et al., 2007).
The study area includes Epos Mountain, in the central-eastern part of Chios Island (Figure 1a). Epos Mt is built up of thick carbonates, related to the upper part of the Mesozoic carbonate sequence of the Autochthonous Unit. The aim of this study is the micropaleontological analysis and paleoenvironmental interpretation of the shallow water carbonates of Epos Mountain. Furthermore, the results are compared to those from previous studies for the same stratigraphic interval in other regions of Greece.

Figure 1. a. Location of the study area. b. Chios autochthonous unit: general view of the internal carbonate platform (Triassic-Lower Jurassic) overlying the volcano-sedimentary complex (Upper Paleozoic–Lower Triassic).

Several samples of limestones and dolomitic limestones were collected following the road from the base of the mountain towards the top and along the Epos plateau. More than 50 samples have been collected from the stratigraphic sequence; twenty-four of them have been selected and prepared at the Laboratory of Historical Geology and BioGeosciences (National and Kapodistrian University of Athens) for the purposes of the current study.
At the lower part of the sequence, the microfacies consist mainly of grainstones/packstones with peloids, ooids, benthic foraminifera, bivalves, gastropods and ostracods representing an internal platform (FZ8; Flügel, 2004), subtidal environment,. These microfacies alternate with facies with fenestral voids pointing to supratidal environments (FZ9; Flügel, 2004). The micropalaeontological content of the samples is characterized by the presence of benthic foraminifera with Duostominidae and Involutinidae (mainly of the genus *Aulotortus*) being the most abundant specimens, pointing to a Late Triassic age, in particular, Norian-Rhaetian.
Upwards, the succession becomes shallower presenting distinct lofer cycles (Figure 2a). Open space structures such as fenestral pores, birdseyes and karst dissolution cavities indicate a supratidal environment and subaerial exposure. The micropaleontological content is poor, with the subtidal layers of the loferitic facies bearing few ostracods, bivalves and gastropods. In some cases, these layers present rare benthic foraminifera and algae.

Figure 2. a. Loferitic horizons. b-c. Subtidal beds with gastropods (b) and bivalves (c).

The micropaleontological and microfacies analysis of the studied material reveals clear similarities of the Late Triassic Epos succession to the sequences described from the Pelagonian domain in mainland Greece; e.g., Argolis peninsula, Corinthia, central Greece, as well as Euboea Island (Varti-Mataranga and Matarangas, 1991; Pomoni-Papaioannou, 2008; Scherreiks *et al.*, 2010; Kostopoulou, 2018).

EXTENDED ABSTRACT 328

The geothermal prospect of the NW Lesvos Island, Greece: Three-dimensional magnetotelluric and gravity exploration

Tzanis A.[1], Chailas S.[1], Spyridonos E.[2]
(1) Section of Geophysics and Geothermy, Department of Geology and the Geo-environment, National and Kapodistrian University of Athens; atzanis@geol.uoa.gr. , (2) PPC Renewables S.M.S.A, 3 Kapodistriou st., Agia Paraskevi, GR-153 43.

Introduction

Lesvos has been part of a broader area of volcanic activity in the Miocene. This has bequeathed the NW sector of the modern island with an intermediate to high-temperature hydrothermal system and field, which has been the target of significant geothermal exploration efforts during the past few decades. Herein, we attempt to re-interpret with modern 3-D inversion tools, legacy magnetotelluric data acquired in the year 2000 by the private sector company Geosystem Srl. on behalf of PPC Renewables S.M.S.A., and to jointly appraise the resulting geoelectric model with Bouguer gravity anomaly data extracted from the databank of the Department of Geophysics and Geothermy of the National and Kapodistrian University of Athens (Lagios *et al.*, 1996). As will be seen below, the results point toward a complex and potentially productive hydrothermal system with several distributed shallow reservoirs, set up by past (Miocene) tectonic activity and still controlled by its legacy to the present.

Figure 1. Geological Map of NW Lesvos. The toothed red line outlines the Lepetymnos Caldera. Coloured lines are faults (various sources).

Volcanic Background

Lesvos, along with the region of the north-central Aegean, belongs to a wider field of past volcanism that extends to northwestern Turkey and was part of the volcanic arc that operated since the Upper Oligocene-Middle Miocene period. The volcanic rocks occupy the entire central and western parts of Lesvos. The pre-alpine and alpine (Carboniferous to Triassic) basement outcrops mainly in southeastern Lesvos, with only minor occurrences in its western extremities. Volcanic activity lasted for almost 6.0 Ma with rocks of mainly shoshonitic composition, while a few calcareous andesites were emplaced at the beginning (Eressos area, 21.5Ma) and the end (Mytilene area, 16.5Ma) of the volcanism. The ensuing history of volcanic activity is based on Pe-Piper *et al.* (2019). At 21.6 ± 0.5 Ma, with new radiometric dating suggesting 23.3 ± 0.5 Ma, andesite□dacite domes intruded through and covered the metamorphic basement, spreading the area of Eressos, western Lesbos (Eressos Formation). This, together with the Gavathas formation, was overlaid

by the Sigri Pyroclastics of several hundred metres in thickness, which mainly consists of tuffs. A prominent welded ignimbrite approximately 25 m thick is interbedded with the upper stratum of the Sigri Pyroclastics west of Antissa. In turn, the Sigri Pyroclastics are covered by the Skoutaros Formation comprising basaltic and andesitic flows palaeomagnetically dated to 17.6–17.9 Ma. Some younger andesites and dacites are also included in the formation. The Polychnitos Ignimbrite Formation consists of seven widespread welded ignimbrite units in eastern Lesbos, each of 30–50 m thickness. It appears to be contemporary with the upper part of the Skoutaros Formation and may have originated in a caldera near Lepetymnos (older units), or in the caldera of Vatoussa (youngest units deposited in the southeast of the Gulf of Kalloni). The Skalohorion (eastern Lesvos) and Sykaminea (northern Lesvos) formations consist of younger andesitic and dacitic lavas palaeomagnetically dated to 17.0 – 17.6 Ma. These were followed by the younger (16.8Ma) basalts and andesites of the Mytilene Formation. Several ensembles of dykes of different ages run in different directions through the above formations. A significant stage in the geological evolution of western Lesvos is the main volcanic phase dated to about 17 Ma, during which the intensity of volcanism increases and culminates with the eruption of the Polychnitos ignimbrites and the formation of the Lepetymnos and Vatoussa calderas.
Our investigation essentially focuses on the area of the Lepetymnos caldera (according to Pe-Piper *et al.*, 2019, see Fig. 1), which has been subject to intense hydrothermal activity during and after its formation. As will be seen in the following, this has resulted in intense alteration along fault zones (which comprise significant fluid transportation and circulation conduits) and has begotten a hydrothermal geothermal system that is still active today.

Data and Methods

The magnetotelluric data used herein was produced by the private sector company Geosystem Srl. in the year 2000 (Geosystem, 2000), on behalf of PPC Renewables S.M.S.A. A total of 52 measurements (stations) were conducted, distributed as in Fig. 2. The original (time series) data were acquired with the Metronix ADU-06 system with GPS synchronization, EMI induction coils and $Pb/PbCl_2$ electrodes. Impedance tensors were then computed with the robust processing method of Larsen *et al.* (1996). For reasons unspecified, the observed (measured) impedance tensors were made available to PPC Renewables only in hardcopy and in the form of physical diagrams. The tensors were rotated (anti-diagonalized) to their intrinsic coordinate frames, and the diagrams displayed the principal apparent resistivities and phases together with their associated rotation angles. The physical diagrams were converted (scanned) to high-resolution digital images, which were rectified to correct distortions and subsequently digitized with custom-built software. In a final step, the principal apparent resistivities and phases were converted to principal impedances, which were subsequently rewound (inverse rotated) to recover as faithful as possible models of the observed impedance tensors.

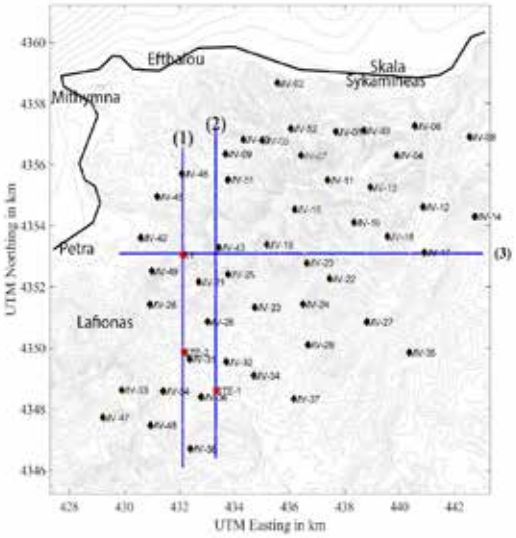

Figure 2. The distribution of the magnetotelluric measurements. The numbered blue lines indicate the locations of the three vertical resistivity cross-sections displayed in Fig. 5, 6 and 7.

The recovered impedance tensors were inverted to resistivity using the three-dimensional **Mod**ular system for **E**lectro-**M**agnetics (ModEM) software of Egbert and Kelbert (2012) and Kelbert *et al.* (2014). The resistivity (geoelectric) struc-

ture of the study area is approximated by a cuboid discretized into a grid of rectangular cells with dimensions 54 (N-S) × 54 (E-W) × 50 (vertically) and *includes* the topography and bathymetry of the study area (initial model). The coordinate system used in the inversion is the Universal Transverse Mercator (UTM) projection, zone 35S The physical dimensions of each cell in the horizontal plane are fixed to 300 m × 300 m; in the vertical direction, cell dimensions are variable with discretization being finer toward the surface of the earth and progressively becoming coarser with increasing depth. The initial resistivity values of cells representing 'the solid Earth' were set to 100 Ωm and were allowed to vary during the inversion. The resistivity values of cells representing 'air' and 'sea water' were respectively fixed to 10^6 Ωm and 0.3 Ωm and were *not* allowed to vary during the inversion. The *final* geoelectric model presented herein is based on the inversion of the *off-diagonal* elements (Z_{xy}, Z_{yx}) of the impedance tensor; it is the *best* of a set of alternative models and was obtained after a long series of trials (conducted by tuning the parameters controlling the inversion). The final RMS error was 1,65 and the final χ^2 metric was 349 with an expected value of 1824. Technically, this is a *very satisfactory* result.
The Bouguer gravity anomaly map of Lesvos was compiled on the basis of the Gravity Data Bank of the Department of Geophysics and Geothermy, National and Kapodistrian University of Athens (Lagios *et al.*, 1996). In the area of Lesvos, gravity stations are distributed evenly, with a spatial density of approx. 2 per 5 square kilometres; this allows for the generation of gravity anomaly grids with 1km spacing and enables the study of geological structures with scales comparable to the distances between stations (a handful of kilometres), including the major fault zones.

Results and Conclusions

Figures 3 and 4 display two horizontal resistivity sections at depths of 0.5 and 1.0 km below mean sea level. Fig. 2 shows the locations of two N-S oriented vertical resistivity cross-sections, of which the western (No. 1) passes through the locations of wells ΣΤΕ-2 and Σ-1 and the eastern (No. 2) through well ΣΤΕ-1. It also shows the location of an E-W cross-section through well Σ-1 (No. 3); finally, Figs 5, 6 and 7 display the resistivity cross-sections 1, 2 and 3, respectively.

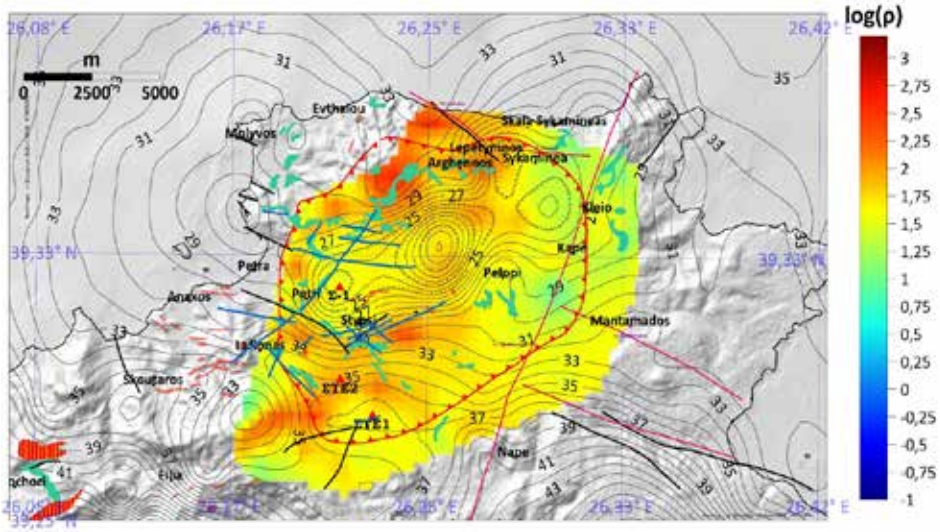

Figure 3. Horizontal resistivity section at the depth of 0.5 km bmsl, including known (mapped) faults and other geological features – see text for details.

In Figs 3 and 4, the general outlook of the geoelectric structure is that of a "mosaic" in which intersecting NE-SW and NW-SE bands of relatively high resistivity (ρ > 200 Ωm) engulf zones of relative conductors (100 Ωm < ρ < 5 Ωm). Resistivity is *noticeably* lower at 500m bmsl, where the relative conductors appear to diffuse laterally to all directions; it increases with depth so that the relative conductors progressively wedge into the resistive basement and vanish at depths greater than 2 km bmsl.
Such a configuration of the geoelectric structure is remarkably consistent with that of known (mapped) faulting features of the area. Therefore, it is consistent with the hypothesis that the relative conductors are collocated with intersecting faulting zones of NE-SW and NW-SE orientation, which generate a system of permeable structures capable of storing thermal fluids that ascend and laterally diffuse through the same faulting zones. Although not shown here, it was observed that at sea level the thermal fluid mixes with sea water intruding through the same fault zones and diffusing through the altered/porous near-surface lithological formations.
This interpretation is consistent with the configuration of the faulting zones relative to the geoelectric conductors mapped in the Petra – Stypsi zone of the study area and the findings of well Σ-1 in particular (Fig. 5 and 7). The geoelectric

model is apparently paradoxical in the vicinity of well ΣΤΕ-2, where a column of resistive material is featured below the surface of the Earth although abundant thermal fluids were found there (Fig. 5). However, ΣΤΕ-2 is located at the boundaries of significant conductors and possibly in the neighbourhood of intersecting faults (see below). Both of these features may explain the presence of fluids as a result of circulation/lateral diffusion from nearby sources.

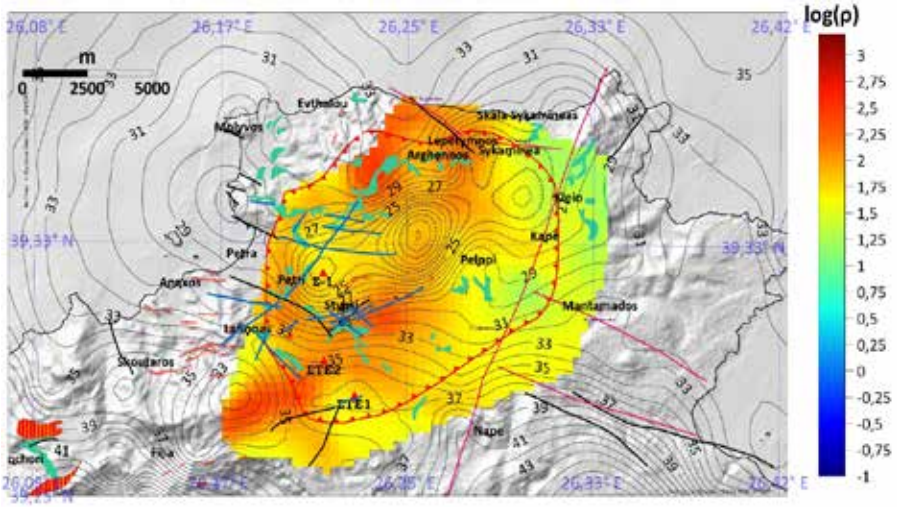

Figure 4. Horizontal resistivity section at the depth of 1 km bmsl, including known (mapped) faults and other geological features – see text for details.

At the southern boundary of the study area, in the neighbourhood of well STE-1, the model is consistent with the findings at the well ΣΤΕ-1, where abundant thermal fluids were observed through and through (Fig. 6). However, the geoelectric structure cannot be adequately constrained in the N-S direction due to one-sided coverage with magnetotelluric measurements. Nevertheless, because the model is consistent with the findings of the drilling exercise, the same conclusions as above can be (tentatively) drawn.

Comparative analysis of resistivity and Bouguer anomaly data

Figures 3 and 4 also display the Bouguer anomaly map of the broader study area and enable its joint evaluation with the 3-D electrical resistivity model. In addition to the gravity and electrical resistivity information, they include: **a)** traces of known faults (mapped by Hecht, 1972-1976) illustrated with black and broken red lines; **b)** traces of known faults mapped by researchers of the Department of Geography of the University of the Aegean (2022) illustrated with blue lines; **c)** the perimeter of the Lepetymnos caldera as per Pe-Piper *et al.*, (2019); **d)** the kaolinization zones mapped by Pe-Piper *et al.*, (2019), illustrated as green patches (also see Fig. 1) and, **e)** the rhyo-dacitic dykes mapped by Hecht (1972-1976), illustrated as elongate orange patches (also see Fig. 1).

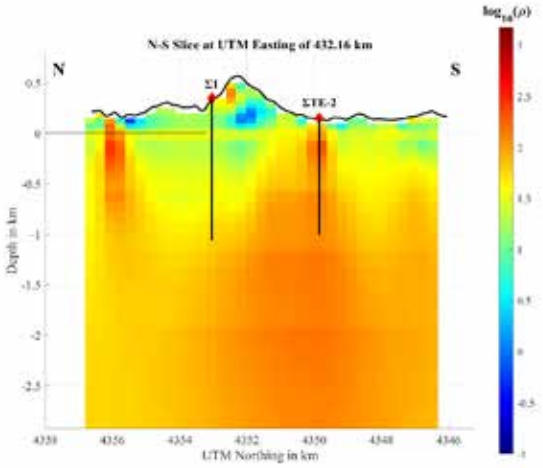

Figure 5. The N-S resistivity cross-section No. 1 through wells Σ1 and ΣΤΕ-2. South is to the right and North is to the left.

The most prominent and characteristic feature is an approximately N70° - N80° alignment of collocated gravity and electrical resistivity lows between the broader areas of Stypsi – Petra and Lepetymnos – Sykaminea towns. Low Bouguer anomalies indicate low-density material beneath the surface and low resistivity values indicate the presence of water. Their coincidence indicates the presence of low-density rock filled with water and, in the geological setting of the study area, alteration/argillization of volcanic rocks due to hydrothermal activity.

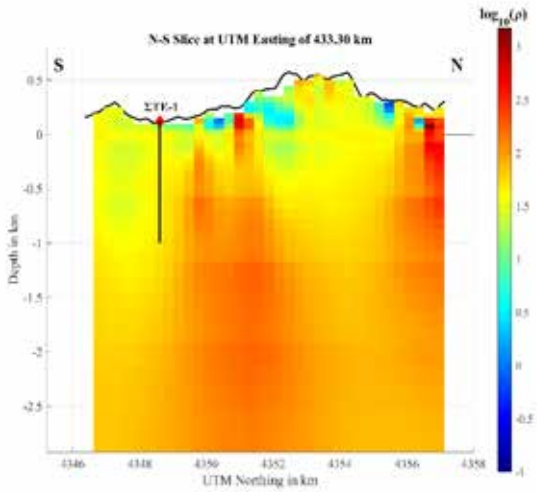

Figure 6. The vertical N-S resistivity cross-section No. 2 through well ΣTE-1. South is to the left and North is to the right.

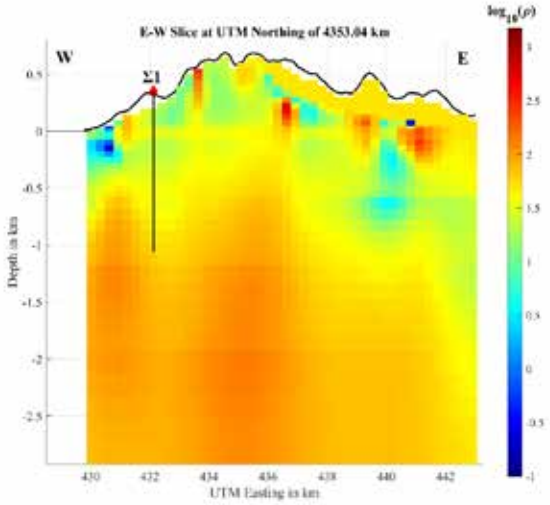

Figure 7. The vertical W – E resistivity cross-section No. 3 through well Σ1.

In the broader area of Stypsi, this low-gravity – low resistivity alignment is also collocated with traces of faults with approximately N70° - N80° orientation. Another very interesting observation is that between Stypsi and Skoutaros, there is a series of outcropping parallel, N80° oriented rhyo-dacitic dykes arranged in a manner suggestive of a direct (genetic) relationship with said faults. If so, the observed fault – dyke configuration would imply that the dykes were emplaced through an N70°-N80° oriented (*oblique–normal*?) fault zone during a *localized* event of syn-tectonic extrusive magmatism. A further (and possibly corroborating) observation is that in the same area, but *near* the Anaxos – Petra coast, the rhyo-dacitic dykes outcrop with an N330° orientation, parallel to the short fault strands of similar orientation mapped at Petra. This may indicate that the syn-tectonic extrusive event took place at, or near the intersection of two associated fault zones. Furthermore, kaolinization zones are produced by hydrothermal activity; if they are elongated and coincide with fault zones, as evident in Figs 3 and 4, then it is safe to conclude that kaolinization is an effect of thermal fluid circulation in faults.

Accordingly, the collocated gravity and resistivity lows may be epiphenomenal to the action of faulting due to which the circulation/transportation of (thermal) fluids depresses the electrical resistivity (epiphenomenon 1) and, hydrothermal alteration/argillization and bleaching of the heavier elements depress the density of the host rocks (epiphenomenon 2). Given the broader tectonic setting of the study area, the above observations indicate the presence of N80° and N330° fault zones, which have established well-defined circulation zones that are operational today, although it is yet difficult to infer the possibility of these faults being tectonically active at present.

Research Highlights:

Strontium isotope analysis ($^{87}Sr/^{86}Sr$) of enamel from Late Pleistocene ungulate teeth reveals a predominant local habitat range of these ruminants within the Mani Peninsula with only minimal migration. Results reveal insights into human subsistence strategies, with hunting focused on fauna from nearby areas.

Introduction

Determining the mobility and provenance of Late Pleistocene fauna are crucial for understanding past ecosystems, predator-prey dynamics, and human-animal interactions. Among geochemical methods, strontium isotope analysis ($^{87}Sr/^{86}Sr$) has proven to be a powerful tool, offering the ability to trace geographic origins and movement patterns through the isotope composition of tooth enamel (Bentley, 2006; Britton and Guiry, 2020). The bioavailable $^{87}Sr/^{86}Sr$, which varies with composition and age of the underlying bedrock geology, enters the food chain through soil, water, and vegetation and is subsequently recorded in the biological (hard) tissues of consumers of higher order (Ericson, 1985).

This study examines the $^{87}Sr/^{86}Sr$ in tooth enamel of ruminant species excavated from the Melitzia Cave in Mani Peninsula, Greece. The faunal assemblage includes species such as *Cervus elaphus* (red deer), *Capra ibex* (ibex), and *Dama dama* (fallow deer), these species were hunted and consumed by the cave's occupants (*Homo sapiens*) during Upper Pleistocene (Darlas and Psathi, 2016), who lived in the numerus cave sites of Mani Peninsula. By comparing $^{87}Sr/^{86}Sr$ in tooth enamel of archaeological faunal remains to a bioavailable baseline derived from modern plant samples, this research aims to establish provenance and assess the habitat use and mobility of the human prey animals. It also seeks to contextualize these findings within the broader palaeoecological and geological framework of Mani Peninsula.

Material and Methods

To construct the bioavailable strontium (BASr) baseline, modern plant samples were collected systematically across 13 geological formations in the Mani Peninsula. A total of 36 leave samples, representing 12 different species of shrubs and trees, were processed. The sampling design accounted for variations in altitude, geology, and vegetation type. The spatial strontium distribution map was created by the Inverse Distance Weight (IDW) method in ArcGIS.

Isolated third and second molars from three ruminant taxa were analyzed to investigate animal mobility. In total, 42 bulk enamel samples were analyzed, and 13 of these teeth were also sequentially sampled to assess seasonal habitat changes.

The Sr isotope analyses were conducted at the Department of Chemical and Geological Sciences of the University of Modena and Reggio Emilia. The samples were prepared according to the protocol described by Lugli et al. (2017). For tooth enamel, 5–10 mg of powder was used, and the modern plants were mixed per sampling site and burned to ash at 500 □ and 15 mg of these ashes were analysed. Sr isotope ratios were determined using the dissolution method MC-ICP-MS by means of a Neptune MC-ICP-MS, housed at the Centro Interdipartimentale Grandi Strumenti (CIGS) of the University of Modena and Reggio Emilia.

Results and discussion

The $^{87}Sr/^{86}Sr$ from plant samples, ranging from 0.70801 to 0.71749, were used to create an isoscape map representing the spatial distribution of bioavailable $^{87}Sr/^{86}Sr$ across the region (Figure 1). Enamel $^{87}Sr/^{86}Sr$ of ruminant teeth from the cave deposits range from 0.70852 to 0.71014 and nearly all of them fall within the range of the Upper Cretaceous to upper Eocene marine limestones (in which Melitzia cave formed) and modern seawater (i.e., sea spray effects) (Figure 2). The average $^{87}Sr/^{86}Sr$ of the enamel samples vary for *C. ibex* between 0.70852 and 0.70861 (mean: 0.70871, 0.000006 SD), for *C. elaphus* between 0.70860 and 0.70911 (mean: 0.70878, 0.0001 SD) and for *D. dama* between 0.70856 and 0.71014 (mean: 0.70894, 0.0005 SD). The lowest ratio occurs in *C. ibex* and the highest in *D. dama* although most of the enamel ratios lie within the narrow $^{87}Sr/^{86}Sr$ range of the limestone rocks in which the cave formed, except for one *D. dama* individual (0.71014) that lies outside of this range. This suggests that most of these animals likely spend their early lives (i.e., the time of tooth mineralization) in the vicinity of the cave. The identification of one individual with a higher $^{87}Sr/^{86}Sr$ value, indicates a short-term migration, suggesting that the individual possibly moved across different geological formations during its lifetime. This non-local value likely fits to $^{87}Sr/^{86}Sr$ of a region

with metamorphic bedrocks, that are exposed in the peninsula's north-eastern part. The findings suggest that this animal either migrated into the area or was hunted there and then transported to the site by predators. Altogether, the enamel $^{87}Sr/^{86}Sr$ range indicates that humans hunted mainly in the surroundings of the Melitzia Cave and do not show any spatial niche partitioning. *C. ibex* exhibited the least isotopic variability, consistent with its narrow ecological niche, its preference for rugged, steep terrains likely restricted its movement to local areas. While *C. elaphus* and *D. dama* show slightly broader variations in their $^{87}Sr/^{86}Sr$ isotope ratios compared to *C. ibex*, the variations show still a narrow range. This indicates that their movement was limited to areas with isotopically similar bedrock.

By integrating strontium isotope analysis with palaeoecological investigation, this study sheds light on the movement and habitat use of Late Pleistocene ruminants in Mani Peninsula. It underscores the utility of isotopic methods in unravelling past faunal behaviours and contributes to broader discussions of human-animal interactions and ecological stability in Upper Pleistocene Mediterranean ecosystems.

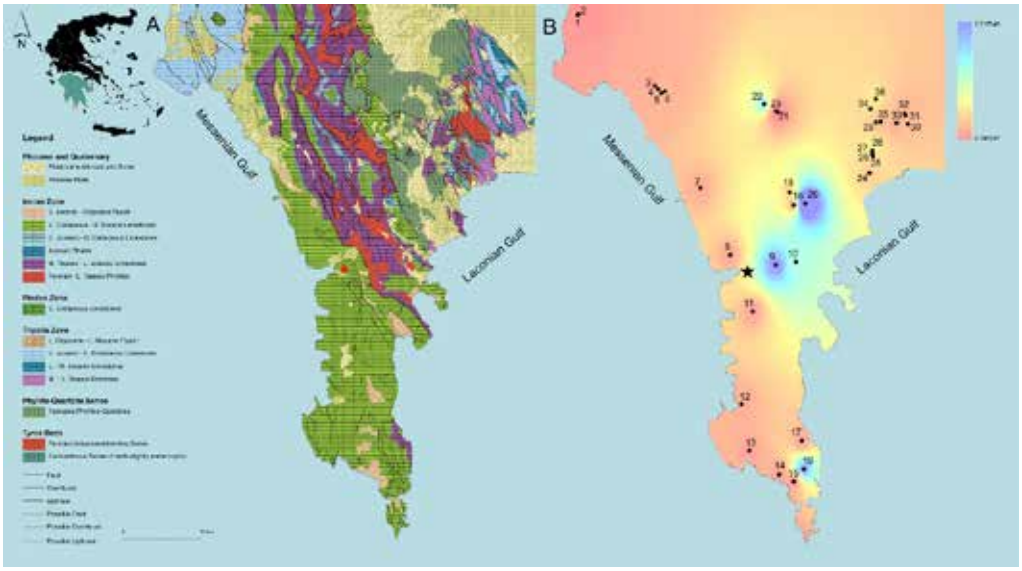

Figure 1. Geological map of Mani Peninsula (modified by Latsoudas, 1984) (A) and BASr baseline for the Mani Peninsula, with the locations of the modern plant sampling sites (B). Numbers on the BASr baseline map indicate sampling sites, while star on each map represents the position of Melitzia Cave. EXTENDED ABSTRACT 330

Application of UAVs in Rockfall Hazard Assessment and Mitigation Measures in the Vrachon Theatre, Byron Area, Greece

Vagionakis N., Andreadakis E., Diamantis K., Stavropoulou M.
Department of Geology and Geoenviroment, Sector of Dynamic, Tectonic and Applied Geology, National and Kapodistrian University of Athens, Athens, Greece

Abstract
The analysis of rockfall hazard on rocky slopes is of vital importance for the safety of engineering works and the protection of human lives, being the subject of numerous scientific studies. Advances in technology, with the use of unmanned aerial vehicles (UAVs) combined with photogrammetric techniques, allow the creation of high accuracy 3D models for rockfall mapping, even in inaccessible areas. Although internationally these methods are widely applied, in Greece the relevant studies are limited. In the area of the Vrachon Theatre in the Municipality of Byron, UAV was used to collect 500 aerial photographs, which were processed with Pix4DMapper. Using AutoCAD and ArcGISPro, a topographic map and cross-sections were created, while RocFall was used for falling simulations. The objective was to assess the hazard, suggest mitigation measures and generate a hazard map.

Introduction
Generally, the study of the hazard and risk assesment of rocky slopes is crucial for engineering projects, for ensuring social security and is the subject of many geotechnical and other studies. Depending on its magnitude, can cause serious damage to structures and threaten human lives. The need to predict and prevent the phenomenon has led many scientists to address it (Budetta, 2004; Lioni, 2010; Ferrari et al., 2016; Hussain, 2018; Wang et al., 2020; Papavasilis, 2020; Vassou, 2022 et al.). Developments in technology have led to new methods and tools that facilitate low-cost data collection and capture. Combining these with remote sensing systems enhances data collection, even in inaccessible areas with difficult morphology. A typical example is the use of unmanned aerial vehicles (UAVs) in combination with photogrammetric techniques, which allows the creation of high accuracy 3D digital elevation models for mapping and subsidence at any scale. For this reason, efforts have been made in recent years to apply these methodologies (Kim et al., 2020; Konstantinidis et al., 2021; Longhui Zhao et al., 2024 etc.). However, few of them have taken place in Greece (Thomopoulos, 2009; Stanota, 2019; Zucher El Azouz, 2020 et al.).
In our study area, i.e. the Vrachon Theatre of the Municipality of Byron (Prefecture of Attica), only one study was carried out (Andrakako and Zacharaki, 2020), in which, however, remote sensing methods and remote applications were not used. In this study 500 aerial photographs were taken through the use of UAV, which were imported into Pix4DMapper software, processed and thus the Digital Surface Model (DSM), Orthomosaic and Digital Terrain Model (DTM) of the study area were constructed. Also, AutoCAD software, in combination with ArcGISPro, was used to create the topographic map, divide the slope into 5 sub-slopes and construct their respective cross-sections, based on which the simulations of possible collapses were carried out using RocFall software. The aim of this work is to assess the rockfall hazard in the area of the Vrachon Theatre, to propose mitigation measures and to construct the hazard map.

Study Area
The Vrachon Theatre is located west of Mount Hymettus, ANA of the Attica basin (Fig.1) and is one of the many quarries that used to operate in Attica. This area has now been exploited by the Municipality of Byron, but also by the Municipality of Daphne-Ymittos, as a place of entertainment for the residents. The intense morphological features, which were exacerbated by its earlier use as a quarry, have stimulated interest in the forthcoming analysis of the hazard of rockfall phenomena in the study area.
Based on the geological map of the I.G.M.E. (today's E.A.G.M.E.) and specifically the sheet Koropi-Plaka, by Latsouda (2003) and at a scale of 1:50. 000, the formations surrounding the Vrachon Theatre are Alpine and belong to the upper tectonic cover of the Aleppouvouni unit, which consists mainly of carbonate, sedimentary rocks and more specifically of Upper Cretaceous limestones. Thus, the study area consists of white to tephra and brownish limestones.

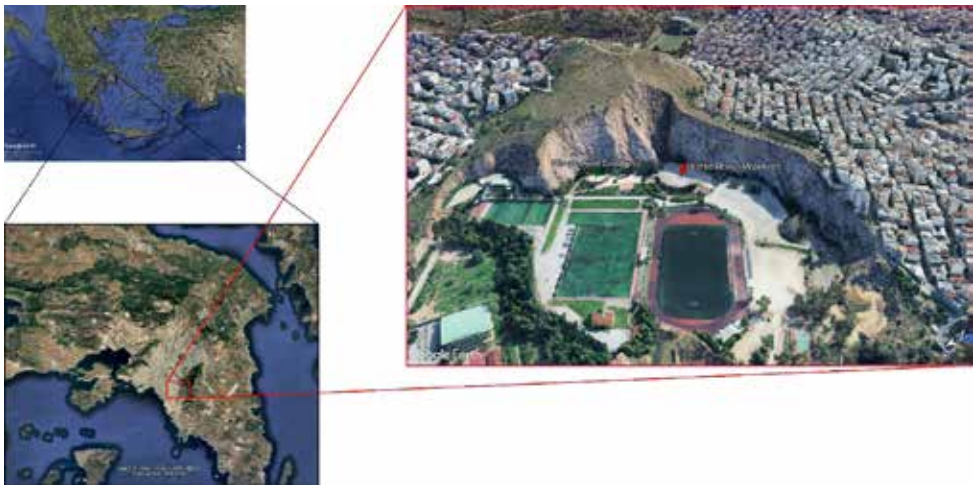

Figure 1. Display and labelling of the study area

The average inclination of morphological slopes observed in the study area is 65° and the altitude ranges from 120 to 260 meters. From a hydrogeological point of view, it is observed that mostly porous formations are encountered, as well as karstic formations, such as limestones. The Municipality of Byron belongs to Seismic Risk Zone I (Greek Seismic Regulation, 2000) and is characterized as an area of very low seismicity. Furthermore, an analysis of seismic events in Greece (1900-2024) shows that no earthquakes have occurred near the area. However, in the stability analyses (RocFall software) we included seismic activity using the relevant index to approximate as closely as possible the stability of the rocky slopes in our study area.

Methodology

The methodology of the research process started with the aerial mapping of the rocky slopes, through the use of unmanned aerial vehicle (UAV) and subsequently, the DSM, the DTM, as well as the orthomosaic of the area were constructed through the Pix4Dmapper program, in order to achieve a more accurate analysis of the research area. Then, with the contribution of the above images, the man-made structures of the area were captured and, through the digitization process, the rock masses of the entire rocky slopes were mapped (Fig. 2).

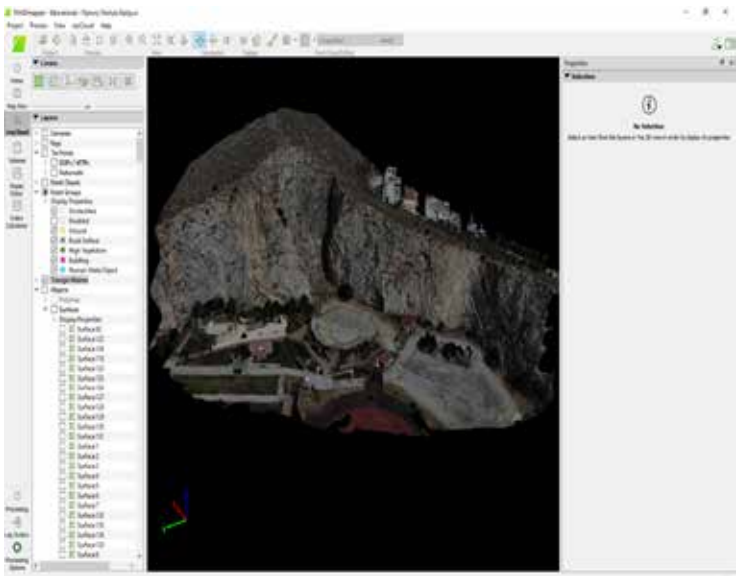

Figure 2. Illustration of the digitized 3D model of the area

The single slope around the Vrachon Theatre was divided into 5 individual slopes, according to their morphological variations, through the 3D model of the area in AutoCAD software (Fig. 3a). An additional element resulting from the combination of Pix4DMapper, AutoCAD and ArcGISPro software was the visualization of the contour curves. Cross-sections were thereafter drawn with AutoCAD, the 13 most precarious ones were selected and a mileage measurement was performed along the study

area (Fig. 3b). In addition, Figure 4 illustrates the above elements, as well as the different materials encountered in each cross-section (Google Earth Pro).

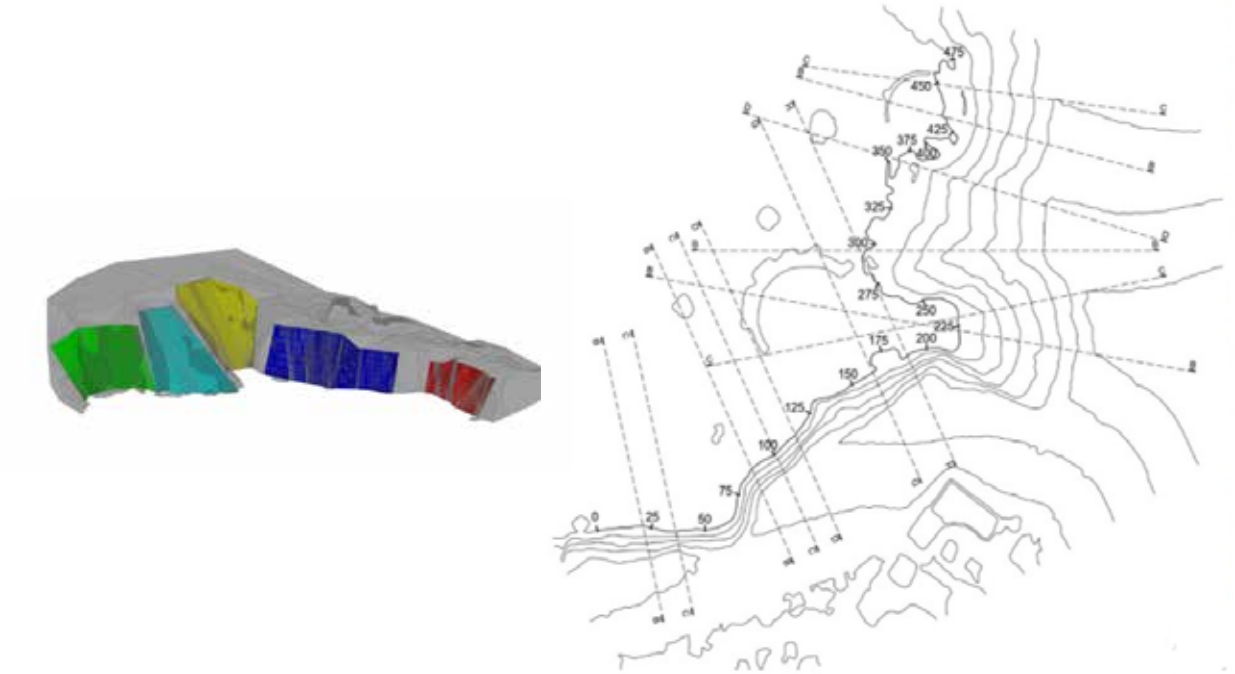

Figure 3. a) 3D solid representation of the 5 slopes, b) topographic map with the 13 high risk locations

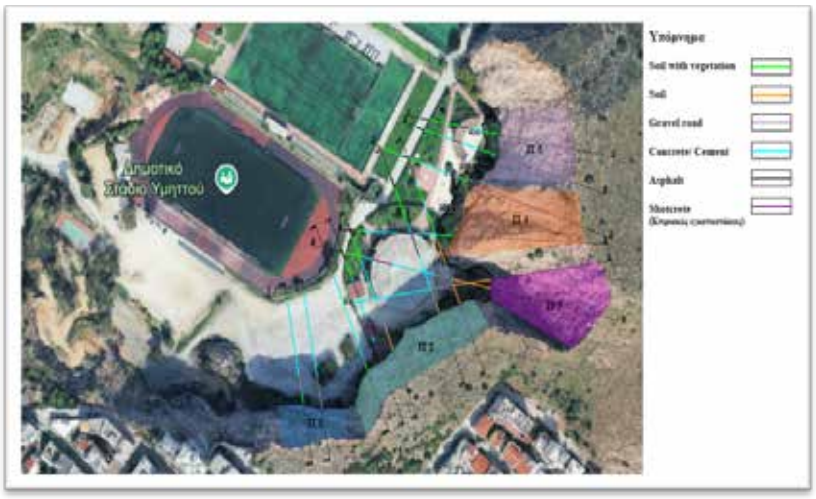

Figure 4. Visualization of the high risk locations through the cross-sections and their corresponding materials in Google Earth Pro

Subsequently, the determination of the rock block weight was implemented, based on which the relevant simulations of their possible paths were carried out. So, taking into consideration the dimensioned ones, we concluded that the majority of them approach the value of 450 kg. The next step carried out was the defining of the seeding positions (seeders) of the potential rock fragments to include all possible cases of fragments taking place near the crest of the slope, which is the worst-case scenario.

Survey results

Figure 5 shows the analyses of the BB cross-section of the first slope, for which the line seeder was initially placed in the area between the two points, with respective heights of 35.504 m and 40 m from the base of the slope, the simulation was configured and the diagrams were drawn showing the final potential positions of the fragments, their total kinetic energy per measurement position, as well as the bounce height.

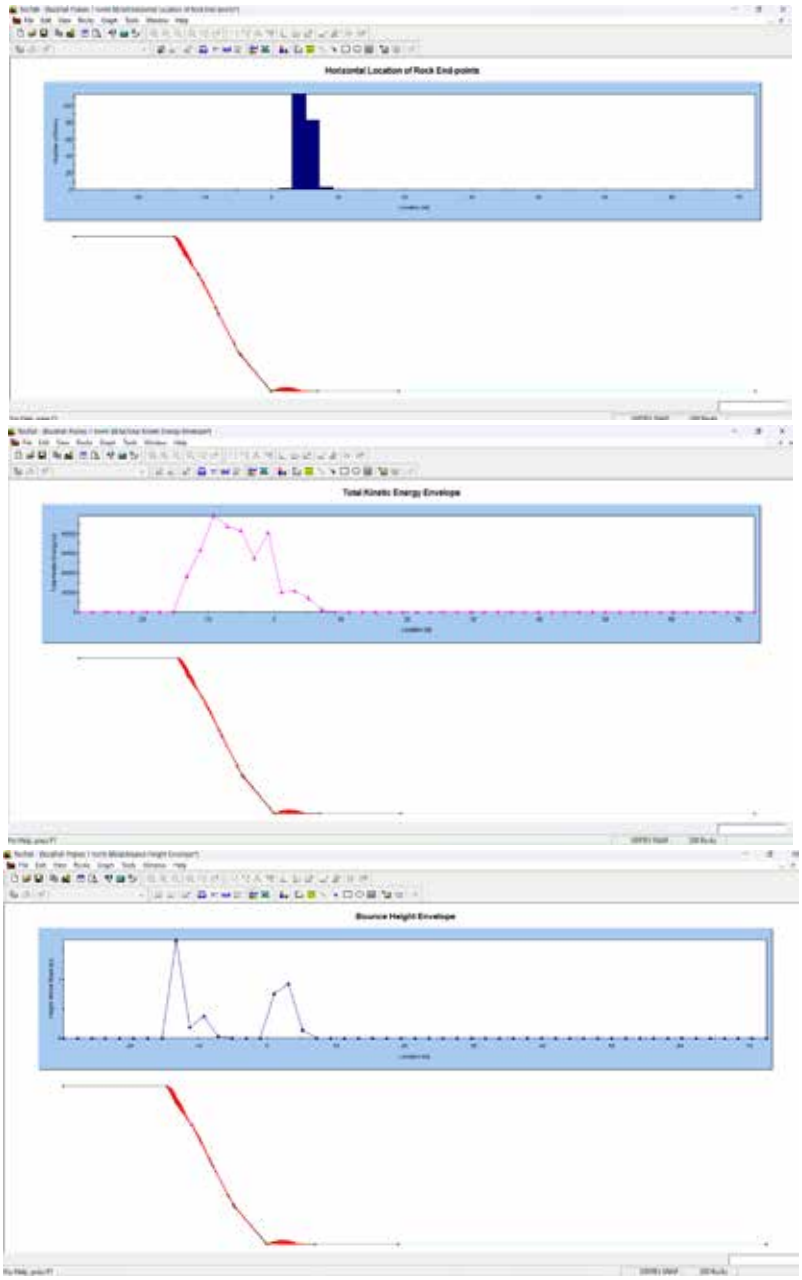

Figure 5. Diagrams of rock fragments of section BB: a) with their horizontal end positions, b) their total kinetic energy and c) their bounce height

According to the above, the decision was made to place or not a suitable retaining fence (barrier) and what characteristics it will fulfill. The fence should therefore be placed in a position where it stops the path of all the fragments and at the same time in this position the kinetic energy should be the minimum possible. Thus, the proposed position is illustrated below, in which the value of the total kinetic energy is distinguished (Fig. 6a).

Subsequently, the simulation was repeated in order to check the energy capacity of the barrier. Figure 6b shows the corresponding diagram of the expected final positions of the fragments, where in this case all of them will be stopped and trapped before the barrier.

We worked in the same way for the sections of the other 4 slopes. Based on the whole analysis above and according to the aggregated results of all the sections, the hazard map (Fig. 7) was constructed, where the planned hazard zones (High Hazardous Zone and Very High Hazardous Zone), as well as the development of a related fencing wall, are marked. Therefore, as can be observed, Slope 2 is the most precarious slope.

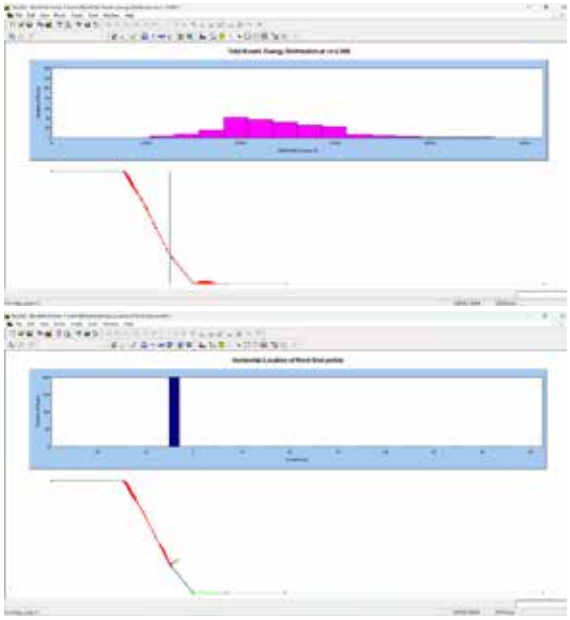

Figure 6. a) Proposed location of the barrier and the distribution of the total kinetic energy of the fragments, and b) final potential end positions of the fragments on it

Conclusions

In this paper we dealt with the rockfall hazard and mitigation measures evaluation of the rocky slopes surrounding the Vrachon Theatre of the Municipality of Byron. An aerial survey of the slopes was carried out using UAVs and 500 aerial images were obtained. These were processed in Pix4DMapper software and produced the 3D digital model of the area, the digital elevation model, the digital terrain model and the orthomosaic of the study area. Based on the above, the topographic map was constructed, where the 13 cross-sections of the most high risk locations were selected using AutoCAD software. Then, according to these, the simulations of the potential rock falls of 450 kg rock fragments were carried out and the relevant diagrams of the potential end positions, total kinetic energy as well as the bounce height were generated. Subsequently, the placement of an interception barrier was proposed, on the basis of which the potential fragments were finally excavated and trapped in it. Finally, the final hazard map was produced, distinguishing the so-called high hazardous Zone, based on the maximum potential end positions of a small number of individual fragments, the very high hazardous Zone, which in turn is based on the maximum end positions of the majority of these fragments, and the corresponding perimeter wall delimiting these two zones, marked in black. Based on all of the above, it was determined that the most precarious and critical slope is Π2.

Research Highlights

Palaeoecological study in sediments from one of the most touristic caves in Greece (the Cave of the Lakes, Peloponnese) and the discovery of a new species of Ostracod.

Introduction

Karst landscapes are characterized by a variety of features formed from water-soluble rocks (Scheffers et al., 2015). They showcase a diverse mix of environmental and climatic conditions, including sinking streams, sinkholes, large spring caves, and enclosed depressions. This environmental heterogeneity, combined with local climate effects and geographic isolation, fosters remarkable biological diversity, including many endemic species. Especially caves, are vital for biodiversity as they provide unique and stable habitats that support a wide variety of life, including many rare and specialized species (Howarth and Moldovan, 2018).

Ostracods, due to their sensitivity to environmental variations, have emerged as valuable model organisms for investigating climate and ecosystem changes (Holmes & Chivas, 2002). They inhabit almost every aquatic ecosystem, including freshwater, brackish, and saline waters—from oceans to streams, and even groundwater and caves—demonstrating their widespread distribution and ecological diversity and high endemism (Martens et al., 2008). This extensive habitat range makes them excellent indicators of physical and chemical conditions in aquatic environments. For central Europe, information regarding cave ostracods has already been provided (e.g. Meisch,2000). In Greece the related works seem to be significantly reduced when it comes to subterranean species (e.g. Karanovic, 2003) and almost absent when it comes to cave environments. The only extensively known work to date is that of Popa et al., (2019) from Melissotrypa Cave in central Greece. However, Karanovic (2003) has highlighted the high ostracod endemism in the Greek karstic system and the need for further studies due to the high possibility of undescribed taxa existence. Therefore, the study of cave ostracods presents a promising frontier for new discoveries.

This work aims on presenting the results of the ostracod analysis conducted on surface samples from a touristic cave (Cave of the Lakes), located in Northern Peloponnese, Greece. The ostracod taphocoenosis revealed new data on the cave biodiversity and depositional environment. Furthermore, a new species is introduced adding valuable information for the little studied cave ostracods of Greece.

Study area-The Cave of the Lakes

The study area lies in Northern Peloponnese, Greece. The Cave of the Lakes is located in Mount Amolinitsa near Kastria, Kalavryta (Fig.1). It is one of the most emblematic geosites of the Chelmos Vouraikos UNESCO Global Geopark (https://chelmosvouraikosgeopark.necca.gov.gr) and receives thousands of visitors each year. Discovered in 1963, the cave extends over 1,980 meters and features rich and impressive speleothems and 13 interconnected lakes located at different levels. It is also an important palaeontological and archaeological site (Sampson, 1997). The cave extends partly within the Cretaceous limestones of the Tripolis geotectonic zone and partly within the Late Cretaceous thin-bedded limestones of the Pindos zone (Fig.2). It has developed along the northwest-directed fault and is characterized by a long, narrow passage with a comparatively high roof. The 1st part is divided from the 2nd one by a small fault. Both parts are developed in the limestones of Tripolis zone. The intensive rock falls that can be seen in the third part are the result of tectonism of the thin platted Pindos limestones.

Figure 1. Location of the study area.

Material and Methods

Sampling in the Cave of the Lakes took place during October 2022, resulting in seven surface sediment samples (CL1–CL7) (Fig.2). Sampling was conducted only along the touristic part of the cave. Samples from dry areas were collected using a small shovel, while those from the lake were obtained using a box corer. Water samples from the lakes were also retrieved. Samples were stored and processed at the Laboratory of Palaeontology and Stratigraphy, University of Patras.
After inspection for living populations with negative results, approximately 300 gr from each sample were dried and treated with 5% H□O□ for at least 24 h, with the solution heated to 90 °C when necessary. Residues were wet-sieved through 125 μm and 63 μm sieves and then oven-dried at 70 °C. Identification and data on the ecology and distribution of ostracod species are primarily derived from Meisch (2000) and Karanovic (2012). The ostracods were photographed, and morphological details were examined using Leica MZ16 stereomicroscope with a Jenoptik Gryphax Altair digital camera and scanning electron microscope Jeol JSM 6390 (Laboratory of Historical Geology-BioGeoSciences, Faculty of Geology and Geoenvironment, National and Kapodistrian University of Athens).
The taphonomic index Adult/Juvenile (Belis et al., 1997) was calculated at the family level as an indicator of environmental energy.

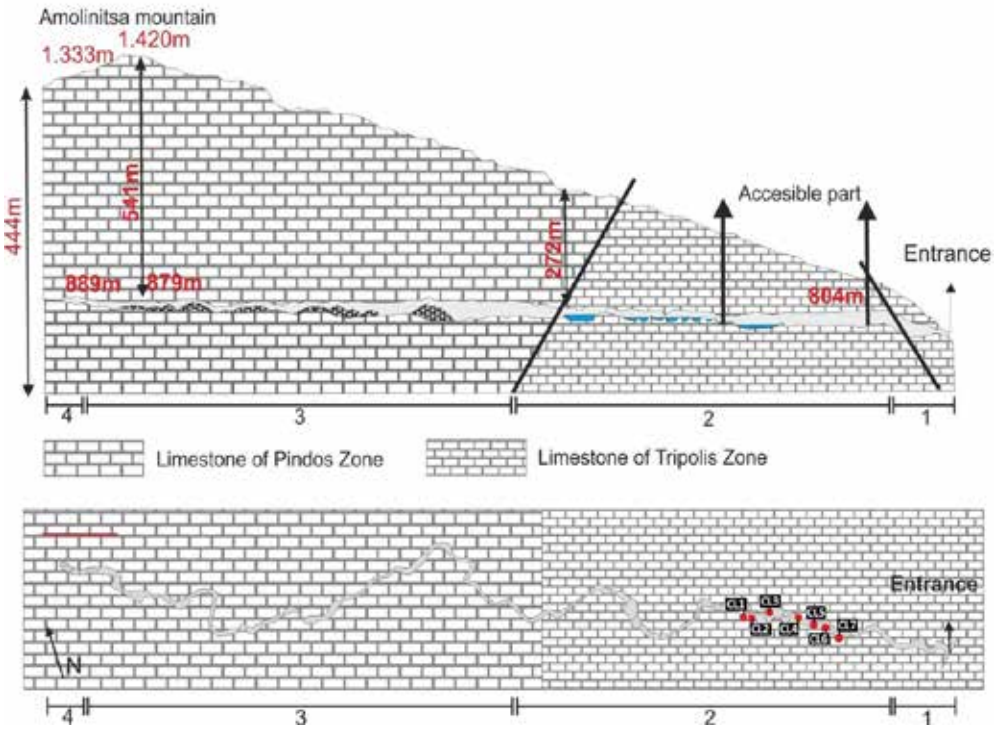

Figure 2. Cross section of Mount Amolinitsa and the Cave of the Lakes. The sampling points are marked in red.

Results

The results of the ostracod analysis revealed low diversity (taxa number 1 in sample CL7 to 3 in samples CL2, CL4, CL5 and CL6) and varying frequency assemblages (7 valves/gr in sample CL7 to 665 valves/gr in sample CL1). More specifically, three taxa were identified.

Neglecandona vernalis dominated the assemblages in all samples (except sample CL7) (maximum number of valves in sample CL4). *N. vernalis* in Germany has been found in small water bodies that dry up temporarily especially meadow puddles and ditches.

A new species of *Trapezicandona* accompanied the taphocoenosis (except sample CL1) with lower frequency (from 1 valve in sample CL2 to 59 valves in samples CL6). Genus *Trapezicandona* is a holarctic hypogean taxon and it is very common in Italy and Spain. Nevertheless, it is the first time that is mentioned from Greece. Detailed morphological study of the studied herein valves revealed that it consists of a new species.

Schellencandona sp. has been found with low numbers (1 in samples CL6 and CL2 to 9 in sample CL1) except samples CL3 and CL7 where it was absent. It is a clearly hypogean stygobite taxon (Meisch, 2000). However, the high endemism of the genus and the low number of valves did not allow its identification to the species level.

The A/J ratio revealed that most of the samples were deposited in situ. More specifically, samples CL1 (A/J ratio: 0.16), CL3 (0.14) and CL5 (0.24) were deposited in situ implying a depositional environment of very low energy. Samples CL4 (0.60), CL6 (1.09) and CL7 (1.73) were deposited in situ, but with taphonomic removal of juvenile valves implying a relatively higher energy depositional environment. The A/J ratio calculated for sample CL2 revealed transported juvenile valves in a low energy depositional environment or a mass death event.

Moreover, in samples CL3, CL5, CL6 and CL7 gastropods of the Hydrobiidae family were also recorded (with very high frequency in sample CL6). Samples CL1, CL6 and CL7 contained a high number of microplastics indicating severe anthropogenic impact.

Conclusions

The ostracod study of seven surface samples deriving from the Cave of the Lakes, Peloponnese, Greece revealed a unique ostracod taphocoenosis. Among them a new stygobiote species is described (*Trapezicandona* n. sp.) contributing to the list of identified cave ostracod species worldwide. Especially for Greece this is a pioneering work since no other detailed works have been published yet. Moreover, the depositional environment inside the cave is inferred as temporal freshwater with no or low transportation energy, uniform in all studied parts of the cave. The high presence of organic material (bat guano) is certain.

The current work is showcasing the perspective of the ostracod research in caves. More scientific work must be done in the cave of the lakes in different directions since a lot of questions arise such as the synthesis of the ostracod assemblage in the other 11 lakes, the search for living populations, the correlation and the possible connection of the subterranean assemblages with the surface ones and the evolution of the lakes' palaeoenvironment through time and its response to climatic effects and the anthropogenic impact.

EXTENDED ABSTRACT 332

Overview of Legislation and Tools for Stream Flood Risk Assessment

Valavani Eleni[1], Siarkos Ilias[2], Tzoraki Ourania[2]

1 Directorate of Technical Works of the North Aegean Region, Greece, valavani_eleni@yahoo.gr, 2. epartment of Civil Engineering, Democritus University of Thrace, 3 Marine Sciences Department, University of the Aegean

Abstract

There is a growing need to manage flood risks, particularly in the context of urban expansion, climate change, land desertification, and deforestation. Due to rapid rainfall and geographical variability, many regions in Greece are prone to flash floods. Infrastructure works such as hydraulic projects, dam construction, and river diversions are essential for mitigating the impacts of flooding. Although multiple laws and regulations exist (e.g., EU Directive 2007/60/EC), the current legal framework remains fragmented and is often inadequately enforced. Public misunderstanding and the lack of centralized data further exacerbate the problem. This study explores the complex issue of flood risk assessment in Greece, with a specific focus on the town of Petra in Lesvos. A hydrological and hydraulic analysis of the local stream was conducted using: a) the Rational Method for peak flow estimation, and b) HEC-RAS software for hydraulic simulation under return periods of 50, 100, and 1000 years. The analysis revealed that the stream in Petra fails to accommodate floodwaters even for the 50-year return period, with many cross-sections experiencing overflow. Contributing factors include narrow channels, riverbank erosion, and inadequate maintenance. The study highlights the urgent need for regular cleaning, implementation of protective measures, and reforestation. While existing tools such as the Rational Method and HEC-RAS are useful, they should be applied cautiously due to their simplifying assumptions. Ultimately, there is a critical need for improved legislative frameworks and technical tools to manage flood risks effectively, especially given Greece's climatic variability and hydrological challenges.

Conservation and Interpretation of Fossiliferous Sites in the Lesvos Island UNESCO Global Geopark

Valiakos I.[1,2], Bentana K.[1,2], Zouros N.[1,2]
(1) Natural History Museum of the Lesvos Petrified Forest, Mytilini, Greece, ivaliakos@yahoo.gr (2) University of the Aegean, Mytilini, Greece

Introduction / Background

The Lesvos Petrified Forest stands as the hallmark of the Lesvos Island UNESCO Global Geopark, representing a unique natural monument celebrated for its remarkable fossilized trees. These fossils provide invaluable insight into the region's geological history. Preserving and interpreting these fossil-rich sites is essential for advancing scientific research, promoting public education, and fostering sustainable tourism. This paper examines key strategies for conserving and interpreting the newly excavated sites within the Geopark framework.

Formed approximately 20 million years ago due to intense volcanic activity in the northeastern Aegean, the Lesvos Petrified Forest is a geological treasure of international significance. It played a crucial role in Lesvos Island's recognition as a UNESCO Global Geopark. Covering an area of 15,000 hectares in the island's western region, the protected area of the Lesvos Petrified Forest offers a rich window into past ecosystems and geological processes.

The Natural History Museum of the Lesvos Petrified Forest serves as the public institution dedicated to the protection and sustainable management of this extraordinary heritage. The Museum also conducts rescue excavations within the protected area when fossils are discovered during public or private construction projects, ensuring their preservation and proper study.

Challenges in Fossiliferous Site Conservation

While fossils may appear robust and enduring, they are, in reality, highly susceptible to various environmental factors that can lead to significant mechanical and chemical deterioration. Elements such as humidity, temperature fluctuations, and exposure to biological agents, including plant roots, lichens and fungi, contribute to their gradual decay. Additionally, human activities such as vandalism and unauthorized fossil collection pose substantial threats to their preservation (Kyriazi, et al. 2008)

Fossiliferous sites face multiple threats that jeopardize their preservation. Natural processes such as erosion and weathering progressively degrade these sites over time. Human activities exacerbate these risks, including uncontrolled tourism, which can physically damage delicate fossils, illegal excavations that disrupt the geological context, and infrastructure development that may permanently destroy valuable paleontological resources. Furthermore, climate change compounds these challenges, as increasing temperatures and the rising frequency of extreme weather events accelerate the deterioration of fossils and their surrounding environments.

Consequently, conservation efforts must extend beyond the fossils themselves to include the broader geological and ecological contexts in which they are embedded. Protective measures such as erosion control, vegetation management, and site stabilization are essential to ensuring the long-term integrity of fossiliferous sites. By maintaining these sites, researchers and educators can continue to derive scientific and educational value from them, benefiting future generations.

Efforts to protect and sustainably manage Earth's heritage and geodiversity are being advanced in UNESCO Global Geoparks. These initiatives align with international frameworks, including Agenda 21 and the Agenda of Science for Environment and Development, which were adopted at the United Nations Conference on Environment and Development (UNCED) in Rio de Janeiro (1992) and reaffirmed at the World Summit on Sustainable Development in Johannesburg (2002). Geology, geomorphology, and landscapes have profoundly shaped human societies, civilizations, and cultural diversity.

The Lesvos Island UNESCO Global Geopark initiative enhances the objectives of the 1972 Convention on

the Protection of the World Cultural and Natural Heritage by emphasizing the interconnectedness of socio-economic development, cultural heritage, and the conservation of natural environments.

Conservation Strategies

Effective site protection involves the establishment and enforcement of protected areas around fossiliferous sites, the implementation of erosion control measures such as soil stabilization and drainage systems, and continuous monitoring and surveillance to deter illegal activities.

Scientific research is indispensable, requiring ongoing palaeontological and geological investigations to deepen our understanding of a site's significance. This includes systematic data collection and analysis on site conditions, microclimate variations, and visitor impact to inform conservation strategies (Velitzelos et.al. 1997).

Geoconservation techniques play a vital role in preserving these valuable resources. Wherever feasible, in situ preservation should be prioritized to maintain the original context of fossils. The construction of protective structures, such as shelters, helps shield fossils from weathering, while fences and designated safe pathways limit human impact without compromising fossil integrity. These paths should be strategically designed with materials that blend with the natural landscape, ensuring accessibility while safeguarding the site's geological and palaeontological features. Additionally, visitor education and guided tours serve as essential tools in fostering public awareness and reducing inadvertent damage to fossil sites.

Figure 1: Emblematic fossilized tree trunk in the main park of the Lesvos Petrified Forest "Kyria Apolithomeni" during and after the conservation works

Controlled excavations, accompanied by meticulous documentation and secure storage of recovered fossils, are critical for scientific research and the preservation of palaeontological heritage. Advanced digital documentation methods, including 3D scanning and photogrammetry, can aid in creating precise and non-invasive records of fossil sites. Moreover, fostering collaboration with local communities, policymakers, and conservation organizations strengthens long-term protection efforts by integrating traditional knowledge with sustainable conservation practices.

By adopting a comprehensive approach that integrates scientific research, infrastructure development,

community engagement, and stringent policy enforcement, fossiliferous sites can be effectively conserved for future generations (Fig. 1). These measures ensure that these invaluable scientific and natural resources remain accessible for research, education, and public appreciation while maintaining their geological and ecological integrity.

Protection measures

A series of protection and enhancement works have been implemented to improve the accessibility, interpretation, and promotion of the fossiliferous sites within the Geopark. These interventions include:

- Protective measures for the preservation and promotion of fossiliferous sites including shelters and protective stone constructions for the control of erosion (fig. 2).
- Infrastructure improvements to facilitate safe visitor access, ensuring accessibility for all, including individuals with disabilities.
- Signage and interpretative projects that provide information on the fossils that appear in the fossiliferous sites, along with awareness campaigns and educational programs for schools and universities.
- Initiatives to promote alternative forms of tourism, particularly environmental and cultural tourism, through targeted promotional and publicity campaigns.

Figure 2. Shelters protecting petrified tree trunks and their extensive root systems

By integrating scientific research with innovative interpretation strategies, the Lesvos Island UNESCO Global Geopark serves as a model for fossiliferous site conservation worldwide. Its comprehensive approach highlights the balance between conservation, education, and sustainable development, ensuring that the palaeontological heritage of the region is preserved and appreciated by future generations.

Interpretation and Public Engagement

The Lesvos Island UNESCO Global Geopark plays a crucial role in conserving and interpreting fossiliferous sites. As a designated UNESCO site, it has a responsibility to balance the needs of conservation with the socio-economic development of the region, support scientific research and promote public education about the geological and palaeontological significance of the area, engage local communities in the management and interpretation of heritage sites, and share best practices and lessons learned with other geoparks worldwide.

The Lesvos Petrified Forest is an outstanding example of a fossiliferous site that combines conservation,

education, and sustainable tourism. The interpretation of fossiliferous sites within the Geopark is a crucial aspect of its management, aiming to enhance public understanding of the geological heritage and promote geotourism.

Interpretation efforts include well-designed information panels, and guided tours that provide insight into the region's palaeontological significance. Interactive exhibits, 3D models, and digital reconstructions allow visitors to visualize the past ecosystems that existed 20 million years ago. Moreover, on-site interpretation through signage and designated trails ensures that visitors can explore the fossiliferous sites without causing damage to delicate specimens.

Figure 3. VR and QR digital tools help the public understand the geological processes that formed Lesvos Island landscape, landforms and led to the creation of the Lesvos Petrified Forest

The Natural History Museum of the Lesvos Petrified Forest employs modern technology, such as augmented reality (AR) applications and virtual reality (VR) experiences, to engage visitors and present scientific information in an accessible and compelling manner. Additionally, educational and outreach programs involving schools, universities, the local communities and visitors foster a deeper appreciation for the importance of geoconservation and the need to protect fossiliferous sites (fig. 3).

Conclusions

The conservation and interpretation of fossiliferous sites in the Lesvos Petrified Forest UNESCO Global Geopark demonstrate the significance of integrating scientific research, infrastructure development, community engagement, and policy enforcement to ensure the long-term preservation of this invaluable natural heritage. The Geopark serves as a model for sustainable management, balancing the protection of fossiliferous sites with public education and regional socio-economic development.

Effective conservation strategies have been implemented to mitigate environmental and human-induced threats, including erosion control, site stabilization, and protective infrastructure. In situ preservation remains a priority, ensuring that fossils retain their original geological context while minimizing damage from external factors. The application of geoconservation techniques, such as the construction of shelters, designated visitor pathways, and fencing, has proven effective in reducing human impact while maintaining site accessibility and visitor engagement (Zouros 2021).

Public interpretation and engagement play a crucial role in fostering awareness and appreciation of fossiliferous sites. The Geopark has invested in comprehensive educational programs, guided tours, interpretative signage, and innovative digital tools, such as augmented and virtual reality applications, to enhance visitor experiences and scientific outreach. These efforts not only improve public understanding of geological heritage but also promote geotourism as a sustainable economic activity for the region.

The series of enhancement projects within the Geopark—ranging from improving accessibility for all

visitors, including individuals with disabilities, to promoting alternative tourism models—illustrates a holistic approach to conservation and interpretation. By integrating cutting-edge scientific documentation methods like 3D scanning and photogrammetry with traditional conservation practices, the Geopark ensures the meticulous recording and preservation of fossiliferous sites for future research and educational initiatives. Moreover, the collaborative efforts between the Natural History Museum of the Lesvos Petrified Forest, the University of the Aegean, local communities, and policymakers highlight the importance of interdisciplinary cooperation in geoconservation. The involvement of local stakeholders strengthens conservation efforts, fosters a sense of ownership, and enhances the sustainable development of the region.

Ultimately, the Lesvos Petrified Forest UNESCO Global Geopark exemplifies best practices in fossiliferous site conservation by maintaining a delicate balance between scientific study, heritage protection, and responsible tourism. Its comprehensive approach ensures that these palaeontological treasures continue to contribute to global scientific knowledge, public education, and sustainable economic growth, while preserving their ecological and geological integrity for future generations.

EXTENDED ABSTRACT 334

Geomorphological mapping and lithological heterogeneity as tools for the assessment of liquefaction likelihood: Piniada Valley case study (central Greece)

Valkaniotis S.[1], Rapti D.[2], Taftsoglou M.[3], Papathanassiou G.[1], and Caputo R.[3]
(1) School of Geology, Aristotle University of Thessaloniki, Greece, valkaniotis@yahoo.com , (2) Department of Chemical, Pharmaceutical & Agricultural Sciences, University of Ferrara, Italy, (3) Department of Earth Sciences, University of Ferrara, Italy

Introduction

Assessment of liquefaction susceptibility of Holocene sediments in alluvial plains is one of the first step for regional planning, hazard mitigation, and land use management in seismically active regions. Subtle geomorphological features resulting from recent depositional processes can significantly improve mapping liquefaction likelihood since they also express the lithology and distribution of Holocene sediments. Widespread liquefaction phenomena were triggered by the 2021 Mw 6.,3, Damasi, Larisa earthquake over Piniada Valley (Ganas, *et al.,* 2021; Papathanassiou, *et al.,* 2022), a narrow section of Pinios river course in central Thessaly (Figure 1). As we compiled a detailed geomorphological/geological map for the purposes of this investigation and correlated it to the spatial distribution of the earthquake-induced liquefaction phenomena, we observed that liquefaction surface occurrences (ejecta, craters. ground fissures, lateral spreading) are highly correlated to point bars and abandoned river channels formed during the last century (Figure 1 & 2). Both geomorphological units consist of mainly sand, with the common occurrence of a thin clayey cap layer if abandoned.

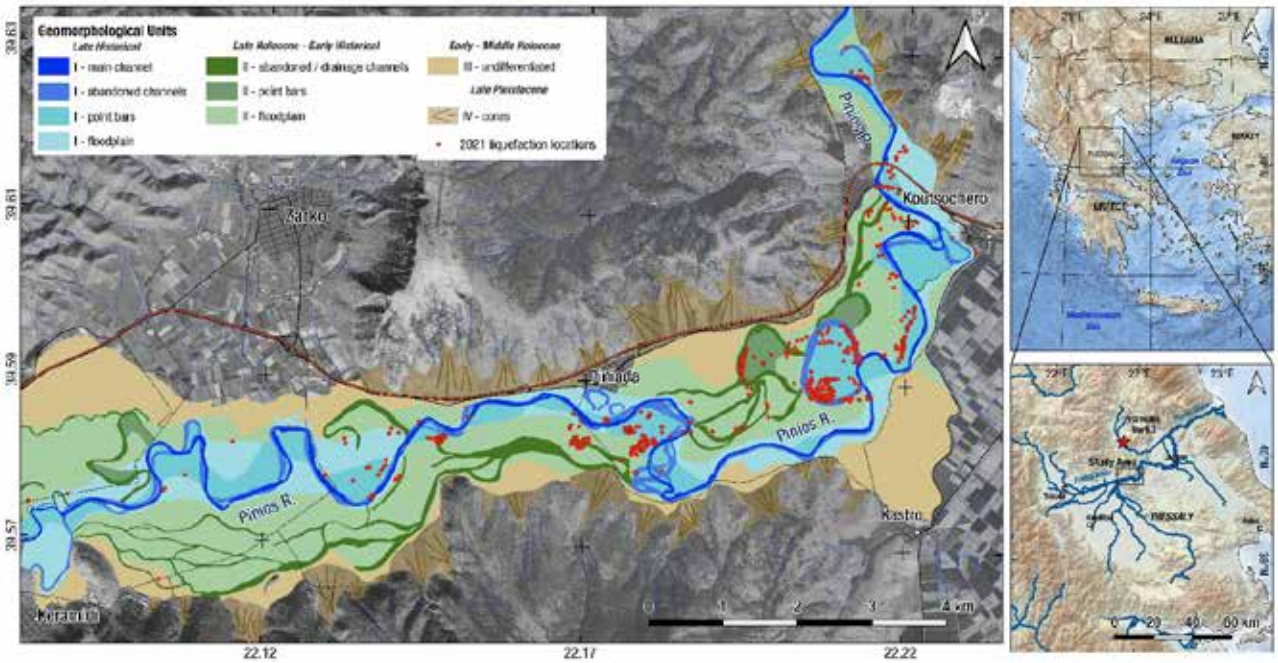

Figure 1. Geomorphological map of the Piniada Valley after Caputo et al. (2021) and Valkaniotis et al. (2024). Liquefaction surface manifestations mapped after the 2021 earthquake (Papathanassiou et al. 2022) are shown as red dots. Inset maps show the location of Piniada valley in central Greece.

Methods/Results

Piniada valley is a narrow section of Pinios river, where Late Pleistocene and Holocene fluvial sediments deposited by the Pinios river meander dominate the valley form (Caputo, *et al.,* 2021; Valkaniotis, *et al.,* 2024). Liquefaction manifestations after the 2021 M_w 6.3 earthquake were mapped in detail using a combination of field, UAS and satellite data (Papathanassiou, *et al.,* 2022). Remote sensing data (optical and radar satellite data) can significantly improve rapid mapping after an earthquake event, and can guide and focus field mapping over large regions (Taftsoglou, *et al.,*

2023). Published geologic map sheets show little variation in Quaternary sediment mapped formations, with only few general groups present as undifferentiated alluvial sediments and terrace deposits along Pinios river. We developed a detailed mapping of the late Upper Pleistocene and mainly Holocene deposits outcropping along the Piniada Valley that was largely based on the field and remote sensing observation of geomorphological features. Using historical topographic maps, detailed digital surface models and remote sensing data (historical aerial imagery and satellite imagery), allows us to improve surficial geological mapping (Taftoglou, *et al.,* 2022; Valkaniotis, *et al.,* 2024). During moderate-to-strong seismic events, such maps could better resolve the distribution and the characteristics of the surficial deposits and hence the potential location of earthquake-induced liquefaction phenomena. At this regard, the behavior of the subsoil layer and the occurrence of liquefaction are basically dictated by the type of predominant material, the general stratigraphic succession and the depth of water table.

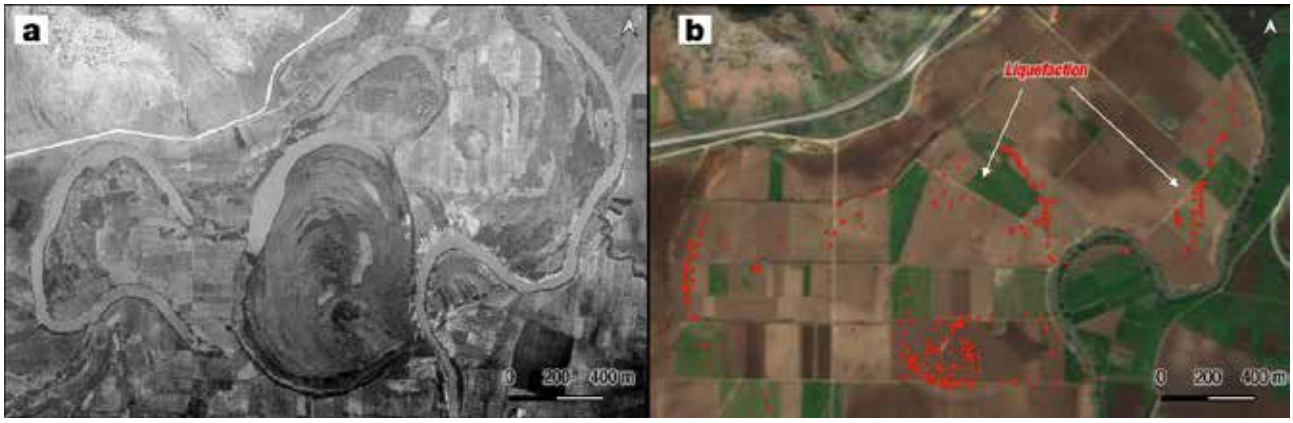

Figure 2. a) Historical aerial imagery from 1935 showing abandoned meander channels and point bars in Piniada valley. b) Liquefaction surface features (red dots) of the 2021 earthquake (Papathanassiou et al. 2022). Liquefaction manifestations correlate with recently abandoned meanders and point bar formations.

Point bars deposits are developed on meandering fluvial systems where the depositional process is strongly influenced by the river channel. Although the prevailing grain size is represented by sand, the lateral heterogeneity (Russel, *et al.,* 2018) plays a crucial role in determining the liquefaction susceptibility and its potential. In order to verify and apply this concept to the Piniada Valley case study, we separated sand and mud prone zones within point bar features and compared their spatial distribution with the occurrence of liquefaction cases during the 2021 Damasi earthquake. Results indicates that most liquefaction phenomena occurred in sand rich shallow deposits. Thus, it is confirmed that in point bars settings, it is feasible to further detect distinct zones with different liquefaction likelihood. If only regional scale geological maps are available, distinguishing or even simply recognizing the different fluvial sedimentary facies is quite challenging; for this reason, a detail mapping should become essential for large geotechnical surveys and a very good proxy of surficial and shallow lithology that can guide the proposed locations of boreholes and/or penetrometric tests. Statistical results from Piniada Valley, highlight that a refinement of existing liquefaction susceptibility classifications (e.g. Youd, *et al.,* 1978) is required. It is proposed to include point bars as a distinct class characterized by a very high susceptibility to liquefaction for material recently deposited, especially of age younger than ~100 years (Valkaniotis, *et al.,* 2024).

Introduction

Severe meteorological phenomena such as storms, hurricanes and cyclones have devastating impact on the population, infrastructure but also the natural environment. Apart from flooding, these events usually trigger numerous landslides along the impacted areas. Mapping and studying of these landslides are necessary steps towards understanding and mitigating these types of natural disasters.

Medicanes (Mediterranean hurricanes), a concatenation of Mediterranean Sea with hurricanes, resemble tropical cyclones but present certain differences like much shorter expected lifespan. Medicane Ianos (September 2020) was the first devastating event that led to extensive destruction in Greece, including flooding, serious damages to infrastructure and numerous landslides (Lekkas, *et al.,* 2020; Zekkos, *et al.,* 2020).

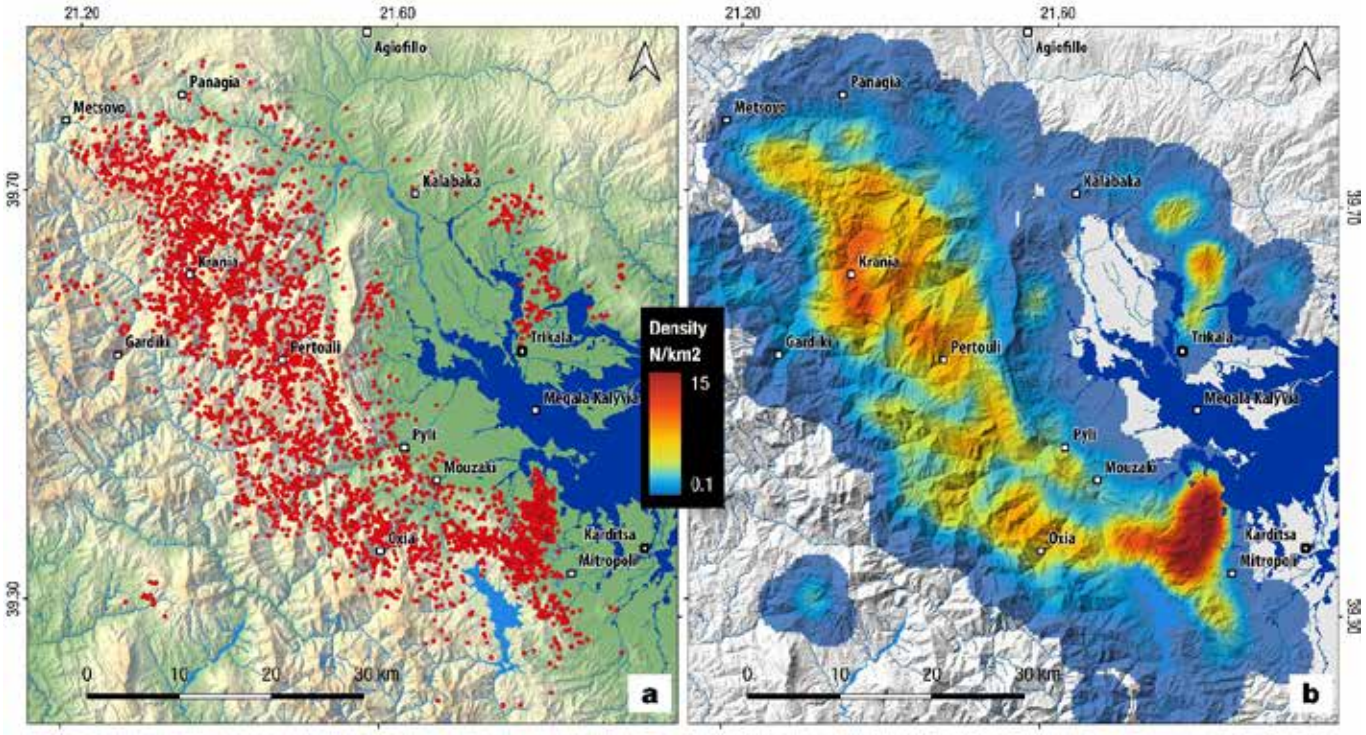

Figure 1. Landslide inventory of Storm Daniel (September 4-8 2023) in western Thessaly (a) and landslide density (b). Red dots show the location of landslide polygons mapped from satellite imagery. Dark blue shows areas on Thessaly plain that were flooded during Storm Daniel.

A large number (>2000) of landslides were triggered by Ianos in the mountainous area of western Thessaly (Valkaniotis, *et al.,* 2022). Storm (Medicane) Daniel, three years after Ianos, landed on Greece in September 2023. From September 4 up to September 7 2023, central Greece and especially Thessaly region, experienced severe rainfall exceeding 1000 mm at places. More than 1400 km^2 of Thessaly were flooded during this event. Debris flows and floods in mountainous watersheds and torrents led to serious damages of property and infrastructure in most parts of Thessaly. Southern Pilio mountain and the mountainous area of western Thessaly (Pindos Mountain range) experienced thousands of

landslides triggered by Cyclone Daniel (Lekkas, *et al.,* 2023; Valkaniotis, *et al.,* 2024). We focused on the landslides triggered in the western Thessaly region, in order to develop an event-based landslide inventory.

Methods/Results

We acquired all available USGS Landsat 8/9 (15 meters ground resolution) and Copernicus Sentinel-2 (10 meters ground resolution) satellite imagery after the event, covering the dates of September 8 up to September 15 2023. Additional frames of Planet imagery (3-4 meters ground resolution) were acquired over the study area of western Thessaly for multiple dates (September 8 – September 14). Parts of the study area were covered by early post-event very high resolution (<2 meters ground resolution) satellite imagery (WorldView-3, SPOT, GeoEye-1) that were acquired through Copernicus Data Archive. A series of post-event field surveys in the study area (Trikala – Karditsa, Thessaly) were performed in the days following the event (Figure 2). During these surveys, satellite imagery rapid mapping was verified and checked in the field. In more than 15 locations, UAS photogrammetric surveys were executed in sites where major landslides occurred.

Figure 2. a) Large complex landslide (rotational-flow) on Triggia mountain range, Trikala. b) Numerous small landslides along forest roads. Pyli municipality, Trikala. c) Multiple landslides along the road slopes of the road Morfovouni-Kanalia (Karditsa).

A preliminary landslide inventory of 3200 landslides was compiled using high resolution Copernicus Sentinel-2 multispectral imagery ten days after the event (Valkaniotis, *et al.,* 2024). Landslides were mapped using visual inspection, with comparison of pre- and post-event images. Manual process was assisted by using semi-automatic methods, such as normalized band differencing, and Google Earth Engine codes for change detection (Valkaniotis, *et al.,* 2022). After the development of the preliminary rapid mapping landslide inventory, we proceeded with the final event inventory, using Planet and VHR satellite imagery for more detailed mapping of landslide locations and polygons. UAS orthophotos and digital elevation models of major deep-seated landslides were also used for detailed delineation. One of the largest landslides with length exceeding 500m was triggered at the Pindos Mountain range, near Pyrra settlement, Trikala region, and created a small landslide dam lake that persists up to this date (Valkaniotis, *et al.,* 2024).

The Daniel landslide inventory of 5446 landslides is presented in Figure 1. Most of the landslides are found along the Pindos Mountain range, with additional concentrations in the hilly areas north of Trikala and near Mouzaki. Studying the distribution of landslides, we can estimate the area of peak rainfall (more than 400-500 mm) on the mountainous part of the affected region as the one that encloses most of the landslides. A comparison with the Medicane Ianos inventory (Figure 3) shows the more severe intensity of the Daniel event in comparison to Ianos, that led to more landslides in the same region but also triggered a large number of rockslides and large deep-seated landslides that were quite uncommon for the Ianos inventory. Distribution and density of landslides shows correlation with geological formations susceptible to landslides, but also with local rainfall amount and rain intensity during Storm Daniel.

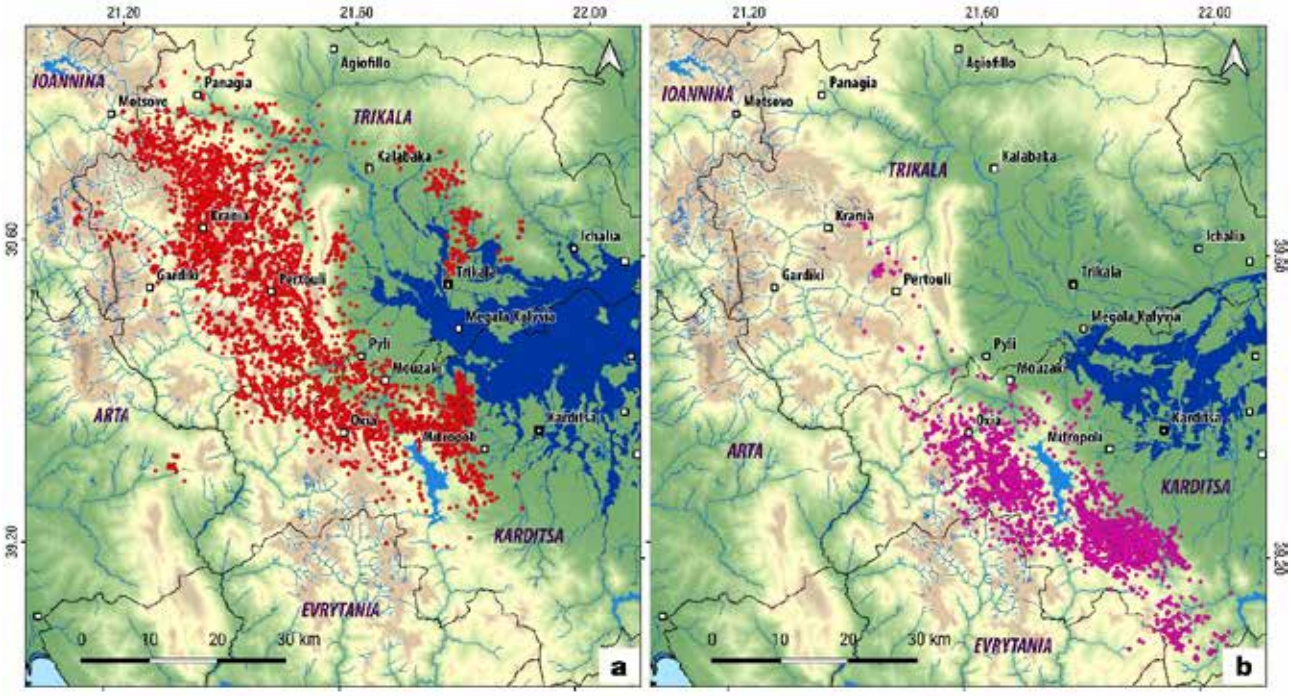

Figure 3. Comparison of Daniel (a) and Ianos (b) landslide inventories. Ianos landslide inventory updated from Zekkos et al. (2020) and Valkaniotis et al. (2022). Dark blue areas mark the location of flooding during Medicane Daniel (a) and Ianos (b) respectively.

EXTENDED ABSTRACT 336

Investigating the interaction between Flood Hazard and Soil Erosion in Northern Evia Island, Greece, using GIS Morphometric Analysis

Kanella Valkanou [1], Efthimios Karymbalis [2], Konstantinos Tsanakas [3]

1, 2, 3 Department of Geography, Harokopio University, Athens, Greece, kvalkanou@hua.gr

Introduction

Among all hydrometeorological events, floods are widely considered the most dangerous to human life, causing both immediate destruction and long-term impacts (Wang et al., 2022). Despite extensive efforts to mitigate flood risks, the frequency and severity of these events continue to rise globally. Recent studies indicate a significant increase in both the economic damage and fatalities caused by floods, with millions of people affected each year worldwide (UNDRR, 2023). In this context, flood hazard mapping plays a crucial role in early warning systems and emergency preparedness, by helping to identify areas at risk by their physical characteristics and vulnerability to flooding (Hagos et al., 2022). The goal is the timely implementation of preventive and preparedness measures to manage flood risk and eliminate the negative impacts of these events.

Effective flood risk mitigation requires among other, identifying watersheds most vulnerable to erosion. Morphometric analysis and quantitative evaluation serve as essential tools for comprehensively understanding and characterizing drainage basins and their systems. These methods provide insights into the development processes of drainage networks and the complex interactions between various soil erosion processes (Bashir and Alsalman, 2023). Recognizing watersheds highly prone to soil erosion provides policymakers, researchers, and planners with valuable insights for developing targeted strategies and implementing mitigation measures.

The objective of this research is to explore the interplay between flooding and erosion. Specifically, the study aims to assess and map flood hazard in the study area by employing Fuzzy Analytical Hierarchy Process (FAHP) method using six (6) flooding hazard factors and to prioritize erosion-prone drainage basins through the application of a composite index based on eight (8) morphometric parameters. This integrated approach facilitates a comprehensive evaluation of the study area's vulnerability, contributing to a deeper understanding of the synergistic effects of these hazards. While much research has focused on flood hazard or soil erosion individually, the combined assessment of these hazards is still limited. This study aims to fill this gap by exploring the interactions of these factors in Northern Evia Island.

Study area

The study area is located in the northern part of Evia Island, in Central Greece, and covers 1842.3 km2 (Figure 1). It consists of one hundred eighty-nine (189) drainage basins, whereas the total channel length of the drainage networks is approximately 3745.6 km (Figure 2) (Valkanou et al., 2022). A significant role in the evolution and shaping of the morphological features of the area is played by the northern Evia Gulf. The fault structures of the study area correspond to two submarine opposing zones of normal faults, oriented NW-SE, which define the mountainous relief of the northern part of the island and separate it from the northern Evia Gulf to the west and the Aegean Sea to the east (Leeder and Jackson, 1993). The submarine fault zones along the eastern and western coasts are responsible for the development of the relief in the study area (Figure 1). Lithologically the study area consists of carbonate rocks, ophiolites, schists, cherts, marls, and sandstones, while alluvial deposits occur along the major channels of the drainage networks as well as at the mouth of the rivers.

Methods

The flood hazard has been calculated using Fuzzy Analytic Hierarchy Process (FAHP) and GIS, which is an advanced extension of the classical method. The weighting coefficients were calculated alongside the fuzzy utility of the alternatives, providing better representation of judgments and uncertainty. The triangular membership function (l, m, u) was used. The parameters were ranked and compared in pairs, resulting in fuzzy weights that were normalized. The results were verified using the consistency ratio, and in the final stage, the parameters were combined through a weighted linear combination to produce the flood hazard map. Six criteria were considered (determined by literature review): slope, elevation, precipitation, lithology, hydrographic density, and land use (Ogato et al., 2020). The natural breaks classification method was used to categorize the watersheds into four classes of flood hazard: very high, high, moderate and low/very low.

The second part of the study evaluates and prioritizes 189 drainage basins by calculating a compound parameter derived from eight morphometric indices within a GIS environment. Linear parameters (bifurcation ratio, drainage density, stream frequency, and texture ratio) and shape parameters (circularity ratio, form factor, elongation ratio, and compactness ratio) were used to assess erosion susceptibility (Gajbhiye et al., 2014). Based on the values of these morphometric parameters the drainage basins were classified into soil erosion susceptibility categories. After the priority ranking, a compound parameter which corresponds

to the average of the ranked values, was calculated. The compound parameter was finally ranked based on the parameters' priorities (small numbers correspond to higher priority). The natural breaks classification method was then used to categorize the watersheds into four classes of soil erosion susceptibility: very high, high, moderate and low/very low.

Figure 1. DEM and main tectonics of the study area

Figure 2. The drainage networks of the study area and their corresponding catchments.

Results

Based on the above mentioned methodology, a ranking table for flood hazard contributing factors and a weighted comparison table were prepared. A summary of the information applied to generate the flooding hazard map, the factors, their weights and rankings, are listed in Table 1. The ranking of each reclassified factor was determined through a comprehensive literature review, with factors of highest influence assigned a rank of 5 and those with the lowest influence assigned a rank of 1.

The flood hazard assessment classified the study area into four hazard categories, as depicted in Figure 4. The results indicate that approximately 30% of the area falls under the "very high hazard" category, 11.8% under "high hazard," 11.2% under "moderate hazard" and 47% under the "low hazard" category. Subsequently, the drainage

basins were prioritized based on the values of the estimated morphometric parameters. The final priority ranking and the composite parameter are presented in Table 2 while the spatial distribution of the prioritized basins is illustrated in Figure 5. Drainage basins No1-37 which are the most prone to erosion, are classified as having a very high priority, covering 16.4% of the study area. Drainage basins No 38-75 follow with high priority, encompassing 46.4% of the area. Finally drainage basins 76-113 are characterized as moderate priority covering 26.8% of the study area. Particularly, specific drainage basins No 40-41, 130-131 and 181 (located south of Mantoudi and north of Rovies) require the highest level of soil erosion management, covering an area of 251km^2. In contrast, drainage basins 63-64, 13-14 and 145, exhibit lower level of degradation and therefore require a lower level of soil erosion priority.

Maps resulting from the two analyses, flood hazard and prioritization, were overlaid, and it was observed that 52.8% of the basins' areas, which were classified as more susceptible to erosion, fall within a very high to moderate flood hazard zone. These zones are located up to 200 m and correspond to low and gentle slopes in the northern part of the study area, while in the western and southeastern parts of the study area, these zones are found at higher elevations and steeper slopes (Figure 3).

The analysis identified areas of very high to high flood hazard, covering 58.2% of the study area, and prioritized the drainage basins based on the compound parameter values, highlighting 113 basins as being most susceptible to erosion (categorized as very high to moderate hazard). Geological factors, including Neogene and Quaternary formations, intense neotectonic deformation in the northern and eastern part of the island, and high precipitation levels, may contribute to increased sediment supply and amplify erosion. This study highlights the critical need for soil conservation measures, particularly in the high priority basins that have the highest erosion risk, to mitigate potential environmental and socio-economic impacts of further soil degradation.

Historical flood events and existing flood hazard maps (YPEN, 2023) align with these findings, confirming the vulnerability of the identified areas. To further validate the results, two additional prioritization methods, based on morphometric parameters (as proposed by Singh et al., 2021, and Kadam et al., 2021), were applied. The results from these methods were in strong agreement with the findings of the present study.

Table 1. Weighted flood hazard ranking.

Parameters	Weight	Reclassified Parameter	Ranking	Parameters	Weight	Reclassified Parameter	Ranking
Land cover	0.36	Coniferous forest, mixed forest and broadleaf forest	1	Rainfall (mm)	0.11	400-500	1
		Land occupied by agriculture/natural vegetation	2			500.001-600	2
		Natural Pastures, grasslands and shrubs	3			600.001-700	3
		Scattered urban development, beaches etc	4			700.001-1.100	4
Slope (degree)	0.27	27.28-68.84	1	Drainage density (km/km^2)	0.05	2.97-4.52	1
		16.48-27.27	2			2.09-2.96	2
		7.3-16.47	3			1.2-2.08	3
		0-7.29	4			0-1.19	4
Lithology	0.18	Group 1 (alluvial deposits, recent talus cones and scree)	1	Elevation (meters)	0.03	743.77-1733.18	1
		Group 4 (limestones, dolomites, greywackes)	2			443.54-743.76	2
		Group 2 (marls, sandstones, schists, cherts, and travertines)	3			204.72-443.53	3
		Group 3 (schists and phyllites)	4			0-204.71	4

Figure 5. Prioritized Ranks Map of Erosion-Prone Drainage Basins Based on Geomorphometric Analysis

Conclusions

A quantitative geomorphological analysis, which forms the basis for assessing flood hazard and prioritizing watersheds according to erosion susceptibility, is the first step in identifying catchments that require flood and erosion management interventions. In this study, land use/land cover, elevation, slope, drainage density, soil, and rainfall were considered critical factors for assessing flood hazard (Figure 4). Drainage basins were then prioritized based on their linear and shape parameters (Figure 5).

The flood hazard mapping identified three (3) main extended areas under the high flood hazard category, near Istiaia (Sarantaporos River), near Psachna (Messapios River) and near Mantoudi (Voudoros River). Smaller areas under the moderate flood hazard category were identified near Aedipsos, Rovies, and Psaropouli. Most high and moderate flood hazard areas are distributed across relatively low and gentle terrain within the study area.

In contrast, the prioritization analysis revealed that 113 of 189 drainage basins, including the two (2) largest watersheds, fall under the very high to moderate erosion susceptibility category. These basins are distributed across the study area, rather than concentrated in specific regions, although areas classified as high flood hazard zones correspond to prioritized erosion-prone drainage basins. This correlation highlights that flooding is strongly linked to increased sediment supply from surface runoff on steep hillsides and areas with high slope gradients. Sediment discharged into the lower reaches increases flood hazard.

It is important to note that not all sediments are deposited in the lower reaches, as demonstrated by patterns observed in the eastern part of the study area. The Dirfis Fault Zone plays a crucial role, as the uplifted footwall is not under high flood hazard, even though the drainage basins in this area are prone to erosion. In contrast, the Telethrio Fault Zone has a synergistic effect on soil erosion and flooding. It crosses the area near Rovies, at the fan apex, converting and maintaining the hanging wall as a sediment deposition zone. This process significantly increases the flooding hazard in the region.

These findings highlight the need for an integrated strategy in flood and erosion management, emphasizing the importance of focused interventions in high-risk areas and promoting a holistic framework for disaster risk reduction. Future studies could explore the impacts of climate change on flood and erosion dynamics in the region, as well as investigate the potential effects of human activities such as deforestation and urbanization on these hazards.

Preliminary results on geological and hydrogeological conditions in Vilia, Attica, Greece

Vardava A. [1], Kyriakopoulos V. [1], Skourtsos E. [1], Filis C. [1]

(1) Department of Geology and Geoenvironment, National and Kapodistrian University of Athens, Athens, Greece, eskourt@geol.uoa.gr

Introduction

The factors that influence the occurrence of a spring are analogous to those that govern the formation of aquifers. In addition to climatic conditions, these include morphology, lithology, and tectonic structures. Therefore, an understanding of the geological setting of the area under study is essential to ensure that the hydrogeological conclusions drawn are accurate, especially when these springs are utilized for the water supply of the local population.

This study focuses on the eastern sector of Mount Kithairon in Western Attica, particularly the hill known as Malliaras or Lestori, situated north of the residential area of Vilia. The objective of the research is to identify the geological and hydrogeological conditions of the region, to interpret the emergence of springs observed on the slopes of the hill, to define the margins of the hydrogeological basin of the springs, and to assess the expected water reserves therein.

Morphology and Geological Setting

The Malliaras hill, which constitutes the area of research, is located on the southern slopes of the eastern section of Mount Kithairon, north of the settlement of Vilia. The hill displays an average orientation of northwest to southeast, extending approximately 2 km in length and 1 km in width, rising from an elevation of 550 m in the vicinity of the settlement to 986 m at its highest southeastern peak.

Geologically, the broader region is comprised of alpine rocks that belong to the Sub-Pelagonian or unmetamorphosed Pelagonian Unit. Within the research area, only the Upper Paleozoic and Triassic formations of this unit are present, represented primarily by a Permian-Triassic mainly clastic formation and an overlying Triassic carbonate sequence. Tectonically, the area is characterized by two thrust sheets, which are separated by two thrust faults, tectonically overlying a comparatively autochthonous carbonate series (Figure 1).

The Lower to Middle Triassic formation is comprised of thin-bedded to bedded limestones of the Hallstatt facies, intercalated with cherts, sandstones, clay shales, and tuffs. This formation in the research area exhibits a small outcrop on the southeastern slopes of the hill, uphill of the Church of Panagia Gkouras, at the base of the upper thrust sheet.

The Middle to Upper Triassic carbonate formations consist of thick-bedded to bedded limestones, dolomitic limestones, and dolomites. In contrast, those of the Upper Triassic are composed of ash-gray to black, thin-bedded to bedded, laminated limestones and dolomitic limestones featuring thin intercalations and nodules of chert. Together, these two formations constitute both the relatively autochthonous series and the upper thrust sheet of the study area.

Thin alluvial deposits are found along the streams surrounding the hill. In contrast, scree and colluviums occupy a significant expanse, covering a considerable portion of the southwestern and eastern slopes of the hill.

The structure of the overlapping thrust sheets has been disrupted by more recent normal faults striking E-W which define the Malliara hill to the north and south and dip to the south. More significant is the large high-angle normal fault distinguished along the base of the southern slopes of the hill, on the northern periphery of the Vilia settlement.

Precipitation

Table 1 presents the monthly precipitation data for the years 2012 to 2023 at the Vilia Station in Attica, of the National Observatory of Athens (N.O.A.). In certain months, there are no precipitation records, as the station was not operational during that time. The months highlighted in gray contain precipitation records, yet these do not accurately reflect the overall precipitation, as the station's data for that specific month was incomplete (possibly due to being non-operational for several days or having sustained some form of damage).

From this table, it is evident that the precipitation in the region varies between 618 mm and 961.2 mm, with an average value of 742 mm over the aforementioned years.

Hydrogeological Classification of Geological Formations

The formation of the Upper Paleozoic – Lower Triassic is considered practically impermeable. The thin interlayers of thin-bedded, marly limestones and of the sandstones do not constitute significant aquifers.

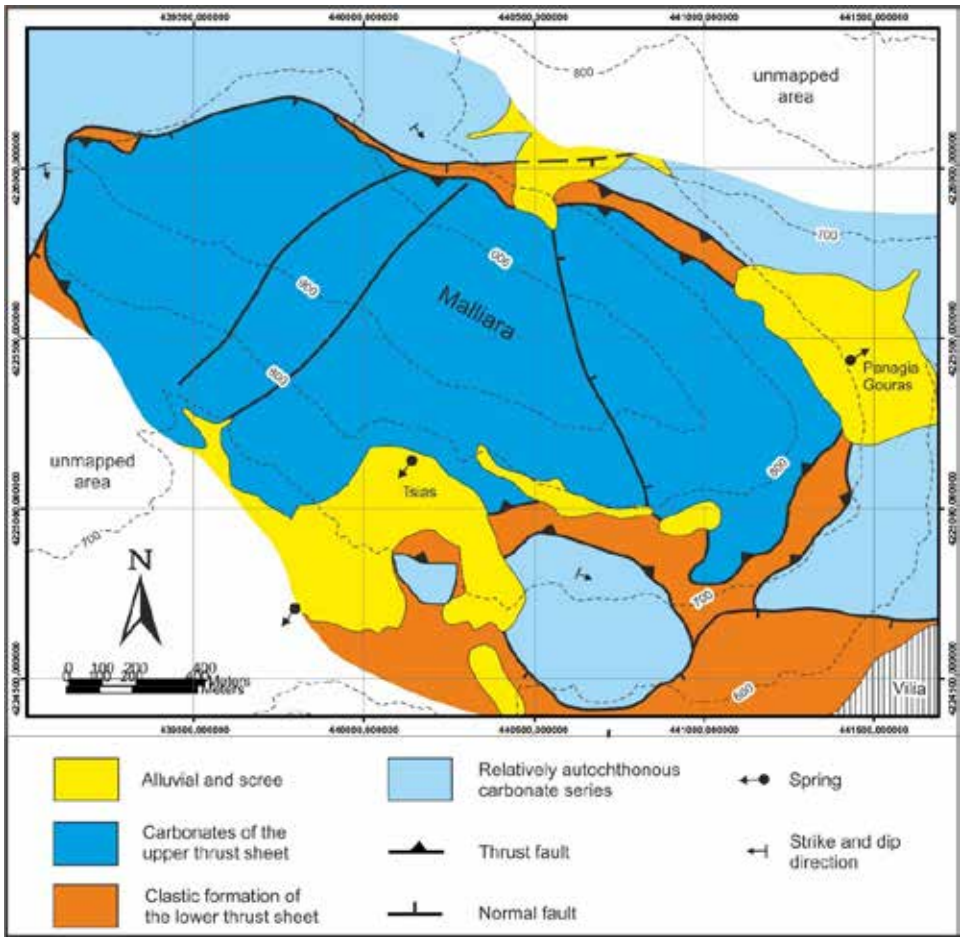

Figure 1. Geological map of the study area.

The carbonates of the Lower - Middle Triassic are wedged between the two thrust sheets. Their thickness is merely around 10 m, essentially forming a cohesive aquifer with the overlying carbonates of the upper thrust sheet.

Table 1. Precipitation records (mm) for the period 2012-2013 at the Vilia Station of the N.O.A.

Year	1	2	3	4	5	6	7	8	9	10	11	12	Annual

The carbonates of the Middle - Upper Triassic that comprise the eastern sector of the upper thrust sheet are characterized by significant fracturing and dense fissuring, which has led to considerable karstification. The carbonates of the Upper Triassic, which form the central and western sectors of the upper thrust sheet as well as the lower comparatively autochthonous series, are characterized by their thin-bedded texture with intercalations of cherts and are frequently dolomitized. However, they are also highly folded, densely fractured, and exhibit surface indications of

karstification. These two carbonate formations present a satisfactory coefficient of permeability.
The alluvial deposits, in practice, show no significant groundwater presence. In contrast, the scree formation demonstrates greater surface distribution and thickness. This formation consists of highly permeable materials and harbors groundwater during the wet seasons.

Aquifers and springs

The presence of groundwater in the research area was identified within the upper thrust sheet and the scree. The groundwater within those formations is discharged from two main springs, along with several considerably smaller ones.
The two main springs are discharged from the upper thrust sheet. The more prominent of the two is in the courtyard of the Church of Panagia Goura, situated at the southeastern edge of the hill and at an elevation of 697 m. This spring has formed at the tectonic contact of the carbonates of the upper thrust sheet and the impermeable clastic rocks of the lower one. Notably, however, the spring appears within a small cavern, situated a few meters lower in elevation than the tectonic contact, encompassed by fallen carbonate masses and scree that have obscured the tectonic contact.

Figure 2. The Panagia Gouras Spring is located in the courtyard of the church within a small cavern. A wall with a metal door has been constructed to isolate the spring, while next to it there is a tank for collecting the outflowing water.

According to an earlier report from EAGME (Gintoni et al., 2021), the discharge rate of the spring in January 2021, which falls midway through the wet season, was recorded at 35 m^3/h, whereas in November 2020, marking the onset of the wet season, it measured 25 m^3/h.
The second spring is located in the southwestern slopes of the hill, also at the tectonic contact between the two thrust sheets and is referred to as the Tsias Spring. This spring exhibits a relatively lower discharge rate than its

counterpart. The water flows within the limestones, where a small collection basin has been constructed, open at the top, from which the water is conveyed through pipes to a reservoir situated approximately one kilometer west of the Vilia settlement, adjacent to the Church of Panagia Zoodochou Pigi.

On the southwestern slopes of the hill, there are lateral debris of considerable thickness and sliding limestone blocks of various sizes, forming a cover overlying the formation of the lower thrust sheet, which extends to the base of the hill. Through this cover, during wet periods significant quantities of water are transported that are discharged from small contact springs at the base of the hill, near the Church of Panagia Zoodochou Pigi.

The occurrence of the two springs is due to the geometry of the fault between the two thrust sheets. This fault contact has the shape of a turtle shell, simulating the morphology of the hill on which it is observed. This geometry results in the formation of an underground drainage axis of approximately N-S strike that is almost identical to the position of a N-S fault crossing the upper nappe. Thus, two separate hydrogeological basins are formed, the largest one is discharged at the spring of Panagia Goura and the other at the smaller Tsias Spring.

The area of the hydrogeological basin of the Panagia Gkouras Spring is estimated to be 0.6 km². According to Table 1, the average annual precipitation over the past decade amounts to 742 mm; thus, the volume of precipitation is calculated to be 445,200 m³. Adopting an infiltration rate between 0.45 and 0.5 for the limestones (e.g., Dounas, 1971; Hatoupis, 2004), the volume of water that infiltrates ranges from 222,600 m³ to 200,340 m³, respectively.

The area of the hydrological basin of the Tsias Spring is estimated to be approximately 0.48 km², resulting in a precipitation volume of 356,160 m³ and an infiltration volume ranging between 178,080 m³ and 160,272 m³.

The recharge of the carbonates of the upper thrust sheet occurs exclusively through precipitation, and consequently, the discharge of the springs is directly dependent upon those inputs. As observed during the field investigation in early summer of 2024, all the small springs had run dry, while the two main springs exhibited a significantly reduced flow compared to the measurements recorded two years prior.

The relatively autochthonous series composed of carbonate rocks does not manifest any springs within the research area. Furthermore, the depth at which an underlying impermeable substrate may be encountered, as well as the geometry of their interface, remains unknown. Along the shores of the cove of Porto Germeno, approximately 9 km west of the study area, submarine springs are observed, which discharge corresponding carbonate formations (Dounas, 1971).

Upon conducting hydrochemical analyses of the springs, the water is found to be bicarbonate and magnesium-rich, which is understandable given that the aquifer is composed of carbonate formations.

Conclusions

The research area is part of the unmetamorphosed Pelagonian Unit, characterized by Upper Paleozoic and Triassic formations. These formations form two superimposed thrust sheets that overlie the relatively autochthonous series. The upper thrust sheet and the relatively autochthonous series comprise carbonate rocks that are identified as aquifer formations and exhibit karstification. These two carbonate sequences are separated by an impermeable layer composed of Permian-Triassic clastic rocks.

The aquifer of the upper carbonates is discharged by two springs observed at the tectonic contact between the two thrust sheets. Their formation is due to the geometry of the thrust fault, which is reconstructed in the form of a turtle shell, thus forming two small hydrogeological basins. The recharge of those springs is directly dependent on precipitation.

The carbonate formations of the relatively autochthonous series constitute a very good target for the investigation of the existence of groundwater in the area to further meet the water supply and irrigation needs of the area.

Introduction / Background

A key characteristic of flysch as a geological formation is its heterogeneity, a property that is generated by its composition, since it is composed of various rocks (clays, sandstones, marls, limestones and conglomerates). The alternation of these layers, especially if they are relatively thin and the clay layers predominate, creates a favorable environment for the development of interfaces in which landslides can occur. These conditions, especially on steep slopes, are aggravated by the presence of groundwater and under particular tectonic conditions.

The usual slope exploration methods, in addition to surface mapping, are enhanced by the digging of trenches and the drilling of geotechnical exploration boreholes. A characteristic of these methods is that they constitute point information and in locations that are most often dictated by local access conditions (vegetation, road network, soil conditions).

Geophysical methods that largely address these problems, such as geoelectric, seismic and ground radar, are called upon to contribute to this problem. Among them, we distinguish geoelectric tomography, as the most suitable for its application in difficult geomorphological environments but also in its ability to provide information with significant resolution for stratigraphy and the presence of groundwater.

This paper presents examples of geoelectric tomography carried out on slopes of a mountainous area dominated by the Pindos flysch consisting of alternations of sandstones, calcitic sandstones and clay shales. The data of the geophysical survey were correlated with those of the trenches and drillings carried out in the area.

From the interpretation carried out, it emerged that geoelectric tomographies have a special contribution in identifying locations where conditions favor landslides and in formulating proposals to prevent the development of landslide phenomena.

Geology geomorphology of the study area

The Flysch of the Pindus zone is found in the research area, which consists of alternations of sandstones and clayey schists with lenticular layers of conglomerates of varying lithological composition and thickness. It has undergone intense tectonics and exhibits a significant thickness that in places exceeds 1000 meters (Geological map of the Hellenic Geological Survey, 1984). With an area of approximately 500 acres, it exhibits an average slope of 17°.

Landslides have been observed in the wider area, which led to the geotechnical investigation of the area under investigation.

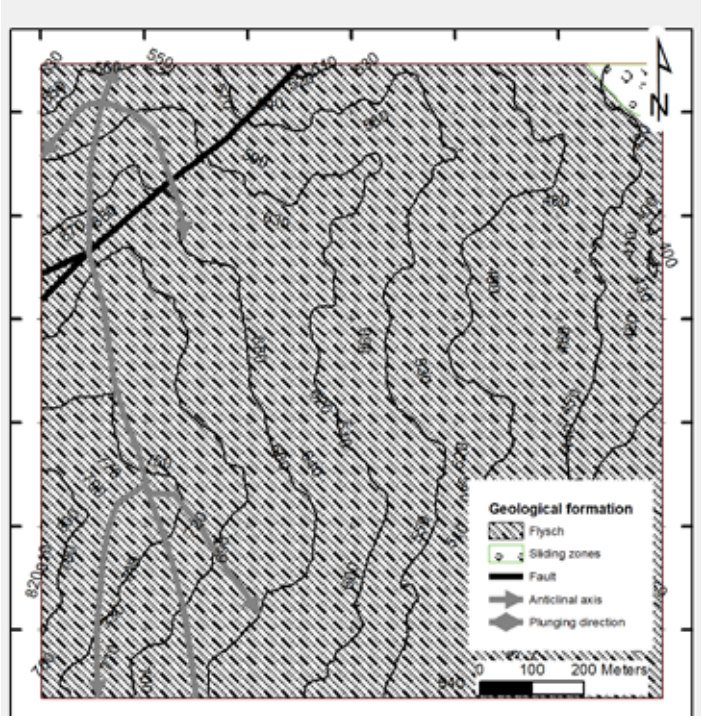

Figure 1. Geological map of the study area.

Geophysical methods for landslides investigation

Geophysical commonly used to the investigation of landslides are Electrical Resistivity Tomography (ERT), Shallow Seismic Refraction (SSR) and Ground Penetrating Radar (GPR) (Taborik *et al.*, 2017). The main target of geophysical investigation is the detection of the possible failure interfaces, taking advantage of the geophysical contrast between different lithological layers. A major role in the activation of such an interface and thus, the provocation of a landslide, is the groundwater content within the layer affected by slide processes.

Both targets are mostly covered by electrical and electromagnetic methods. Especially, geoelectrical tomography can provide accurate and reliable geoelectrical 2D and 3D models of the stratigraphy of an area under investigation along with the detection of groundwater, since the water content has a significant impact to the resistivity of the geological layer.

According to Pilecki (2017), the main advantages of the geophysical methods are the efficiency, the non-invasion, the multi-information, the penetration depth and the resolution they provide. Among the disadvantages of geophysical methods, is the ambiguity of the results of geophysical interpretations which is stronger in case of malicious data or limited resolution to the depth. To overcome this issue, more than one geophysical method is better to be used, and/ or geophysical results need to be correlated with geotechnical information.

Case study: Field data acquisition, processing and results

Forty (40) geoelectrical tomographies were measured in the survey area. At each line, 24 electrodes were used at an inner distance of 2, 3 and 4 meters, depending on the desired depth of investigation and the local conditions. Dipole-Dipole and Multi Gradient arrays were measured, allowing the combination of the two data sets for the final inversion calculated in DC2dPro software (Kim, 2009).

Geophysical data were correlated with geological information provided by geotechnical drillings and pits. In five boreholes full core sampling has been done while in five boreholes piezometers have been installed. For the investigation of the weathering zone, twenty pits were dug, at 4 meters depth.

Below are presented typical examples from the combined interpretation of geophysical and geotechnical data.

ERT R24- BH 1

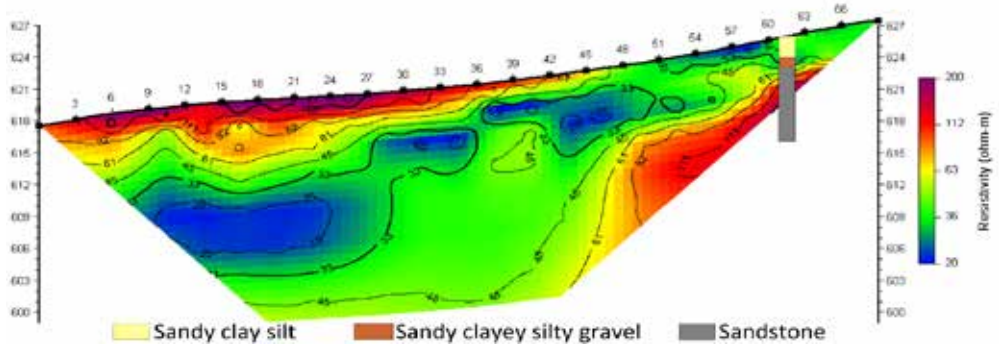

Figure 2. Borehole 1 superimposed to ERT 24 (from South to the North).

In Figure 2, we can see the resistivity model ion ERT 24 where the findings of the BH1 are sown. The first layer is 2 meters thick, and it is described as ashy - ash-yellow, very cohesive sandy clay loam of medium plasticity (decomposed flysch). The thin layer below is described as medium density clayey sandy gravels and the deeper formation (2.5 to 7.3m) is attributed to ashy sandstone.

The correspondence with resistivity values is shown in the next table.

Table 1. Correspondence of geological layers and resistivity values

Geological description	Resistivity (Ωm)
Ashy - ash-yellow, very cohesive sandy clay loam of medium plasticity (decomposed flysch)	25-32
Medium density clayey sandy gravels	33-45
Sandstone	80-110

In the first place, we can notice the very well correspondence between the resistivity model and the observations in the borehole samples.
The most important fact, however, is the lateral change of the geological structure just a few meters far from the location of the borehole. The first jump of 4 meters of the sandstone is noticed just 3 meters to the south (beginning of the ERT) and the second of more than 12 meters, in the next 11 meters. The more clayey formation (blue lenses) seems also to have water content (resistivity values in the range of 33 to 45 Ωm).
In this case we can notice that, even the borehole met the sandstone -which is considered to be the stable formation in the area- at the depth of 2.5 meters, just several meters away, a fault makes the area possible to slide in certain conditions.
ERT R33- BH 2

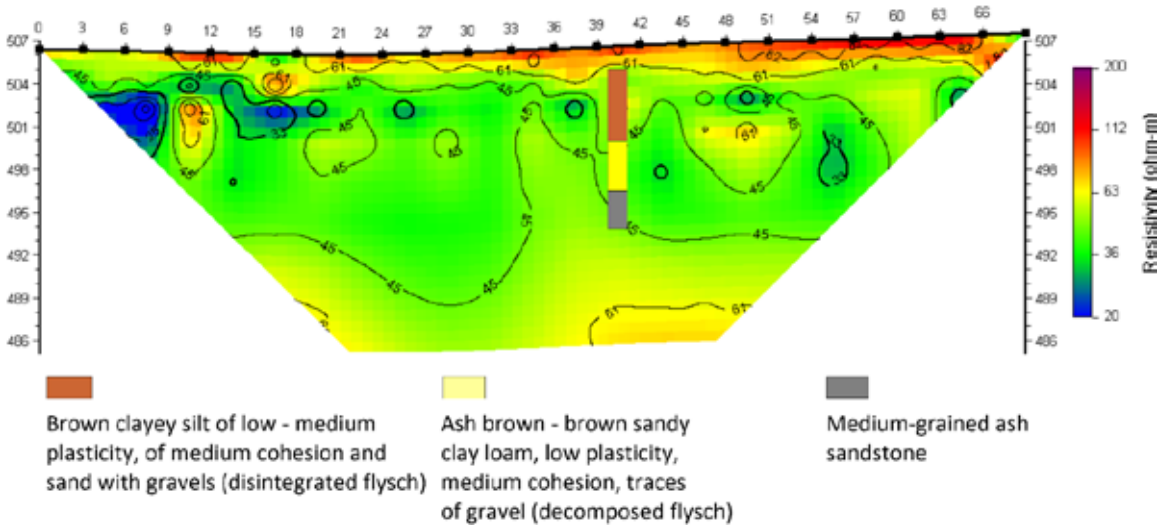

Figure 3. Borehole 2 superimposed to ERT 33 (from South to the North).

The borehole was drilled 10 meters to the east of the line and at the elevation of 505 meters. We can see that the most conductive resistivity layer corresponds to the green area (resistivity values between 45 and 33 Ωm) with less gravel than the overlying layer. The deeper layer is described as medium grained sandstone, while at the area between 6.5 and 7 meters, ash blue disintegrated flysch with indications of possible sliding (slickensided).

ERT R17- BH 4

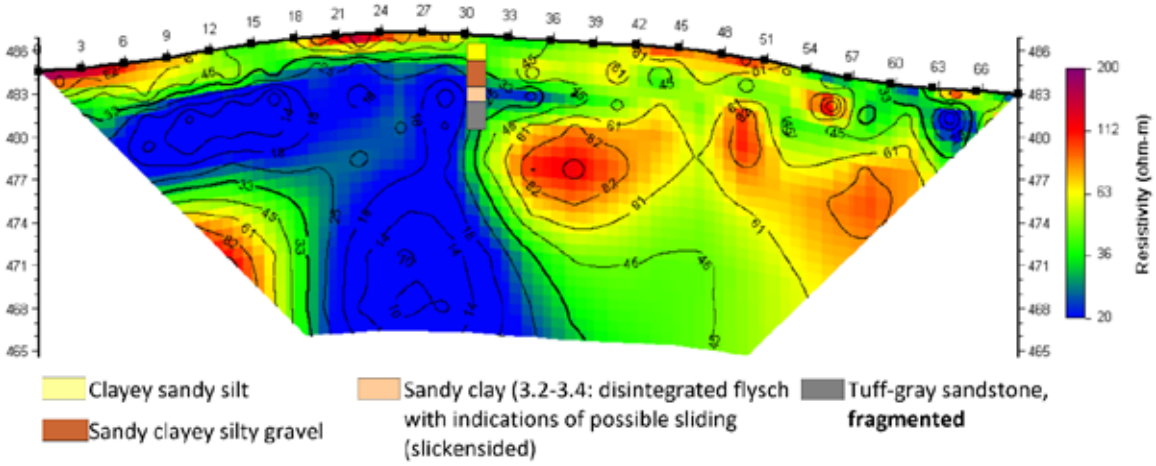

Figure 4. Borehole 4 superimposed to ERT 17 (from North to the South).

This is probably the most indicative example of the ERT contribution to the geotechnical evaluation of a slope. Surficial layers correspond to clayey sandy silt and sandy clayey silty gravel, followed by a thin layer which is described as

possible sliding and at the bottom (of the borehole) the fragmented sandstone.
The borehole is in total agreement with the resistivity model which shows that the borehole is drilled exactly on the fault. The formation at the northern half part of the resistivity model is very clayey showing the disintegrated of flysch, probably decomposed clay shale. The most important information arising from this example is that the model is entirely a 2D model and the borehole information is not enough to reveal this structure.

Concluding remarks

Investigation of slopes, geologically constructed by flysch formation, aiming to the detection of possible failure surfaces, is very difficult, because of the high inhomogeneity of the structure.
Information from boreholes, even is a direct and indisputable, is still a point one. This is an important disadvantage for the investigation plan since, in addition, the amount of boreholes that can be drilled is limited because of access problems and the high cost of geotechnical, full core sampling drillings.
In this article, the contribution of the Electrical Resistivity Tomography method aiming to combined interpretation with geotechnical data is suggested.
Especially in large areas, where flysch is met and inclination of the slope(s) is high, electrical resistivity tomography is suggested among other geophysical methods that could be used. The main reason for this suggestion is that, except for the fact that it can be easily adapted to rough terrains, it can provide reliable information about the presence of groundwater in 2 and 3D complicated geological models.

Introduction

During the Hellenistic period (323–32 BC), the city of Aigion, in the NW Peloponnese, Greece, was a prominent city-state and served as the capital of the Achaean League. The population of the city grew rapidly during this period, and the city also experienced economic growth. After the defeat of the Achaean League by the Romans in 146 BC, Aigion gradually lost its political importance and primacy on the see routes to Patras, the main gateway for the Romans to and from the Italian peninsula. The city flourished again in the 1st century BC, when Italian merchants were settled there. By the end of that century, the population had increased again and economic vitality had been established. After extensive archaeological research kilns, waste pits, workshops and probably a site associated with ancient Agora have been discovered in the city. Located in the northwestern Peloponnese, the area in which the city is situated, is geologically part of the Pindos geotectonic unit, which is a sequence of carbonate and silicate rocks, with a total thickness of 1050m. This sequence is overlain by the syntectonic classical sequence of the Pindian flysch. The Upper Triassic-Jurassic formations and Jurassic-Lower Cretaceous age have been identified in this unit. The Upper Triassic-Jurassic formations consist mainly of sandstones and marls alternations with limestone intercalations, while the upper strata consist of stratified limestones. Similarly, the Jurassic-Lower Cretaceous formations which consist of thin red siltstones and chert alternations (Xanthopoulou, 2019), underlie the Cretaceous pelagic limestones.

This paper, part of the research activities of the KERAMOS Research Group at the Department of Geology, University of Patras, Greece, investigates the mineralogical and petrographic characteristics of Greek transport amphorae and two fragments of tiles discovered in the Trapeza Aigion area in northwestern Peloponnese, where Ancient Rypes was located.

The study aims to shed light on ceramic technology in the region during the Hellenistic – Early Roman period by analyzing this ceramic assemblage. Specifically, it explores the origins of the raw materials used in their production (Amphoras types I, II and III), the ceramic manufacturing processes, and the technical expertise of the potters. Additionally, the study examines trade aspects and production techniques of the era, offering a comprehensive framework for understanding the economy and society of the period.

Methods

A sample set of 27 specimens were carefully selected among the studied repertoire of the amphoras assemblage considering the representativeness of the three main amphoras typologies (I, II, and III). In more detail, amphorae of type I (A5, A7, A9, A10, A11, A15, A16, A17, A18, A19, A20, A21, A22, A23, A24; n=15) have a height of 64 cm, with a rim diameter of about 12 cm, a base diameter of 3.5 cm, a maximum body diameter of approximately 40 cm, and with a capacity of approximately 38 litres (Filis, 2019). The rim is usually beak-shaped, rarely oval in cross-section and quite thin (Filis, 2019). The neck of the amphoras of type I is mainly cylindrical, relatively narrow and short, and in some cases has slightly inwardly sloping walls (Filis, 2019). The amphora has a broad oval shaped body with an extremely narrow knob type base and its outline is curved (Filis, 2019). The handles of the amphorae, are thin and oval in cross-section, are slightly upwards and then curve sharply (Filis, 2019). In some cases, on their outer surface two or three vertical grooves can be observed, while they can also be rolled (bifid) handles, similar to the Koan type amphorae (Filis, 2019). Often only one of the handles has a rectangular banded stamp, measuring approximately 7x1.8 cm, with the name of the potter - fabricant engraved on it (Filis, 2019). Type II (A1, A4, A6, A8, A12, A13, A14, A25; n=8) is similar to the so called Greek Brindisian amphorae type, which is characterized by a high, vertical or outwardly sloping, thick rim, with a curve on its upper surface and two characteristic plastic bands, the upper one being larger than the lower one, placed on the upper part of the short neck (Filis, 2019). At the height of the band, solid, coarse handles of circular or almost circular cross-section are attached (Filis, 2019). These take at the upper part of the neck and then arch to the shoulder (Filis, 2019). One handle bears a rectangular banded type stamp, with names probably associated with ceramic workshop owner or the fabricant. In the type III amphorae (A2, A3; n=2), the rim is thick, quite high, with an angular outline and a maximum outer diameter ranging from 13.3 to 14.8 cm. The neck is low and has conical-shape, surrounded by two similar horizontal plastic ridges (Filis, 2019). It is estimated that the body of the type III amphorae was broadly ovoid, while the knob type base is small hemispherical (Filis, 2019). The han-

dles are solid, fairly robust, circular cross-section, with curves and more often without stamps (Filis, 2019). Two tile samples were also included, potentially playing the role of reference material.

The selected specimens were thin sectioned and grinded to powder using an agate mortar in the Minerals and Rocks Research Laboratory of the Department of Geology at the University of Patras. The thin sections prepared were examined using a Zeiss AxioScope A.1 polarizing microscope aiming to describe their mineralogical and petrographic characteristics which comprise the composition and the textural characteristics of the groundmass, the mineralogy of the non-plastic inclusions according to the methodology proposed by Whitbread (1995). Representative photomicrographs both under plane polarized light (PPL) and in crossed polars (XP) were captured employing a Jenoptik ProgRes C3 videocamera attached to the microscope and processed with ProgRes Capture Pro 2.5 software. The X-ray powder diffraction (XRPD) of the prepared powders was performed using the Bruker D8 Advance diffractometer of the Research, Minerals and Rocks Laboratory of the Department of Geology, University of Patras. This diffractometer has a Ni-Cu filter for Ka radiation and operates at 40kV/40mA conditions and is equipped with the Bruker LynxEye high-speed silicon strip detector. The scan range covered was 2°-70° 2θ with an interval of 0.015° every 0.1s. The qualitative analysis of the XRPD patterns obtained was performed using the DIFFRACplus EVA software (Bruker-AXS, Madison, WI, USA) based on the ICDD Powder Diffraction File (2006 version). The XRPD analysis has permitted us to study the mineralogical composition of the analyzed samples for further confirmation of the petrographic results and in addition for obtaining information about the newly formed mineral phases, which are indicative of the firing conditions during the manufacturing process.

The information obtained from the petrographic analysis is important for identifying the source of the raw materials, for determining the composition of each sample and subsequently for understanding how it was produced, while information on the firing temperature of each sample and on the source of the raw materials can be obtained from the XRPD analysis in combination with the results of the petrographic analysis.

Results and Discussion

The examination of the thin sections under the polarizing microscope has led us to identify four petrographic fabric groups based upon the similarity of their textural and compositional characteristics. The EG1 group contains ferro-micaceous micromass with a wide variation in grain size (Figure 1A), the EG2 group, where the two tiles are classified, is characterized by the presence of micritic calcite and monocrystalline quartz (Figure 1B), the EG3 group by the presence of ferro-calcareous micromass and the absence of silt class in the finer paste (Figure 1C) and the EG4 group by the presence of ferro-calcareous micromass with pores (Figure 1D). The micromass of each group is ferrous-calcareous, excluding the group EG-1 which has a ferrous composition. Additionally, the clay paste of the EG-1 group has a micaceous composition, while the others have a calcareous one. Moreover, the use of grog seems to be a common practice as it is observed in all petrographic groups except from the group EG-2.

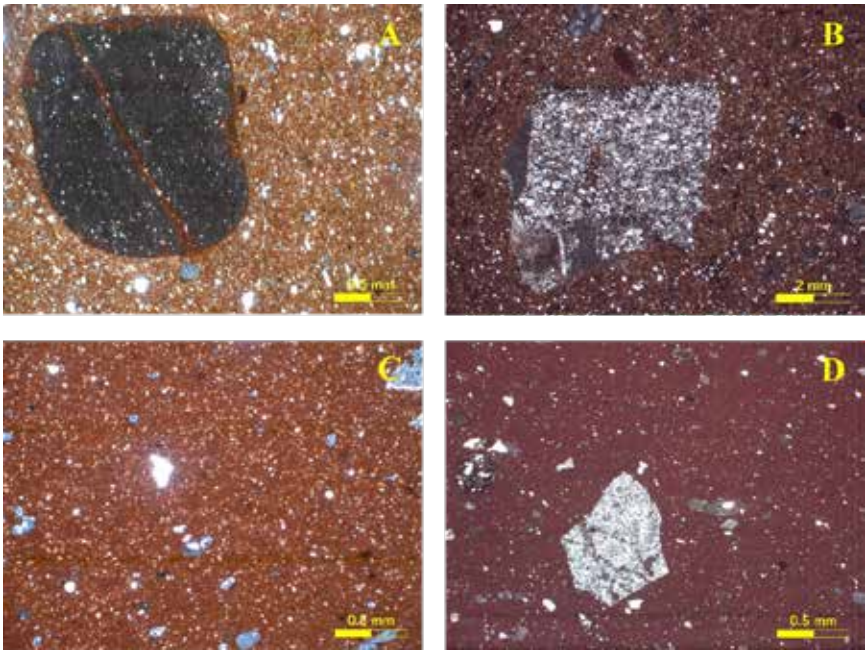

Figure 1: Representative photomicrographs of the petrographic fabric groups established during the present study. A. EG1 (sample A7); B. EG2 (sample A27); C. EG3 (sample A15); D. EG4 (sample A23). All pictures are taken in XP

In more detail, the EG1 group includes 12 samples (A1, A4, A6, A7, A8, A9, A12, A13, A19, A21, A24 and A25). The micromass appears optically inactive, with an olive-greenish brown color when observed under plane-polarized light (PPL) and light brown color under crossed polars (XP). In samples A1 and A8, mottled areas are observed due to the presence of secondary calcite and only these areas are optically active. Samples A1, A6, A7, A8, A9, A12, A13, A19, contain chert fragments in contrast to the remaining samples in this group. Sandstone fragments were also observed in samples A1, A6 and A8, while samples A6 and A19 also include fragments of reused pottery (grog). Regarding the plastic material, clay pellets are observed in sample A7 and characteristic clay striation lines are identified in samples A12 and A13. Finally, the predominant mineralogical component of the fine-grained micromass is white mica.

As for EG2, this group consists of 5 samples (A2, A3, A18, A26 and A27) with an optically inactive micromass with a brown color in plain polarized light (PPL) while in crossed Nicols (XP) the color is reddish brown. The dominant minerals of this group comprise monocrystalline quartz as well as micritic calcite. Moreover, opaque minerals are also observed in the samples and the micromass is impregnated by secondary microsparite. Finally, sample A18 contains brown mica and siltstone.

The EG3 group consists of 8 samples (A5, A10, A11, A15, A16, A17, A20 and A22) with an optically inactive micromass with a dark brown color in observation in the plain polarized light (PPL), while in the crossed Nicols (XP) it is reddish brown. The dominant mineral is monocrystalline quartz, whereas grog and secondary calcite are observed in most samples. In addition, in samples A5, A11, A17, chert fragments are present, with A17 containing siltstone fragments. Moreover, in samples A5, A10, A11, A15 and A16, striation lines are observed.

The EG4 group consists of 2 samples (A14 and A23) with an optically inactive ferro-calcareous micromass with many voids while quartz is the dominant mineral and grog is also present. Finally, in most of the samples the clay treatment is very good, which suggests very good know-how of the potters, especially as regards the addition and mixing of the clay with those materials that could give their ceramics the particular properties they wanted.

According to the evaluation of the XRPD patterns the samples studied were classified based on their common qualitative and semi-quantitative mineralogical characteristics into three mineralogical classes. The Class I includes 5 samples A11, A16, A21, A25, A26 (tile), which comprise quartz, calcite, plagioclase, illite, and only few quantities of diopside hematite and ± gehlenite. The presence of these minerals indicates that these samples were fired at moderate temperatures, and more specifically below or very close to 850°C (Gliozzo, 2020a). The class II is represented by 6 samples A1, A2, A3, A19, A20, A24 which consist of quartz, calcite, plagioclase, diopside, hematite, and ±gehlenite. The presence of these minerals indicates a firing temperature between 850°C-900°C, possibly reaching even higher temperatures (950°C) in some of the samples (Gliozzo, 2020a). The class III consists of 16 samples A4-9, A10, A12, A13 A14, A15, A17 A18, A22, A23, A27 (tile). The samples of this class consist of quartz, plagioclase, diopside, hematite, ±calcite and ±gehlenite. The presence of these minerals indicates a firing temperature above 900-950°C (Gliozzo, 2020a). It should be noted that the presence of calcite in the latter two classes (II and III) is due to the secondary formation of this mineral due to the burial condition, as was also verified by the petrographic evidence.

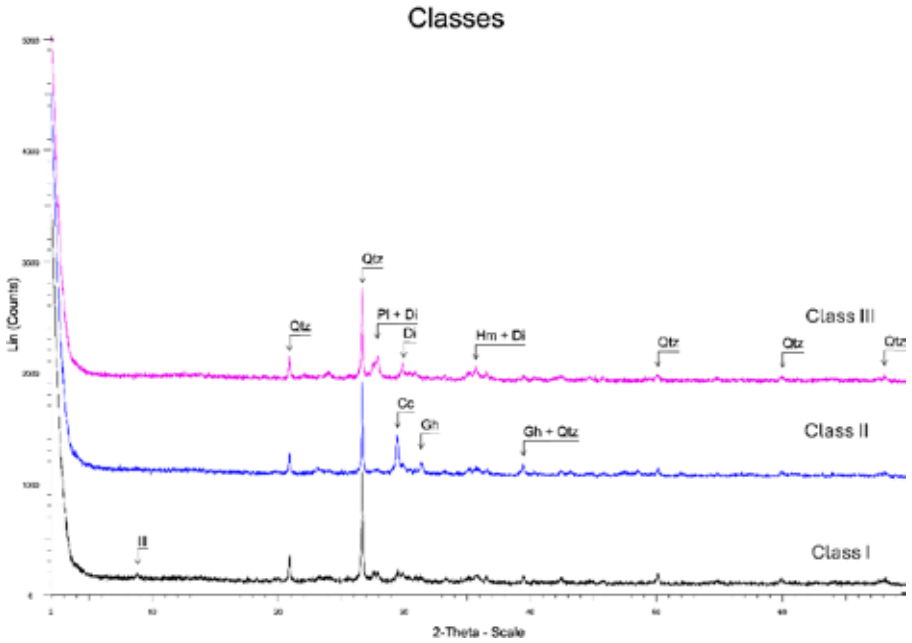

Figure 2: Representative diffractograms of the main mineralogical classes identified in the present study through XRPD. Qtz: Quartz, Pl: Plagioclase, Hm: Hematite, Gh: Gehlenite, Dio: Diopside, Cc: Calcite, Ill: illite

The correspondence between the data obtained from the petrographic analysis of the thin sections through the polarizing microscope and the XRPD analysis is presented in Table 1. With the exception of the samples classified in petrographic fabric group EG-4, which are fired in temperatures above 950°C, no specific firing pattern is emerging for the samples assigned to the rest of the fabric groups (ie. EG-1, EG-2 and EG-3).

Table 1: Comparative table of mineralogical classes and petrographic groups

Mineralogical classes XRPD	**Petrographic fabric groups**			
	EG-1	**EG-2**	**EG-3**	**EG-4**
Class I EFT< 850 °C	A21, A25	A26	A11, A16	-
Class II 850 °C <EFT< 950 °C	A1, A19, A24	A2, A3	A20	-
Class III EFT> 950 °C	A4, A6-A9, A12, A13	A18, A27	A5, A10, A15, A17, A22	A14, A23

The petrographic results showed that all the fabric groups are compositionally correlated with the local lithogeology and are differentiated in terms of technological choices of the potters and probably the use of different sources of the raw materials.

The results were correlated with the mineralogical composition of the sediments in the surrounding area. More specifically, according to Filis, 2019 the clay source of the Hellenistic transport amphorae could be either the Selinous River or the region of Neratzies Aigialia to the west of Aigion, close to the river Salmeniko. The Selinous river catchement is richer in chert material compared to the one of Neratzies (Filis, 2019). Moreover, Xanthopoulou (2019), collected calcareous sand samples, comprising mainly fragments of micritic limestone and subordinate to rare sparitic calcite, from the Selinous River. These sands are also rich in radiolarian chert and mudstone. Xanthopoulou also collected samples from sandy marls, sands and sandstones and clay layers formations cropping out in the area. Some of these also contain siltstone fragments. Lastly, the clayey raw material from the same area studied by Xanthopoulou (2019) are of illitic-chloritic composition and contain mixed-phases which include mainly illite-smectite, chlorite-smectite, chlorite-vermiculite and to a lesser extent mica-vermiculite (Xanthopoulou, 2019). Another possible source could be the area around Kerinitis River where, based on Xanthopoulou (2019), clays have a similar composition to those studied in proximity to the Selinous River.

Conclusion

This paper analyzed samples of Hellenistic-Early Roman stamped transport amphorae from the area of Aigion. The above samples were analyzed mineralogically and petrographically using optical X-ray diffractometry and optical microscopy respectively. The identified mineralogical phases indicate that the majority of the ceramics were fired at temperatures above 950°C. Furthermore, a comparison of the composition of the samples with the local geology of the area (Xanthopoulou, 2019) suggests that the raw materials for the production of the stamped amphorae could originate from the wider Aigio area, possibly from the Selinous River catchment (Filis, 2012, Filis, 2019). Finally, there is a very high level of homogeneity in the production of pottery, with a high level of expertise among the potters.

Acknowledgements

We would like to thank Mr Panagiotis Mpalasis for the preparation of the thin sections as well as Dr Paraskevi Lampropoulou for performing the XRPD analysis of the samples.

Introduction / Background

Research Highlights

The 1986 Kalamata earthquake (Mw 6.0) in Messiniakos Gulf (SW Peloponnese, Greece) triggered underwater landslides or slumping, leading to the movement and redistribution of sediment in shallow waters.

The submarine canyons, main fault zones controlling the evolution of the gulf, and areas of tectonic uplift, which are crucial for geohazard assessment, although investigated with advanced methods, were found to be, more or less, in agreement with previous key findings (Pavlakis et al., 1989)

Background

Marine and coastal environments often face significant geohazards, including earthquakes, submarine landslides, and rapid morphological changes (Chiocci et al. 2011). The Messiniakos Gulf, located in southwestern Peloponnese at the western part of the Aegean arc system, close to the Hellenic Trench, exemplifies such dynamic environments (Papanikolaou et al., 1988a). Intense seismic activity, the prevalence of normal faulting, and notable crustal uplift are among the key geodynamic processes that dominate the region's evolution due to the subduction of the African plate beneath the Eurasian plate (Figure 1). The region is a complex multi-fractured neotectonic macrostructure, characterized by the presence of large grabens and horsts bounded by wide fault zones, trending approximately NNW-SSE and E-W (Mariolakos and Papanikolaou, 1981, 1987; Mariolakos et al., 1985; Fountoulis, 1994; Mariolakos et al. 2004; Fountoulis and Mariolakos, 2008; Fountoulis et al., 2014).

Previous studies have highlighted the role of active faulting in shaping the Gulf's geomorphology and emphasized its vulnerability to seismic events (Papanikolaou et al. 1988b; Papoulia et al., 2001; Papoulia and Makris et al., 2004). The seismicity of the area, exemplified by the 1986 Kalamata earthquake (Mw 6.0), highlights the importance of assessing geohazard risks in this region. This earthquake, caused by an NNE-SSW striking normal fault, not only led to extensive damage in the Kalamata region but also revealed instability in terms of bottom surface sediment and sliding phenomena, situated in the northeastern corner of the gulf and other geomorphic changes in the Gulf. Co-seismic uplift of shorelines at the northeastern coast of the Messiniakos Gulf during the Holocene was observed by tens of meters, particularly adjacent to significant marginal faults (Pavlakis et al., 1989). This event, combined with the region's ongoing tectonic activity, served as the primary motivation for this research.

The present research highlights the complex relationship between tectonics and geomorphology in the Messiniakos Gulf (Varotsou 2024).

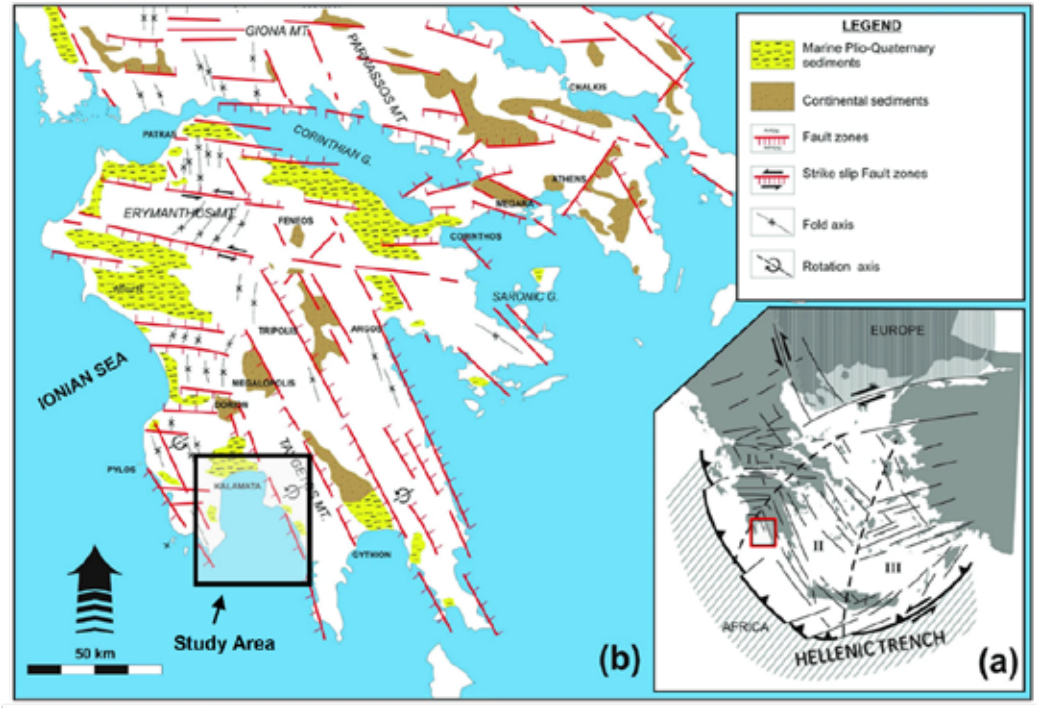

Figure 1. (a) Inset map displaying the three morpho-neotectonic regions and the 3 sectors of the Hellenic arc. (b) The neotectonic map with the main marginal fault zones of the post-Alpine basins in southern continental Greece, highlighting the location of the study area (Black frame) (modified from Papanikolaou 2021a, b).

Objectives

The general objective of this study is to explore the morphotectonic features of Messiniakos Gulf using high-resolution multibeam bathymetry data. By integrating recently acquired bathymetric data through GIS-based analysis, this study aims to provide a comprehensive evaluation of the Gulf's morphotectonic characteristics and their implications for geohazard risks. By producing a detailed bathymetric map and analyzing the morphotectonic map, morphological changes that reflect a landscape influenced by significant tectonic activity may be revealed.

Methods

Bathymetric data were obtained in the course of four different hydrographic surveys conducted by the Hellenic Navy Hydrographic Service in 2006, 2015, 2017, and 2023, using both single-beam and multibeam echosounders. During the 2006, 2017 and 2023 cruises, multibeam data were acquired onboard the Hydrographic - Oceanographic Vessel NAFTILOS, and on board the Hydrographic Vessel LAUNCH 14 in 2015.

During the 2006 cruise, bathymetric data were acquired using the Kongsberg EM1002 multibeam, which generates 111 beams at a 95 kHz frequency, with an operational depth up to 1000 meters. During the 2015 cruise, the Teledyne RESON SeaBat 7125 multibeam echosounder was used, operating at either 200 or 400 kHz, with a depth range of 1–500 meters. Swath data from the 2023 cruise were obtained with the hull-mounted RESON SeaBat 7160, which operates at 44 KHz nominal frequency, with equidistant beam spacing mode, forming 512 beams per swath. Single-beam data were collected using Atlas Deso-25 echosounder during the 2006 and 2017 cruises on board the Hydrographic / Oceanographic Vessel NAFTILOS, as well as during the 2015 cruise on board the Hydrographic Vessel STRAVON.

The processing of multibeam data utilizing QPS QIMERA software involved multiple steps, including sound velocity corrections, removal of erroneous beams, filtering noise, and adjustments of navigation data. The bathymetric datasets were then merged to create a Digital Terrain Model (DTM) with a consistent grid of 20 m spatial resolution, supplemented in areas not covered with swath data, by additional data sources (EMODNET, https://emodnet.ec.europa.eu/en/bathymetry).

The morphotectonic analysis focused on primary and secondary morphometric parameters like slope and curvature. Slope maps were created to show slope gradients and identify, map, and characterize major tectonic structures. A

drainage analysis using ArcGIS tools mapped drainage pathways and basins, illustrating the impact of topography on hydrology.

Results and Conclusion

The study culminated in a simplified morphotectonic map displaying significant morphotectonic features in the area derived from the analysis of the detailed bathymetric map and morphological slope map (Figure 2, Figure 3). It emphasizes the importance of high-resolution data for understanding the geomorphology and tectonics of the Messiniakos Gulf.

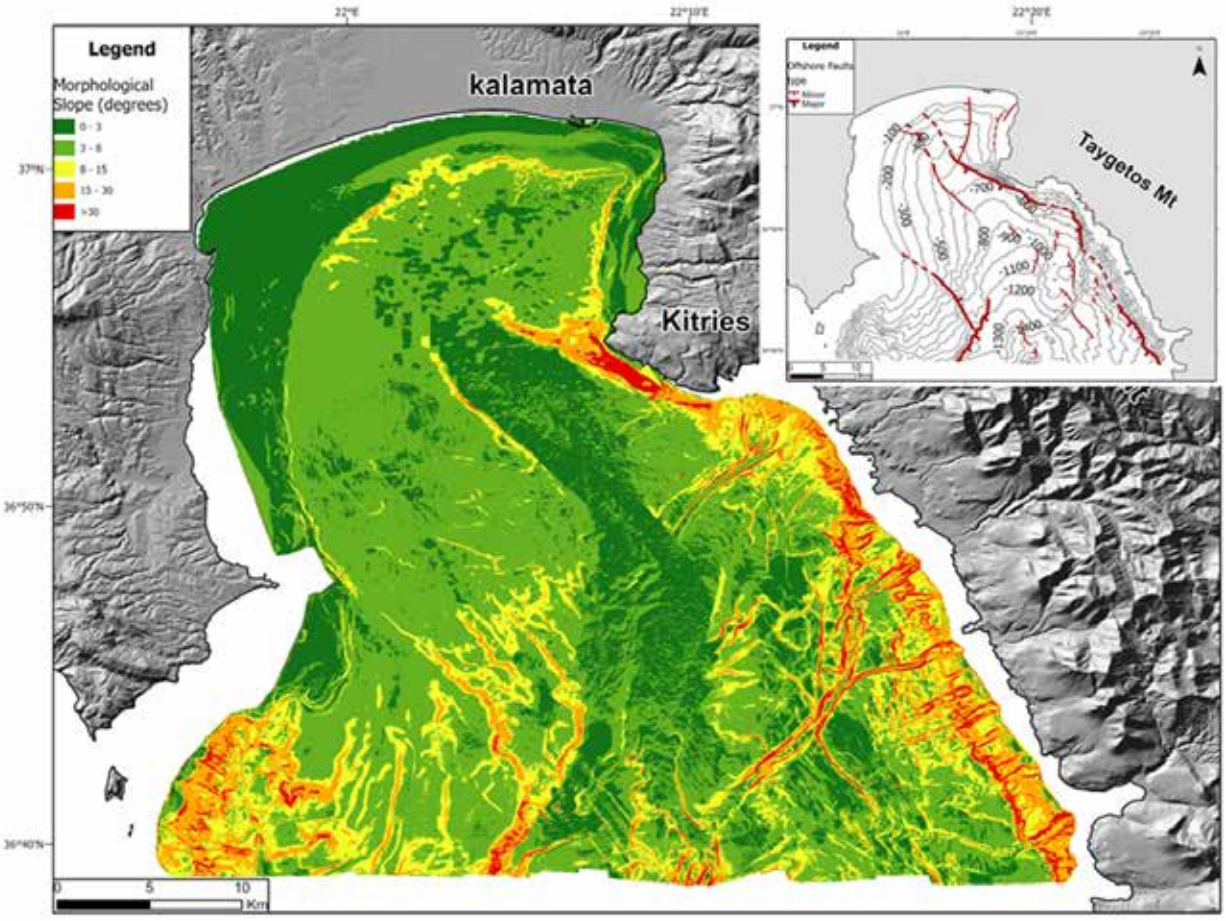

Figure 2. Morphological Slope Map of the area studied. The inset tectonic sketch map demonstrates Major- indicated by the high slopes and Minor morphological discontinuities. The degree of slope steepness is illustrated by green to red colors – flat surfaces as deep green, flat to shallow slopes as light green to yellow, shallow to moderate slopes as light orange, and steep slopes as red.

The analysis revealed an asymmetric, oriented NNW-SSE basin, characterized by steep slopes up to 40° along its eastern margin. This forms a distinct NW-SE narrow geometric zone, approximately 1.5 km wide, striking parallel to the Kitries coastline and extending southward with NNW-SSE orientation. This steep slope zone corresponds to the major active normal fault zone bordering the eastern part of the half-graben structure of the Messiniakos Basin to the southwest, where the maximum thickness of Plio-Quaternary sediments has been deposited, as it has been verified by lithoseismic profiling (Papanikolaou et al. 1988b). In contrast, the non-deformed western margin is rather homogeneous represented by consistent gradients (2-5 °) and a shallow area indicating the extended continental shelf.

Submarine canyons were discovered for the first time, aligned NE-SW and N-S, extending from the continental shelf to depths exceeding 1,400 m. The edge of the continental shelf aligns with the horizontal plane of the Holocene transgressive unconformity, formed by the global sea level rise following the last glacial period. By examining the interplay between eustatic sea-level changes and tectonic activity, driven by fault slip rates, this study identifies a

significantly higher uplift rate in the northeastern part of the Gulf. Notably, the edge of the continental shelf is traced all along the Messiniakos Gulf (Figure 3), except on the northeastern coast of the gulf where it has been partly buried and distorted, due to fault throw rates and the sliding phenomena.
Thus, since the Holocene transgression, the total uplift has been measured at 4–31 m, determined by the change in depth of the shelf break, compared to the findings of Palvakis et. al., (1989).

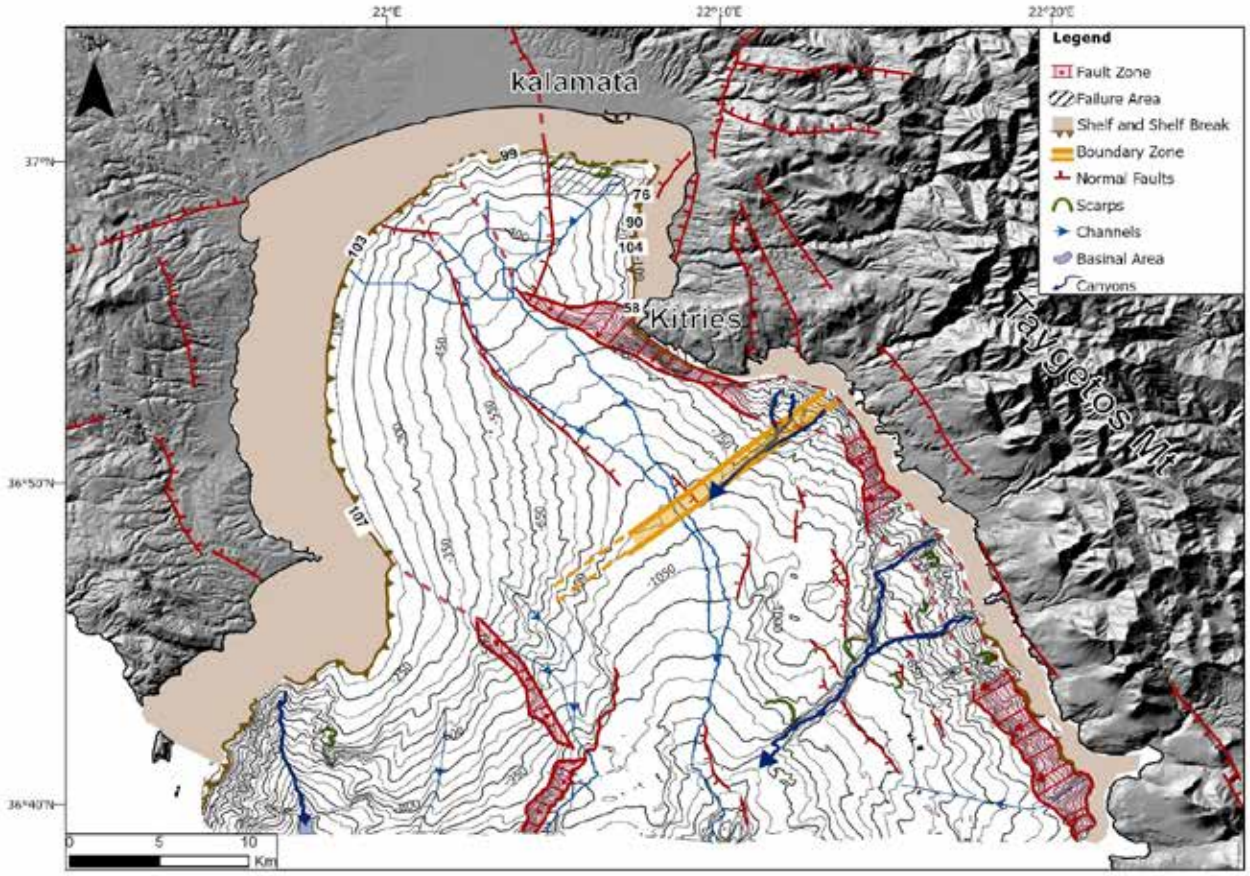

Figure 3. Simplified Morphotectonic Map of Messiniakos Gulf. The continental shelf is extended up to 6 km mainly along the western part of the Messiniakos Gulf, whereas the marginal NNW-SSE fault dominates the eastern part with a narrow shelf of 1 km. Onshore faults are denoted with red solid lines (after Ganas et al. 2013).

The morphotectonic synthesis highlights the interplay between tectonic uplift, sediment deposition, and erosion in shaping the Messiniakos Gulf. Active fault zones along the eastern margin likely influence canyon development and drainage patterns. The spatial correlation of seismicity with geomorphic features suggests that fault activity remains a primary driver of landscape evolution. The absence of extensive submarine fans indicates limited sediment transport from the shelf to the deeper basin, possibly constrained by fault-controlled topography. Submarine drainage analyses revealed a dendritic pattern, with prominent channels guiding sediment flows to the deepest parts of the Gulf.
The analysis of high-resolution bathymetric data, following the interpretation of previously published single-channel seismic reflection data (Papanikolaou et al., 1988b; Palvakis et al., 1989), has revealed seafloor primary as well as secondary scarps and signs of active deformation. These features suggest slope failures that completely distort the continental shelf and indicate mass transport towards the southwest (Figure 3). This activity is associated with the Kalamata earthquake (Mw 5.7) that struck on September 13, 1986, just a few kilometers south of Kalamata Harbor. More specifically, the resulting microfracture zone coincides with the northern edge of the previously described N-S fault zone. This zone, recorded shortly after the earthquake, aligns with the event's NNW-SSE fault plane solution, reinforcing the correlation between seismic activity and observed seafloor instability. All these findings emphasize the dynamic nature of the Gulf's geomorphology and highlight areas with a heightened potential for geological hazards.
In conclusion, this study underlines the importance of integrating high-resolution bathymetric data with GIS tools to effectively map geohazards. The findings contribute to a refined understanding of the Messiniakos Gulf's active tectonic regime and provide a framework for assessing future geohazard risks in the region. Continued monitoring

and advanced modeling are recommended to quantify fault dynamics and associated risks to coastal and submarine infrastructures.

Acknowledgments
We would like to acknowledge the Hellenic Navy Hydrographic Service for the provision of the bathymetric data used in this paper and the excellent cooperation.

Assessment of Geo-environmental Status of Trichonis Lake, Greece: Mineralogy, Sedimentology, and Chemistry

Vasilatos C.[1], Megremi I.[1], Gkioka Z.[1], Theori N.[2], Cuida Lopez E.[3], Stoica A.I. [3], Economou-Amilli A.[2]
(1) Faculty of Geology & Geoenvironment, National and Kapodistrian University of Athens, Athens, Greece, vasilatos@geol.uoa.gr (2) Faculty of Biology, National and Kapodistrian University of Athens, Athens, Greece (3) Department of Landscape, Water and Infrastructure, University of Natural Resources and Life Sciences, Vienna

Research Highlights

Sediments of Trichonis Lake are dominated by quartz and calcite, reflecting the lithological influence of surrounding limestone and flysch formations.

Reduced nutrient levels in lake water since the late 1990s highlight the positive ecological impact of decreased agricultural pressures, providing a foundation for sustainable lake management strategies.

Introduction / Background

European Union countries have evaluated all freshwater habitats larger than 50 hectares to comply with the Water Framework Directive 2000 (European Commission, 2000). To support biological, hydromorphological, and physico-chemical monitoring, a range of indicators and multimetric indices has been developed. These include factors such as morphology, hydrology, nutrient levels, thermal conditions, salinity, pollutants, and priority substances. Geochemical indicators such as pH, sediment mineralogy, and the concentrations of ions, nutrients, and potential pollutants in soil and water, are normally used to assess habitat quality and quantify the environmental stress affecting ecosystems (ecological status) (e.g. Vasilatos et al., 2019).

Trichonis Lake, located in western Greece, is the largest and one of the deepest natural freshwater lakes in Greece, with a maximum depth of 58 m and a surface area of approximately 98 km² (Figure 1). On the northeastern side of the lake the steep slope of Panaitoliko Mountain is visible, while the southwestern side is bounded by the ridge of Arakinthos Mountain. The wider "Trichonis basin" is a neo-tectonic graben approximately 30 km in length and 10 km in width (Doutsos et al., 1987); its hydrological basin extends to an area of 402 km^2 (Koutsoyiannis et al., 2008) and its southern boundary is defined by a prominent WNW-ESE trending normal fault. Geologically, the area belongs to the External Hellenides, specifically the Pindos and Gavrovo geotectonic units (Figure 2). Trichonis Lake occupies the eastern margin of a fractured tectonic trough at a semi-circular shape. This trough was formed primarily due to the intense tectonic activity of the region and partially by the collapse of limestone masses into existing underground caverns, which constitute an extensive karstic network. These karsts are continually enlarged by the erosive and solvent action of water, leading to the collapse of overlying layers and contributing to ongoing changes in the morphology of the region (Evangelidis et al., 2008; Kiratzi et al., 2008, Benekos et al., 2013). Trichonis Lake main geomorphological characteristics are summarized in Table 1.

Table 1. Geomorphological characteristics of Trichonis Lake (cf. Tafas et al., 1997).

Max. length	18.2 km
Max. width	7.5 km
Max. depth	58 m
Mean depth	30.45 m
Lake volume	2.99 x 10^9 m^3
Shore length	52.1 km
Surface area	98.2 km^2
Drainage area	215 km^2

The water level of the lake is artificially controlled by a dam being constructed to regulate its discharge at an average altitude of 15.5 m with a fluctuation of ±1 m. This dam communicates by means of a 2.8 km long Trichonis-Lysimachia Unifying Trench with Lysimachia Lake, to which its excess water potential is channeled.

The lake is recognized for its rich biodiversity, including endemic fish (e.g. Vardakas et al. 2022), freshwater hydrobiids

(e.g. Radea et al. 2017), and algae species (Economou-Amilli 1979, 1982); and generally, for the presence of unique aquatic plants, as well as its role in local hydrology and as a water source for nearby communities. However, like many freshwater ecosystems globally, Trichonis faces environmental pressures due to agricultural activities, urban runoff, and sedimentation processes, potentially threatening the health of its ecosystem. In previous studies (e.g., Kehayias & Doulka, 2014; Overbeck et al., 1982; Tafas et al., 1997) due to its limnological and biological characteristics Trichonis was classified as a carbonate-type, low-conductivity lake ("class II, low salinity" warm lake) with an oligotrophic to mesotrophic ecosystem. Furthermore, Kehayias & Doulka (2014), using zooplankton as a biotic indicator, suggested that Trichonis Lake is undergoing a transitional shift toward a eutrophic state, emphasizing the need for continuous monitoring and inspection of the ecosystem.

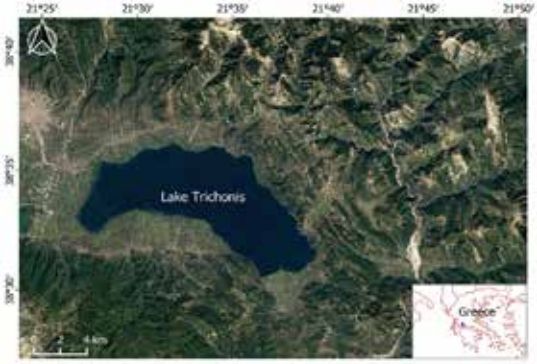

Figure 1. Location map of the study area (Perivolioti et al., 2021).

Objectives

The objective of this study is to assess the geo-environmental status of Trichonis Lake by analyzing the mineralogical and sedimentological characteristics of its sediments along with the physicochemical parameters of lake water. This analysis aims to identify changes in sediment composition, assess nutrients concentrations, and evaluate the impact of anthropogenic activities, offering a comprehensive assessment of current environmental condition of the lake and helping guide future management efforts.

Methods

Study Area and Sampling Sites

Bottom sediment and water samples were collected from various sites throughout Trichonis Lake in September 27-28, 2024, to capture a representative profile of the lake's sedimentary environment (Figure 2). Sampling sites were selected to encompass areas near potential pollution sources, such as agricultural runoff zones and areas adjacent to urban settlements, as well as deeper, central lake locations to account for natural sediment deposition.

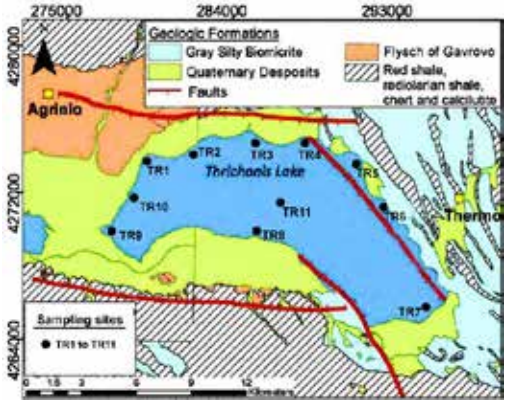

Figure 2. Simplified geological map of the study area (modified after Benekos et al., 2013) with the sampling sites.

Sediment Sampling, Preparation and Analysis

Sediment was retrieved from each site using a stainless-steel dredge bottom sludge sediment grab sampler

(Figure 3). Sediment samples were collected in 2 L plastic bags. Before the experimental procedure, the coarse organic matter was removed from the samples. In the laboratory they were air-dried, homogenized, and sieved to remove particles larger than 2 mm. Fine fractions were preserved for further mineralogical, sedimentological, and chemical analyses. The granulometric characterization was conducted according to Folk's methodology and classification (Folk, 1974). Mineralogical analysis was carried out by using an X-Ray Siemens D 5005 Diffractometer, equipped with a Cu tube and a graphite monochromator, in combination with the DIFFRACplus software package at NKUA, Department of Geology and Geoenvironment. The organic matter (OM) content was determined using dry combustion, involving drying at 105°C for 24 hours and combustion at 380°C for 6 hours in a muffle furnace (Vasilatos et al., 2019). The $CaCO_3$ (%) content was estimated by combusting the above samples at 950°C for 1 hour.

Figure 3. Sampling in Trichonis Lake. Photographs have been captured from sampling site TR4 (Figure 2).

Water Sampling, Preparation and Analysis

pH, redox potential (Eh), conductivity, total dissolved solids (TDS) and dissolved oxygen (DO) measurements were performed *in situ*, using a portable Multiparameter Analyzer (CyberScan Series 600, EUTECH). Water samples (Figure 3) were filtered through 0.45 μm membrane filters, collected and stored in polyethylaine containers. They were divided into two groups; the first group was persevered for the measurements of anions while the second was acidified by addition of concentrated HNO_3 for the measurements of cations. Then they were all stored at cooling conditions (~ 4°C) into a portable refrigerator.

Chemical analyses for NO_2^-, NO_3^-, NH_4^+, PO_4^{3-} and SO_4^{2-} were performed using a HACH DR/2400 spectrometer. The detection limits of the methods were 0.007 mg·L^{-1}, 0.05 mg·L^{-1}, 0.013 mg·L^{-1}, 0.01 mg·L^{-1}, and 3 mg·L^{-1}, respectively.

Results and Discussion

Sedimentology

Particle size data (Figure 4) can reveal sediment transport patterns and indicate environmental conditions impacting sedimentation, such as changes in water flow or anthropogenic disturbances.

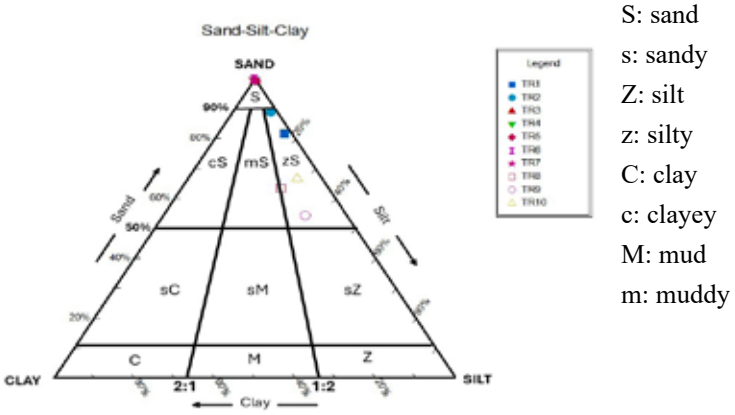

Figure 4. Bottom sediments granulometry according to Folk's (1974) classification scheme.

Sedimentological analysis indicated that sites near limestone formations are classified as sand while samples nearby flysch formations are silty sand, dominated by finer sediment fractions (Figure 4). This distribution suggests that sedimentation processes in the lake are controlled by the mineralogical composition of the adjacent lithologies and rock erosion.

Sediments Mineralogy and Chemistry

Quartz and calcite were confirmed in all samples originated from the surrounding flysch and limestone formations (Table 2). Clay minerals (chlorite and muscovite) and feldspars have been identified in samples adjacent to the flysch and related Quaternary deposits (Figure 2). These findings align with typical mineral assemblages expected in freshwater lake sediments within flysch and limestone-rich areas.

Table 2. Mineralogical composition of the bottom sediments (qualitative).

	TR1	TR2	TR3	TR4	TR5	TR6	TR7	TR8	TR9	TR10
Quartz	+	+	+	+	+	+	+	+	+	+
Calcite	+	+	+	+	+	+	+	+	+	+
Aragonite								+		
Orthoclase		+					+			
Albite	+	+						+	+	+
Anorthite		+						+		
Muscovite	+	+						+	+	+
Chlorite	+	+						+	+	+

+ referring to the presence of the mineral phase

The organic matter content in the bottom sediments ranged from 0.1% to 6.2% (Table 3). The maximum value (6.2%) was observed at sampling site TR9, located near the opening of the Trichonis-Lysimachia Unifying Trench, pointing out the ecological importance of this trench. The high value of organic matter content at that site is a strong indicator of ecological processes like increased biological productivity or enhanced sediment accumulation. Samples with the lowest organic matter content showed the highest quartz content based on their X-ray diffraction (XRD) patterns

Table 3. Quantitative analysis of the Organic Matter and $CaCO_3$ content of the samples.

	TR1	TR2	TR3	TR4	TR5	TR6	TR7	TR8	TR9	TR10
Organic Matter (%)	1.7%	1.2%	1.0%	0.1%	1.2%	0.6%	1.0%	5.3%	6.2%	2.6%
$CaCO_3$ (%)	19.4%	23.0%	39.0%	39.8%	11.6%	69.4%	19.3%	52.4%	67.3%	42.3%

Water Chemistry

Physicochemical parameters, concentration and chemical composition of the major anions of water samples from Trichonis Lake are presented in Table 4. All measured water parameters comply with the standards for water intended for human consumption (European Commission, 2000).

The measured pH values range from 6.52 to 7.90, falling within the typical range for lake water associated with limestone or flysch lithologies. The observed high concentrations of NH_4^+, NO_3^-, and PO_4^{2-} in the sample TR8, as well as of NO_3^-, NO_2^-, and PO_4^{2-} in the sample TR4 suggest a tangible impact of agricultural and urban runoff on Trichonis Lake. The consistent SO_4^{2-} levels (27.1–28.4 mg/L) across sampling sites indicate minimal influence from human activities, which would cause greater variability near potential sources. Instead, these concentrations may stem from natural processes, such as the presence of evaporitic formations in the wider area.

Nutrient levels are much lower than in 1980–1997 (Koutsoyiannis et al., 2008) but similar to 2000–2002 (Koutsoyiannis et al., 2008) presumably due to the late-1990s abandonment of extensive tobacco cultivation around the lake, which had caused ecological strain.

Table 4. Measurements of the water physical and chemical parameters.

	Units	TR1	TR2	TR3	TR4	TR5	TR6	TR7	TR8	TR9	TR10	TR11

Comparison with Other Mediterranean Lakes

Even though Trichonis Lake has been classified as a typical warm lake, it resembles more closely to temperate lakes than tropical ones (Tafas et al., 1997) exhibiting shallow metalimnia that characterize lakes of higher latitudes.

The bottom sediments of Trichonis Lake are primarily composed of quartz, calcite, and clay minerals such as chlorite and muscovite, reflecting the geological influence of surrounding flysch and limestone formations. This composition is characteristic of carbonate-type lakes in limestone-dominated regions (Tafas et al., 1997; Kehayias & Doulka, 2014). In contrast, many Mediterranean lakes exhibit more diverse sediment compositions depending on local geology, including higher proportions of volcanic materials (e.g., in volcanic lake basins) or organic-rich sediments in eutrophic systems (Karathanasis & Hajek, 1993; Gkenas et al., 2012; Michaloudi et al., 2013; Köprücü & Polat, 2017).

The relatively low organic matter content (ranging from 0.1% to 6.2%) in Trichonis sediments aligns with its oligotrophic to mesotrophic status, whereas highly eutrophic Mediterranean lakes often exhibit significantly higher organic matter concentrations due to increased biological productivity and nutrient input (Overbeck et al., 1982; Tafas et al., 1997; Kehayias & Doulka, 2014). The high $CaCO_3$ content (up to 69.4%) further distinguishes Trichonis as a carbonate-rich system, a feature not universally observed in Mediterranean lakes, where sediment composition varies widely.

Nutrient levels (e.g., NH_4^+, NO_3^-, and PO_4^{3-}) in Trichonis Lake water are relatively low compared to heavily impacted Mediterranean lakes, although localized agricultural and urban runoff has resulted in elevated nutrient concentrations in specific sites, indicating ongoing anthropogenic pressure (Petaloti et al., 2004). When compared to other Mediterranean lakes, Trichonis exhibits nutrient levels and chemical parameters indicative of a transitional ecosystem, less impacted by eutrophication than many lakes in the region.

Conclusions

Comprehensive assessment of the geo-environmental status in Trichonis Lake revealed insights into its sedimentological, mineralogical, and chemical characteristics, as well as into the impact of natural and anthropogenic factors.

Key conclusions include:

- The sediments are predominantly composed of quartz and calcite, reflecting a lithological influence of the surrounding flysch and limestone formations. Variations in sediment texture, ranging from sand to silty sand, highlight localized sediment transport and deposition processes.
- Organic matter content ranged from 0.1% to 6.2%, with higher values near areas of enhanced biological productivity, such as at the Trichonis-Lysimachia trench. This differentiation signifies the ecological importance of sedimentary organic matter accumulation in assessing ecosystem “health”.
- Physicochemical parameters, including pH, Eh, and TDS, are consistent with those expected in freshwater systems influenced by limestone and flysch. Elevated nutrient levels at specific sites point to agricultural runoff and urban influences, although the overall nutrient concentrations declined since the late 1990s, likely due to reduced agricultural pressures, including the cessation of tobacco cultivation.
- While some localized contamination is evident, such as elevated NH_4^+, NO_3^-, and PO_4^{3-} levels near agricultural areas, the consistent SO_4^{2-} levels across sites suggest limited anthropogenic influence on this parameter. The mineralogical composition of the lake sediments also emphasizes the dominance of natural geochemical processes in shaping its chemistry.
- Overall, Trichonis Lake shares some commonalities with other Mediterranean lakes in terms of its sensitivity to anthropogenic impacts and nutrient dynamics. However, its distinct carbonate-rich sediment composition and relatively stable water chemistry highlight its unique geological and ecological context. This underscores the importance of tailored conservation efforts to preserve the lake’s ecological balance amidst regional anthropogenic pressures.

This study provides a baseline for understanding the geo-environmental dynamics of Trichonis Lake and offers valuable guidance for future conservation and management strategies aimed at maintaining the health of this vital

freshwater ecosystem. Findings underscore the need for continued monitoring and sustainable land-use practices to mitigate anthropogenic pressures and preserve the ecological integrity of the lake.

Research Highlights

- Aerial LiDAR point cloud acquisitions provide exceptionally high-quality basemap data for rockfall simulations.
- Detailed mapping of the Santorini caldera slopes offers valuable insights for rockfall risk assessment.

Introduction / Background and Objectives

Rockfalls are among the most common and hazardous types of landslides, posing significant risks to human activities (Notti *et al.,* 2021). They can cause extensive damage to infrastructure, including buildings, roads, and railways, and may even result in loss of life. As tourism continues to expand around the Santorini caldera, attracting millions of visitors each year, assessing rockfall risks becomes increasingly essential (Vassilakis *et al.,* 2024). However, the unpredictability of rockfalls, the complexity of their triggering mechanisms, and the numerous factors influencing their paths make their analysis particularly challenging (Westoby *et al.,* 2020), especially in the aftermath of the seismic sequence in February 2025. Effective rockfall risk assessment necessitates comprehensive data collection and interdisciplinary approaches for detailed analysis and accurate interpretation (Lim *et al.,* 2010). The precision of these interpretations is secured by employing datasets gathered from Light Detection and Range (LiDAR) sensors mounted on aerial platforms, such as unmanned aerial vehicles (UAVs).

On Santorini Island, where tourism is closely linked to the steep slopes of the caldera, the need to analyse highly localized rockfall phenomena has led to a growing demand for extremely high-resolution topographic data, within a relatively short time frame (Jiang *et al.,* 2021). The contemporary technology enables the rapid acquisition of high-density elevation data across large and inaccessible areas, capturing fine-scale topographic details of the caldera cliffs with high slope inclinations, and surface roughness. Consequently, the generation of ultra-high-density point clouds -integrating elevation information and surface colour data- has become essential for developing Digital Surface Models (DSMs) and ortho-photo-mosaics which are essential for simulating rockfall trajectories, determining impact zones, and identifying unstable rock masses. To address this need, we utilized close-range remote sensing data from UAVs alongside high-resolution satellite imagery, both of which have been widely applied in hazard mapping and risk assessment for floods, forest fires, soil erosion, and large-scale landslides, among other hazardous phenomena. In this context, this work aims to tackle the challenges of rockfall assessment, with a particular focus on five locations placed on the steep coastal cliffs of the Santorini Island volcanic complex (Fig. 1a). These are: (i) Ammoudi bay, (ii) Armeni bay, (iii) Thira Old Harbour, (iv) Athinios New Harbour and (v) Korfos bay at Therasia Island.

Methods

During the Santorini-Anydros paroxysmal seismic earthquake sequence of February 2025, during which more than 20,000 earthquakes were recorded, several LiDAR point clouds were collected by a laser scanning system deployed on an Unmanned Aerial Vehicle flying at various altitudes and flight plans, above the steep slopes of Santorini caldera, at the aforementioned locations (Table 1).

A LiDAR sensor employs advanced laser echo technologies to penetrate ground vegetation, regardless of lighting conditions. LiDAR has a natural advantage in surveying regions covered with vegetation since it can partially penetrate the canopy to acquire information about the earth's surface itself. Due to this LiDAR specification, this type of sensor is ideal for outcrops covered by medium density vegetation and therefore essential for not confusing the canopy of small bushes and trees with fallen boulders. By utilizing several filtering algorithms, it accurately detects and classifies ground features, producing extremely precise elevation data. This makes LiDAR point cloud acquisition an essential technique for determining the exact location and key characteristics of rockfalls -among other earth surface deformations- especially for rockfall back analysis, as well as for change detection through multi-temporal surveys (Esposito *et al.,* 2017; Mora *et al.,* 2018; Bernard *et al.,* 2021; Konsolaki *et al.,* 2024).

Figure 1. Index map of Thira volcanic complex with the areas of interest marked with red rectangles (a) and the equipment involved with the LiDAR sensor mounted on the UAV (b).

However, UAV LiDAR surveys have certain limitations, including Network-RTK signal loss (Panagiotopoulou *et al.,* 2022), which can cause decrease of the UAV accurate location during the data acquisition, not to mention increased sensitivity to meteorological conditions, which can cause laser beam scattering. Both of the above could result much difficultness in acquiring accurate target data. Until very recently, the high cost of these highly precise devices also restricted the widespread use of LiDAR for landslide monitoring, in general. Unlike ground-based LiDAR systems, the aerial ones are not limited by terrain constraints and can generate highly accurate data within a short timeframe (Lague *et al.,* 2013; Farmakis *et al.,* 2020).

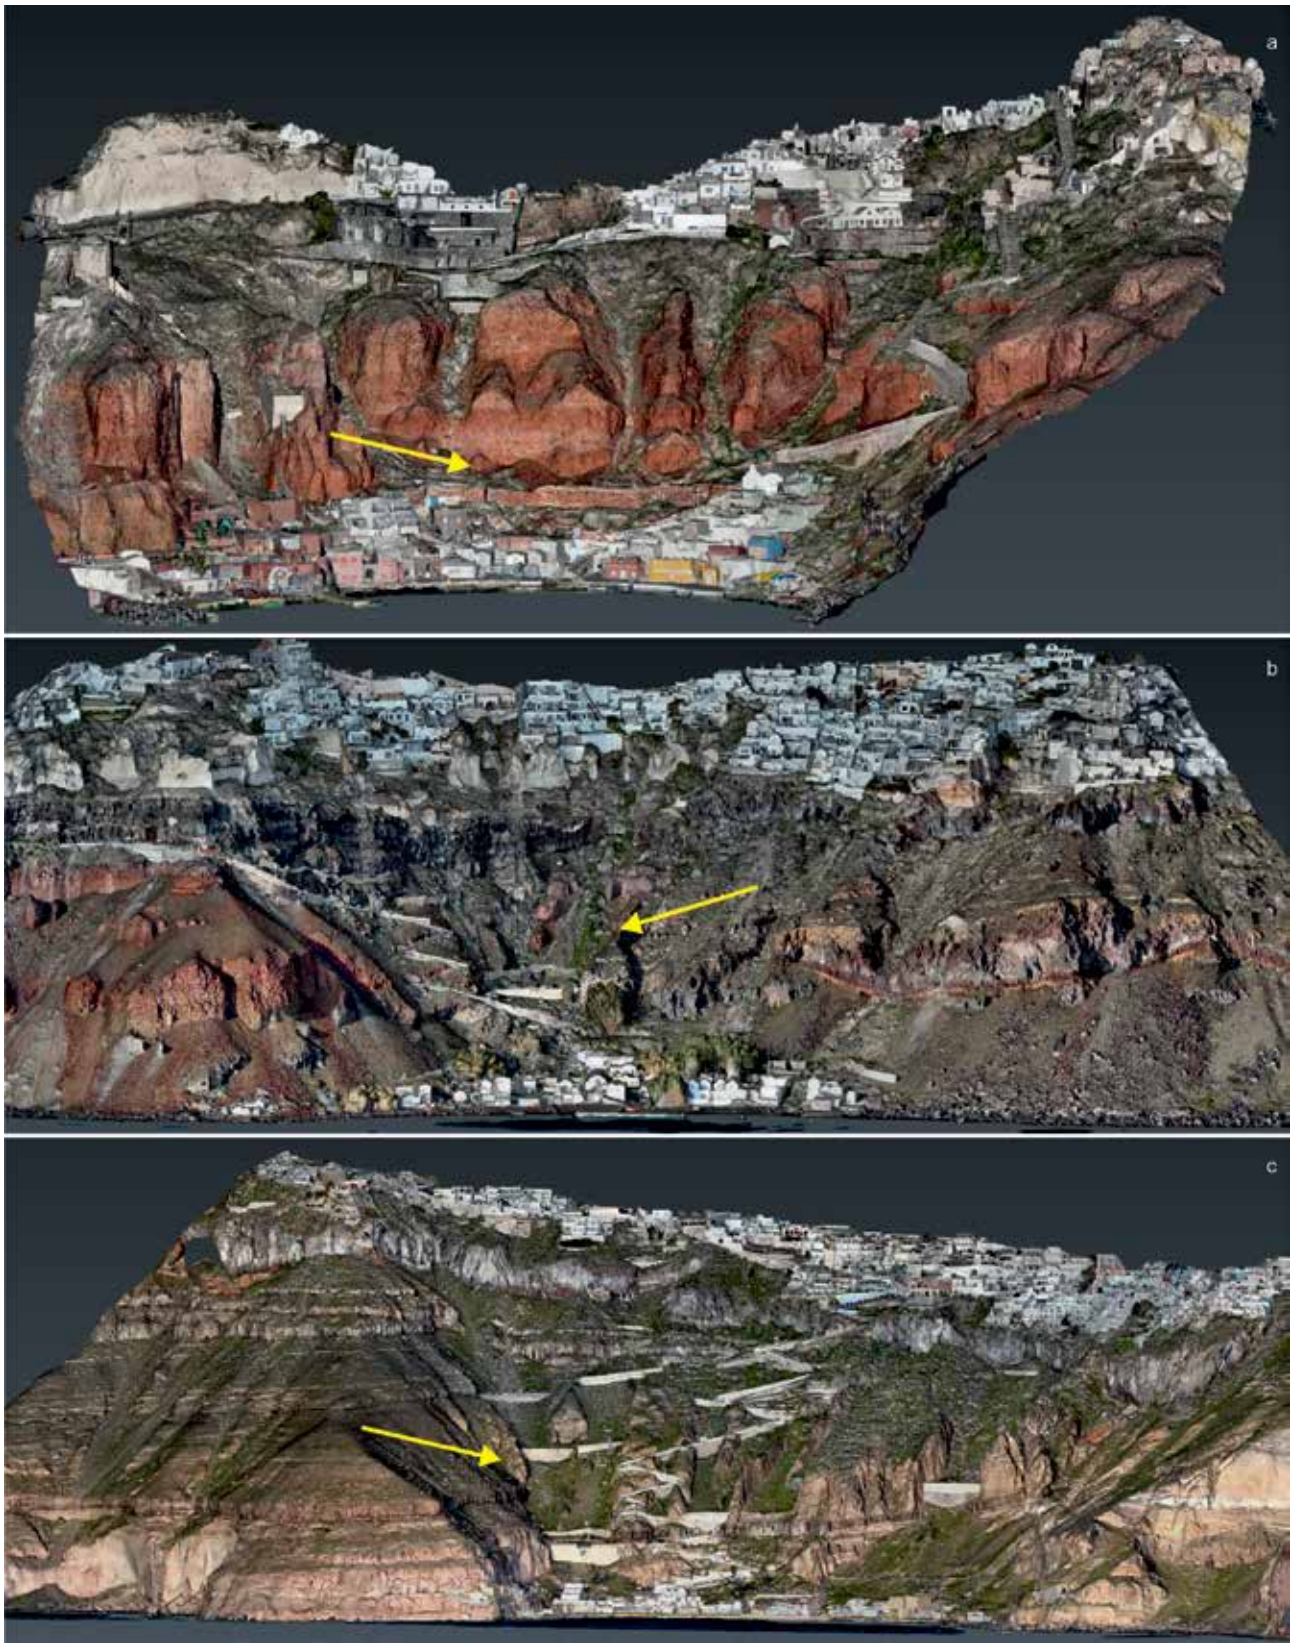

Table 1. Information and specifications of the 5 flights that were carried out during the study.

Area	Take off altitude (m ASL[1])	Flying altitude (m AGL[2])	Aerial Photos	Points of cloud	Point Density (poi/m^2)	DSM Resolution (cm)	Ortho-Image Resolution (cm)	XY Error (mm)	Z Error (mm)
Ammoudi	113	30	802	71,350,599	557	5	2.53	9.07	8.13
Armeni	113	50	325	46,464,874	391	5	2.98	14.99	16.13
Old Harbour	265	45	1,577	223,600,457	568	5	5.18	7.51	6.64

1: Above Sea Level in GGRS'87, 2: Above Ground Level

The equipment we used during this study included a Zenmuse L2 LiDAR sensor mounted on a DJI Matrice 350 RTK UAV (Fig. 1b). On average, the point clouds density reached about 500 data points per square meter. The points were acquired simultaneously with high resolution aerial photographs, which were used for coloring each point of the cloud and produce seamless ortho-photo-mosaics, after photogrammetric processing.

The raw data was processed to remove outliers and noise and used also to generate surface 3D models that were used to inspect previous rockfalls in the study area (Fig. 2). Point cloud classification, Digital Surface Model (DSM) and ortho-photo-mosaic generation for each one of the areas of interest, were performed using DJI-Terra software (v.4.4). The statistics of the processing results show that there was an absolute vertical accuracy of 12.94 mm and a horizontal accuracy of 9.29 mm (root mean square error).

Results – Risk Assessment

The derived datasets were in turn used for the inspection of rock block stability at each one of the five areas, studied within this project. In particular, the geotechnical analysis for the determination of potentially unsafe rock masses was focused on the high-detailed mapping of every single rockfall that happened the recent years. Furthermore, specialized software was used for the simulation of rockfalls in three dimensions, using the constructed 3D models as basal datasets, on which the examination of wedge and plane sliding could be possible and would initiate rock falls at the caldera. The analysis revealed every single rockfall that happened the recent years. Additionally, the efficiency of the already installed measures was examined, and it was rather clear that in most cases they were successfully designed and constructed.

The application of the described methodology, covering the five onshore areas of the island that seem to delineate its most vulnerable parts to rockfalls, proved to be a valuable tool for integrated rockfall simulations and consequently led the way for designing additional reliable safety measures (Toe *et al.,* 2018). Conventional methods, such as mesh and cable nets, as well as barriers -already installed at high-risk locations- could be upgraded or enhanced in certain cases, particularly where recent rockfalls have altered the slope morphology. Furthermore, proposals for new installations have been submitted to local authorities to further mitigate risks in highly frequented areas while maintaining respect for the local environment and simultaneously prevent rocks from reaching manmade constructions.

Conclusions

Understanding rockfall behaviour and evaluating the potential for reactivation necessitate a detailed analysis of the movement patterns of surface materials. As real-scene 3D technology continues to evolve, its applications are expanding across diverse fields, driving a growing demand for greater precision and higher-quality 3D models. In disciplines such as geomorphology and geology, especially in rockfall risk assessment, there is a critical need to develop highly accurate real-scene 3D models.

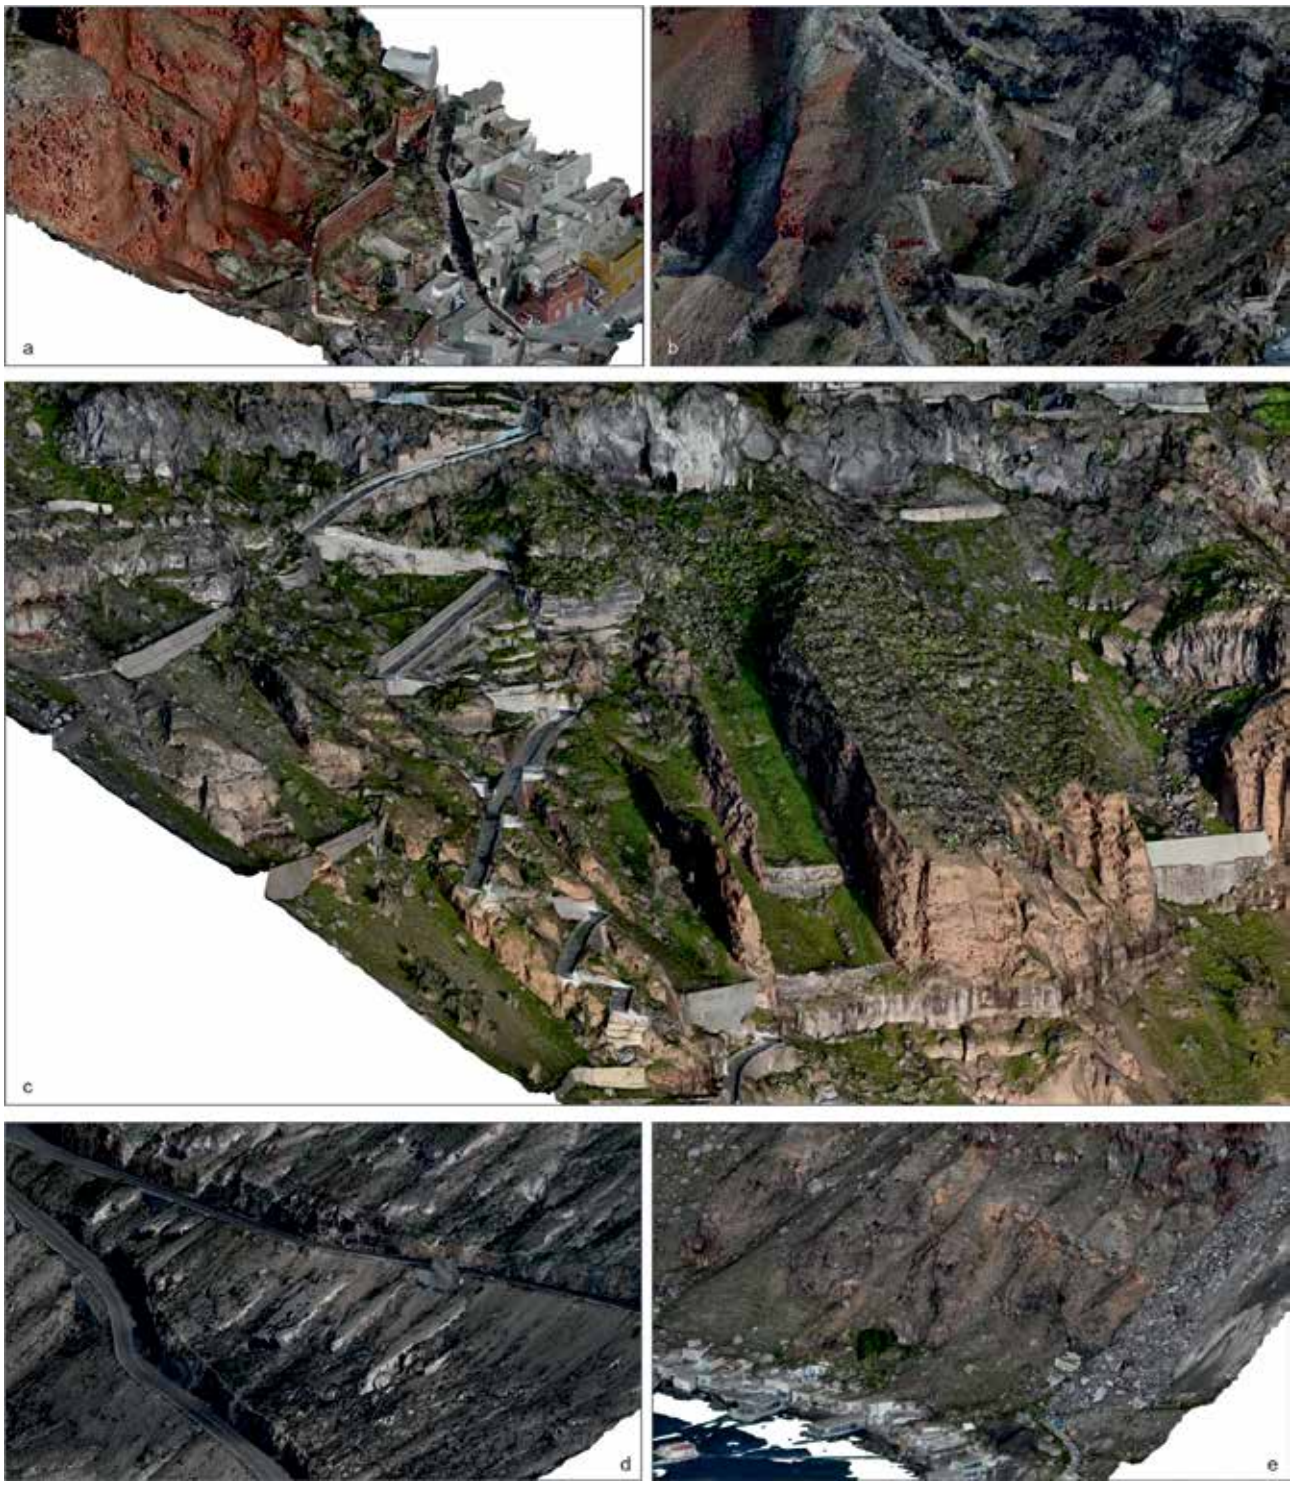

Figure 3. Enlarged images of the five photorealistic 3D models for retaining walls at Ammoudi filled with debris (a), barriers along the path at Armeni (b), retaining walls partially filled with debris below the cable car and other locations upstream the Old Harbour (c), barriers along the road to Athinios (d) and debris upstream Korfos village without any precaution measures (e).

This study presents a novel approach that combines UAV photogrammetry with LiDAR data to achieve high-precision hazard mapping. The proposed methodology follows a streamlined workflow, beginning with field data acquisition using UAV mounted sensors, followed by data fusion that optimally leverages each sensor's capabilities in capturing terrain features. While UAV photogrammetry has limitations in detecting surfaces obscured by dense vegetation

but also confused small trees and bushes with boulders, the processing of LiDAR data that can partially penetrate foliage, can make their integration particularly advantageous. For the selected active rockfall locations, LiDAR and photogrammetric raster images were combined based on terrain characteristics, including vegetation coverage and anthropogenic elements.

The results highlight that integrating data from both sensors enables highly accurate mapping by utilizing the most appropriate technology for each terrain condition, thereby enhancing the analysis of rockfall dynamics and kinematics. The insights gained from this study underscore the necessity of integrating geospatial techniques in steep slopes monitoring. This approach is not only effective in detecting immediate changes but also holds potential for long-term predictions of slope instability. As the Santorini caldera cliffs face increasing environmental and anthropogenic stressors, methodologies like the ones applied in this study would become crucial for proactive hazard management and mitigation efforts. Despite the effectiveness of the proposed method, challenges remain in the semi-automated zoning process, emphasizing the need for advanced machine learning techniques to improve automation and better distinguish between bare ground and vegetation. Future research will focus on refining this approach and conducting continuous, long-term monitoring of the study area, which will continue suffer from rockfalls due to the volcanic lithologies.

In conclusion, the methodology developed here offers a robust framework for future studies and can be adapted to other regions facing similar risks. Ongoing monitoring and refinement of these techniques are essential for improving the predictive capabilities and ensuring the safety of vulnerable touristic environments.

Acknowledgements

The authors would like to express their gratitude to the local authorities (Thira Municipality, Coast Guard, Santorini Cable Car) for their assistance during the field work and E.P.P.O. for providing financial support for the field work of this project.

Scaling Relations Between Earthquake Magnitude and Source Duration with Applications to Greece

N. Vavlas[1], A. Kiratzi[1]

(1) Aristotle University of Thessaloniki, Thessaloniki, Greece, navavlas@geo.auth.gr; kiratzi@geo.auth.gr

Research Highlights

The engineering significance of earthquake source duration lies in its direct impact on the design and safety of structures, earthquake engineering, and seismic hazard assessment. This research, while focusing on global datasets, provides essential insights into how seismic source parameters can be scaled and interpreted across varying depths and faulting mechanisms.

Introduction

Earthquake magnitude is commonly linked to parameters describing fault geometry (rupture length, width and area) by empirically obtained scaling relations (Papazachos *et al*., 2004; Somerville, 2021; Thingbaijam *et al*., 2017; Wells and Coppersmith, 1994). They are fundamental for estimating rupture dimensions from earthquake magnitudes, or conversely, predicting the maximum potential magnitude based on fault characteristics. Such estimates are vital for seismic hazard assessment and engineering applications.

Here we focus on the connection between moment magnitude (M_w) and the source duration (t_d) of an earthquake (e.g., Courboulex *et al*., 2016; Ekström *et al*., 1992; Ekström and Engdahl, 1989; Furumoto and Nakanishi, 1983; Kanamori and Given, 1981; Singh *et al*., 2000; Somerville *et al*., 1999). The source duration of an earthquake refers to the time over which seismic energy is released by the fault rupture. A longer source duration typically correlates with sustained ground shaking, which can influence the way buildings and infrastructure respond to the earthquake, specifically in the near field. In engineering terms, a longer shaking duration can result in: (a) increased structural damage, as structures may suffer more extensive damage if the shaking lasts longer, particularly those with resonant frequencies close to the earthquake's frequency content and (b) Nonlinear behaviour: Prolonged shaking increases the likelihood of materials undergoing nonlinear deformations, such as cracking or liquefaction, which can undermine the structural integrity of buildings and infrastructure.

In terms of seismic hazard models, the contribution of having relations to calculate the source duration from the magnitude is significant, because the likelihood of ground motion over an extended period, can be critical for critical infrastructure as hospitals, bridges, dams, storage sites, schools, pipelines among others. Moreover, longer duration shaking in soft soils can lead to amplified ground motion and increase the likelihood of structural damage. In areas where induced seismicity is a concern, such as regions with Carbon Capture and Storage (CCS) or hydraulic fracturing activities, source duration provides insight into the potential for long-duration events that may affect infrastructure over extended periods and helps inform the monitoring and management of such activities.

It is often suggested that source duration scales with seismic moment as $t_d \propto (M_0)^{1/3}$, assuming constant static stress drop (Δ_σ), and constant rupture velocity (V_R) (e.g., Duputel *et al*., 2012; Ekström *et al*., 2005; Furumoto and Nakanishi, 1983; Kanamori and Brodsky, 2004; Singh *et al*., 2000). The above studies have also indicated that the ratio between td and $(M_0)^{1/3}$ can vary with seismogenic region or when different global datasets are used. The satisfaction of the above with invariant Δ_σ and V_R implies that there is source similarity, that is to say, a predictable scale-invariant pattern exists for all earthquakes. However, the question of whether earthquakes truly scale self-similarly remains open as several studies (e.g., Mayeda *et al*., 2007; Malagnini *et al*., 2008; Mayeda and Malagnini 2010; Denolle and Shearer 2016; Poli and Prieto 2016; Morasca *et al*., 2019) challenge this and suggest that earthquakes may not always follow a self-similar behavior.

Data and Methods

Two empirical approaches were used to relate M_w to t_d were adopted. The first one utilizes centroid time-delays as proxies for source durations (t_d), following the methodology established by Duputel *et al*. (2013). The global dataset of the authors as reported in their original paper was used, consisting of 798 global earthquakes from 1991 to 2012 with magnitudes ranging from 6.3 to 9.2, and depths up to ~650km (top panels of Figure 1).

The second dataset includes directly measured t_d values from the global Source Time Function (STF) database of SCARDEC (from Seismic source ChAracteristics Retrieved from DEConvolvolving teleseismic body waves; Vallée and Douet, 2016). It includes 3,950 earthquakes from the period 1992 to 2022, with magnitudes ranging from approximately 5.5 to 9.0, spanning all depths and faulting styles lower panels of Figure 1).

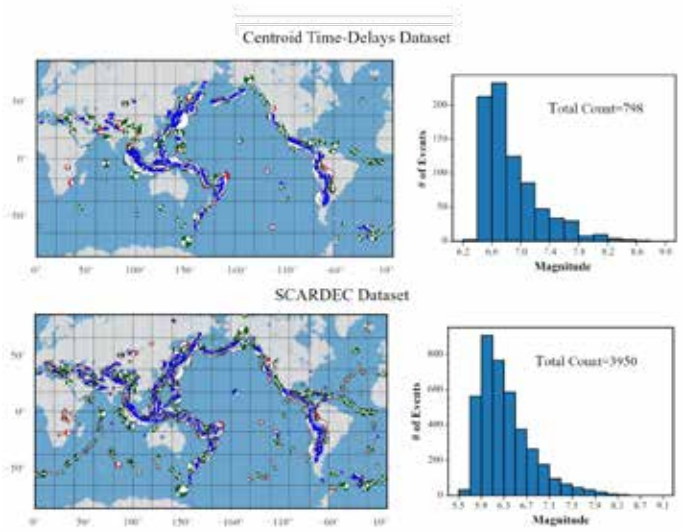

Figure 1. The two global datasets utilized in this work: Top panels show the focal mechanism dataset of Duputel *et al*., (2013), with faulting type percentages of 44% for reverse, 42% for strike-slip, and 15% for normal faulting. Bottom panels show the SCARDEC database of source time functions, with color-coded focal mechanism beachballs in map view. The colors represent the faulting types: green for reverse faulting (46%), blue for strike slip faulting (36%), and red for normal faulting (18%).

Source Durations from Centroid Time-Delays

Centroid time-delay (τ_c) is defined as the time difference between the earthquake's hypocenter origin time (t_o), and the centroid time (t_c), which represents the point in time when the best-fitting point source is located, thus ($\tau_c = t_c - t_o$). Centroid time, t_c is routinely calculated during Global Centroid Moment Tensor (GCMT) inversion, which also determines the centroid's geographical coordinates and depth.

In the GCMT inversion, the Source Time Function (STF) of an earthquake is modeled as a symmetric triangular function (Figure 2[a]). The centroid time (t_c) corresponds to the peak of this triangle, while the half-duration (t_h) is derived from an empirical relationship with respect to seismic moment (M_0). Therefore, τ_c is more reliably constrained compared to t_h, and doubling it leads to a reasonable proxy for the source duration (t_d):

$$t_d \approx 2\tau_c \quad (1)$$

The examined dataset of Duputel *et al*. (2013) includes centroid time-delays from both the GCMT inversion and the W-phase source inversion algorithm (WCMT). The geometric mean of these two values was computed, resulting in data pairs of M_w and t_d that were later used in a regression scheme.

Source Durations from the SCARDEC Source Time Function Database

The SCARDEC database estimates the source time function (STF) of an earthquake using teleseismic body-wave deconvolution. For each event, it reports both average and optimal STFs. The "apparent" STF is derived by deconvolving synthetic point-source waveforms from observed recordings, reflecting the azimuthal dependence of the STF. It is influenced by the varying radiation of seismic energy to different stations, which may incorporate effects from both the source process and wave propagation through the Earth.

The average STF represents an aggregation of high-quality P-wave apparent STFs, providing a global perspective of the earthquake source. This averaging minimizes biases in the overall shape of the STF, as directivity effects are generally modest for teleseismic P waves. However, this process may smooth out high-frequency details that are significant in spectral analyses. To address this, an optimal STF is chosen for its similarity to the average STF and its ability to produce a good fit between synthetic and observed waveforms when convolved with point-source synthetics. Using the average STFs, the start and end times of moment release were determined (Figure 2[b]). The time difference between these two instances was used to estimate the source duration, t_d which in combination with the M_w values reported in the database, produced (t_d, M_w) regression pairs.

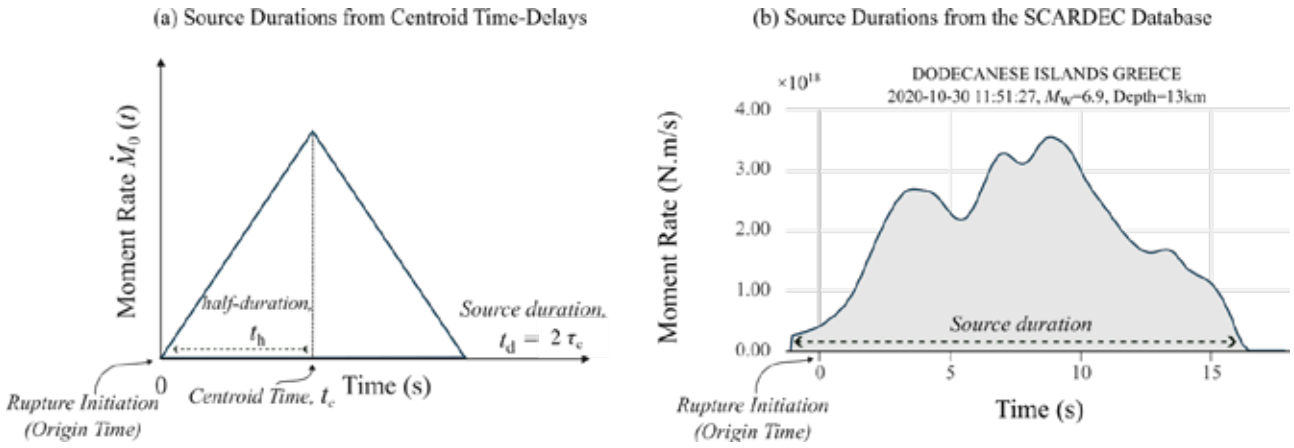

Figure 2. Source duration (t_d) of earthquakes as obtained from: (a) the isosceles triangular Source Time Function (STF) used in the GCMT inversion. The centroid time, t_c, is defined as the point in time where the peak of the STF is observed (clearly coincides with the top vertex of the triangle) and expresses the point in time where the best fitting centroid is located. Since the source is assumed to have a symmetrical STF, doubling the centroid time-delay (τ_c) yields the total source duration t_d. (Duputel *et al.*, 2013). (b) The source duration as obtained from the STFs included in the SCARDEC database, where t_d can directly be measured (an example is shown here).

Results: Analysis of Scaling Relationships

To investigate the scaling relationship between earthquake magnitude and source duration, we performed linear regression analyses on two key datasets: the centroid-time delays dataset for half-durations (τc) and the SCARDEC Source Time Function (STF) dataset for source durations (td). These datasets were further segmented based on faulting mechanisms and seismic depth to explore regional and structural variability in scaling behavior.

Separate regressions for shallow (≤60 km) and deep (>60 km) events, as shown in Figure 3, reveal a clear distinction between the two depth categories. Deep earthquakes exhibit shorter source durations, consistent with theoretical models like the Brune circular crack model (1970, 1971), which predicts faster moment release for deeper events. Specifically, shallow events have a longer mean duration of 14.3 seconds and higher intercepts, while deep events show a shorter mean duration of 6.7 seconds. This trend supports the hypothesis that deeper earthquakes, experiencing higher stress conditions at depth, release seismic moment more rapidly than their shallow counterparts.

A comprehensive analysis of potential variations in scaling relationships based on faulting mechanisms (e.g., strike-slip, normal, or reverse) revealed no significant dependence on these parameters. This suggests that, regardless of faulting style, the scaling between moment magnitude (Mw) and source duration (td) holds consistent, providing a robust method for estimating earthquake source durations based on magnitude alone. Such relationships are critical for improving seismic hazard models, as they allow for more accurate predictions of ground shaking in regions with limited seismic data.

Furthermore, we examined the regional applicability of the centroid-time delays dataset by focusing on a subset of Global Centroid Moment Tensor (GCMT) data for Greece (19°–30°E, 33.5°–42.5°N), which included 667 earthquakes from 1976 to 2020, with magnitudes ranging from 4.6 to 7.6 and depths extending to 160 km. The Greek dataset exhibited substantial scatter, particularly for earthquakes with magnitudes smaller than Mw 6.5. This scatter is likely attributed to the limited range of magnitudes, coupled with the smaller number of larger magnitude events, which hindered the development of a reliable scaling relationship within this subset alone.

To improve the analysis, the Greek dataset was supplemented with larger magnitude events from global datasets. This inclusion resulted in a more discernible trend with a high linear correlation coefficient of 0.81, suggesting that a broader dataset improves the robustness of the scaling relationship. However, the applicability of this scaling behaviour to smaller magnitude events within this specific region remains uncertain. The higher variability observed in lower-magnitude events could be due to increased uncertainty in the origin time and centroid time estimates, as well as the absence of stronger (Mw ≥ 6.3) earthquakes that might help better define the scaling trend.

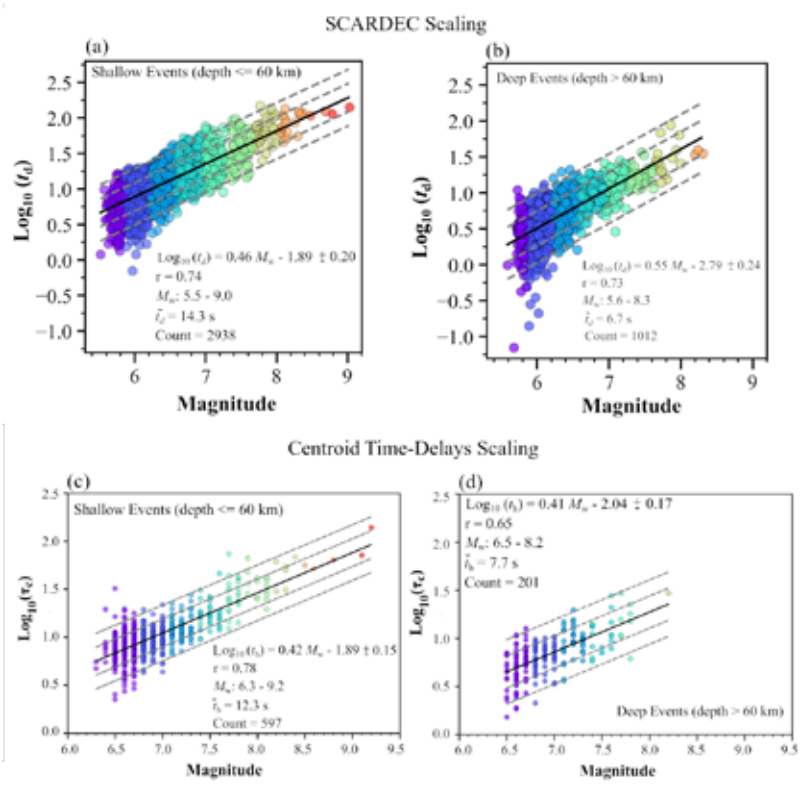

Figure 3. Linear regression between earthquake magnitude and the logarithm of source duration based on source time functions from the SCARDEC database for shallow (a) and deep events (b). (c, d) Show analogous regressions for earthquake half-duration, using the centroid time-delay dataset.

Discussion and Conclusions

In this work, the scaling between earthquake moment magnitude, M_w and source duration, t_d, was examined, using two distinct datasets, to assess variability across depths and focal mechanisms. While for different faulting styles, slight differences were noted among normal, reverse, and strike-slip faulting (not presented herein), notable differences were observed across earthquake depths, with deeper earthquakes exhibiting shorter source durations across both datasets, implying more rapid moment release.

Using the herein obtained scaling relations, for the generic cases (no constraints on focal mechanism or focal depth), we created a catalog of source durations for earthquakes in the Greek region, for both historical and instrumental events (Figure 4), to gain an overview on their spatial distribution and their statistical distribution. Note that these two distributions are not equivalent, as the relationships were applied only within their valid applicability range.

Table 1 summarizes the scaling coefficients and regression parameters for all the scaling relationships presented in this work. The regression formula is given by:

$$log_{10}(t_d) = b\,M_w + a \pm \sigma \qquad (2)$$

where *a* and *b* are the regression coefficients and σ represents the regression error.

Table 1. Coefficients from linear regressions (Eq. 2) between source duration (t_d) and moment magnitude (M_w). For the centroid time-delay datasets, regressions presented below were conducted for double the half-duration ($2\tau_c$) which equates to the source duration (t_d) and allows a direct comparison between the relationships.

Dataset	b	a	σ	r	Mag. Range	Count
Centroid Time-Delays (Generic)	0.42	-1.61	0.17	0.71	6.3–9.2	798
Centroid Time-Delays (Shallow)	0.42	-1.59	0.15	0.78	6.3–9.2	597
Centroid Time-Delays (Deep)	0.41	-1.74	0.17	0.65	6.5–8.2	201
SCARDEC (Generic)	0.48	-2.11	0.26	0.66	5.5–9.0	3950
SCARDEC (Shallow)	0.46	-1.89	0.20	0.74	5.5–9.0	2938
SCARDEC (Deep)	0.55	-2.79	0.24	0.73	5.6 – 8.3	1012

*Note: *Generic scaling relationships involve no constraints on depth; shallow refers to depth ≤ 60 km; deep refers to depth > 60 km.*

The scaling relationships derived in this study enable the retrospective prediction of source durations for historical earthquakes. For instance, the source durations for the very strong earthquakes of 365 and 1303 CE, shown in Figure 4, were estimated based on the established scaling relations. This predictive capability holds particular significance for earthquake early warning systems. Building upon previous work (Vavlas *et al*., 2021), we demonstrate how these scaling relationships can be utilized to estimate early warning timelines for hypothetical earthquake scenarios. These estimations rely on the symmetry often present in Source Time Functions (STFs) and account for factors such as the spatial density of monitoring networks, rates of ground motion attenuation, and other relevant theoretical considerations.

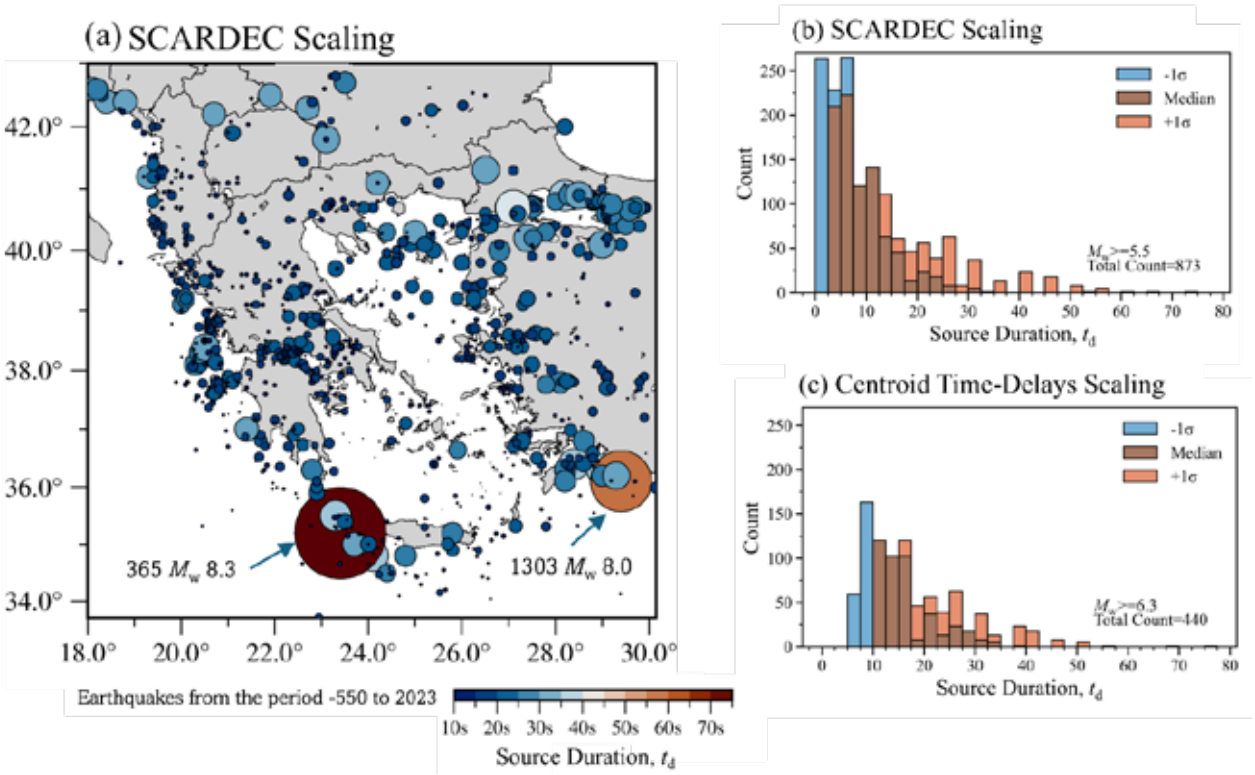

Figure 4. Spatial and Statistical Distribution of Source Durations. (a): Distribution of source durations of historical and instrumental strong earthquakes derived using the generic scaling relationship from the SCARDEC STFs. The map shows earthquake epicenters color-coded by source duration (t_d) and circle-size proportional to magnitude. (b) Frequency distribution of source durations (t_d) based on the median prediction of the scaling relationship, including a range of values corresponding to one standard deviation above and below the median. (c) Similar (b) but derived from the generic scaling relationship of centroid time-delays. All calculations were made for earthquakes with magnitudes above the lower applicability limit of each scaling relationship and adopting the generic regression case, i.e., no constraints on depth or faulting mechanisms.

This workflow allows the estimation of early warning timelines for customized scenario earthquakes, considering the spatial density of monitoring networks, the attenuation of ground motion with distance, among other theoretical factors. The above processes have been containerized and can be applied to provide warning timelines for critical infrastructure from scenario earthquakes from induced seismicity or from scenario earthquakes from seismic hazard disaggregation.

EXTENDED ABSTRACT 344

Microseismicity Monitoring of the Broader Stypsi Geothermal Field Area (Northern Lesvos Island, Greece) Using a Local Seismological Network

Ventouzi Ch.[1], Papazachos C.[1], Kkallas Ch.[1], Spyridonos, E.[2]
(1) Aristotle University of Thessaloniki, Thessaloniki, Greece, xrusven@geo.auth.gr, (2)PPC Renewables S.M.S.A., Athens, Greece

Introduction

The broader Stypsi region, located in NW Lesvos, Greece, has attracted significant interest as an area of high geothermal potential. Understanding the microseismicity of geothermal areas is crucial for the evaluation of their geotectonic setting and associated active stress field prior to any resource exploitation. Moreover, there have been cases where induced seismicity has been attributed to geothermal energy exploitation (e.g. Woo et al., 2019). As a result, the monitoring of microseismicity in such areas has attracted the attention of both industry and society.

The present study focuses on the installation and operation of a dense local seismic network in the previously mentioned area of particular interest. Data from this local, as well as permanent seismological networks are employed and processed with recently developed machine learning methods, to enhance the resolution of seismicity analysis. The results verify that the current permanent network of seismological stations (Hellenic Unified Seismological Network, HUSN) is not able to detect the background microseismic activity, as well as the seismic sequences generated by relatively small magnitude earthquakes. This is clearly demonstrated in the present study, where for the operation time of the local network only 1/10 of the manually located events were identified by HUSN, even though the same detection algorithm was employed. The obtained results are in agreement with the dominant trans-tensional seismotectonic regime of Lesvos, with most events being associated to normal and strike-slip faults, revealing a roughly N-S extension. We also present results from the use of a deep learning model (SEISBENCH toolbox), which managed to detect a very large number of events (~6000 events-initial determination) that were missed by the conventional STA/LTA detection algorithms of the acquisition software currently used (Seiscomp). The results suggest that the combination of dense local network of seismological stations, with novel machine learning techniques can provide significantly improved results regarding microseismicity monitoring in similar environments.

Figure 1. Map of the current N Lesvos (FDSN code 4H) local network (yellow squares). Station LES5 has been relocated to LES5N. The region of interest for possible future geothermal exploration is depicted by two (2) polygons.

Data and method

A surface network of five (5) high-sensitivity 24-bit mid-range (10s-98Hz) seismographs was installed in October 2023, as depicted in the map of Figure 1. The FDSN code 4H (2023) has been assigned to this network for future reference (see https://www.fdsn.org/networks/detail/4H_2023/). Since October 16, 2023, all data for these seismological stations are collected on a dedicated server, using the Seiscomp software (https://www.seiscomp.de/). This open-source software has become the “golden” standard for similar work, used by almost all European networks, as well as the Hellenic Unified

Seismological Network. The software and its tools allow easy data visualization, as well as the necessary data processing and event analysis. It provides automatic and interactive seismological data acquisition, processing, and data exchange over the internet by using the SeedLink transmission protocol. Since the database creation is performed, seismic events within ~15km from the area of interest were identified using an automatic detection algorithm employed by Seiscomp, for event identification and preliminary relocation. After the initial automated determination of earthquake epicenters, a manual analysis of all seismic events has been conducted by manually picking P and S phases. This was initially performed using the advanced NonLinLoc location code (http://alomax.free.fr/nlloc/, (Lomax *et al.*, 2000) embedded in Seiscomp, as well as a 1D velocity model extracted from the 3D tomographic model of Papazachos and Nolet (1997). To discriminate local events from regional seismicity, a large number of real-time regional neighboring stations from the Hellenic Unified Seismological Network (HUSN), as well as from Turkish stations (Kandili Observatory) have been included in the acquisition. Magnitudes for all recorded events were estimated using the local magnitude M_L, as calculated using the Hutton and Boore (1987) relationship, which uses the maximum trace amplitudes recorded on standard Wood-Anderson horizontal seismometers. For events with larger magnitudes (eg. $M_L \geq 1.9$), if the first motions of P waves were clearly recorded by more than 4 stations (typically more, using regional stations), a focal mechanism of the earthquake was also calculated using the approach offered by the Seiscomp software.

From the beginning of the network operation (October 16, 2023) until January 10, 2025, 1044 events have been manually picked and relocated within the broader region of the study area. Figure 2 presents a map of the local seismicity recorded by the N. Lesvos local monitoring network, as well as from the Hellenic Unified Seismological Network (HUSN) and Turkish stations (Kandili Observatory). Events with $M_L < 1.0$ are shown as black dots, while yellow circles show events with magnitudes $1.0 \leq M_L < 2.0$ and light green circles represent earthquakes with magnitudes $2.0 \leq M_L < 3.0$. In the legend red circles illustrate events with magnitude $3.0 \leq M_L < 4.0$ and white star events with $M_L \geq 4.0$. While such magnitude events were not recorded during the operation of the Lesvos local monitoring network (maximum recording magnitude of $M_L = 3.9$), on January 21, 2025, a $M_L = 5.1$ earthquake occurred in the coastal area of Efthalou and Sikaminea. In Fig. 2 we also present information (black lines) for all known active faults in the broader Stypsi area, as provided by the tectonic map of Stypsi-Lesvos by the Department of Geography of the University of the Aegean (compiled by Prof. Zouros and colleagues), while the light-green ones depict possible faults. The regions of interest for possible geothermal exploration are depicted by two (2) polygons, while green squares and blue triangles depict existing boreholes performed by the Greek PPC Renewables. We also show the seismological stations of the local N. Lesvos monitoring network. The dashed circle indicates a region with a radius of 15km centered around the network area, where quantitative calculations (i.e., Gutenberg-Richter distribution) were performed for the study area. Figure 3 presents the seismicity recorded over the 15-month operational period of the network, during which only 155 earthquakes were located by HUSN (Combined earthquake catalog generated from the online catalogues of the Aristotle University of Thessaloniki and the National Observatory of Athens, Institute of Geodynamics, Athens).

As can be seen from the map of Figure 2, the majority of the events is clustered in the Northern part of Lesvos, mainly in the areas of Efthalou, Lepetymnos and Sikaminea, with magnitudes $2.0 \leq M_L < 3.0$, roughly at a 6km distance to the NE from the Areas of Interest (AoI). In this area we observed a prolonged seismic excitation (seismic swarm), lasting several hours, on the 19th of August 2024, starting from about 02:00PM until 13:00 AM (GMT). 118 events from this swarm have been relocated, revealing an almost E-W trend for the corresponding seismicity distribution. A second seismic sequence was recorded in the same area of the previous excitation, where a $M_L = 3.9$ earthquake occurred on 27 October 2024 16:56:01 local time, ~1km North of Argennos and to the NNW of Lepetymnos village. This event corresponds to the largest one recorded since the beginning of the operation of the local network. This led to a sequence requiring the manual relocation of almost twice the number of the events located since the beginning of the network operation, since in the previous trimester the number of the events of the catalog was ~600 and this number increased to ~1050 until January 10th of 2025. In just two days after the $M_L = 3.9$ earthquake, 204 earthquakes were manually picked and relocated in the same area. After the third day, the number of the events recorded returned to “normal” (background) levels. The spatial distribution of the events located by the October 27-30, 2024, seismic sequence indicates a WNW-ESE trend, similar to the August 19th excitation. In the marine area of Stypsi gulf, a few kilometers (~5km) to the east of the areas of interest, a few lower magnitude events $1.0 \leq M_L < 2.0$ occurred. In the same region, the second largest event recorded to date had magnitude $M_L = 3.3$ occurred on 2024-09-15. For the whole area of interest, only one event with magnitude $M_L < 2.0$ has been recorded within 15 months since the deployment of the local network, while only two earthquakes with magnitude $2.0 \leq M_L < 3.0$ have occurred nearly ~2km outside of the area of interest (on land). Almost ~2.3km to the NNW, in the marine area of Mythimna, three earthquakes with magnitudes $2.0 \leq M_L < 3.0$ have occurred, and several others with lower magnitude for the last 3-month period. The difference in the number of earthquakes recorded by the local network compared to those identified by the permanent seismograph network is striking. This difference is mostly pronounced for earthquakes with $M < 2.0$, underlining the necessity of the installation of local networks in areas of special interest.

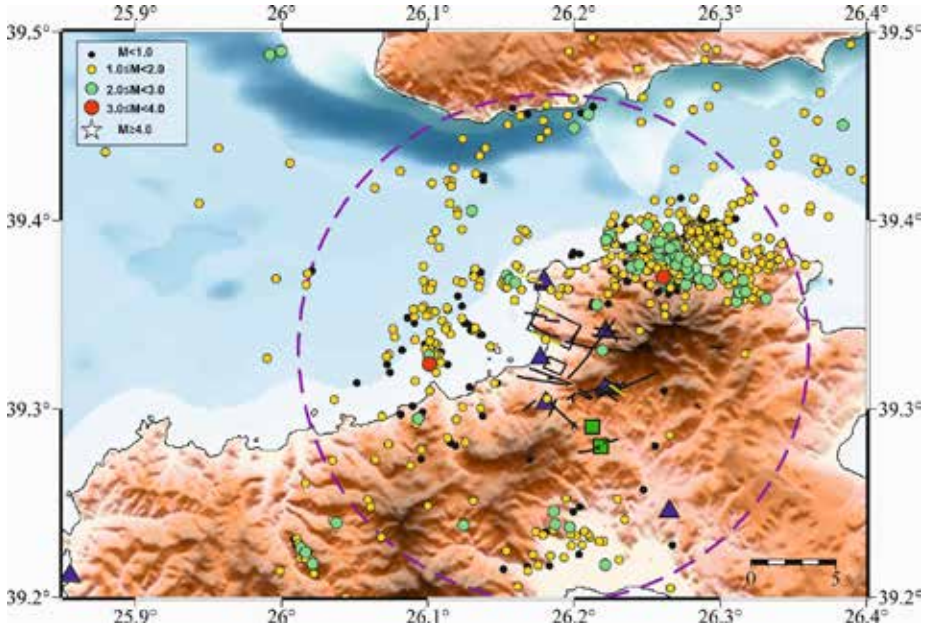

Figure 2. Map of the recorded seismicity for the study area of N. Lesvos for the period of 16 October 2023-10 January 2025 (15 months of local network operation). Blue triangles indicate the operating seismological stations of the N. Lesvos local monitoring network, as well as regional stations (PRK and SIGR), while green squares depict exploration boreholes performed by PPC Renewables. The two black polygons indicate the regions of interest for possible geothermal exploration. Black and light green lines show the active faults and the possible faults, respectively. The dashed circle indicates the area of 15km radius, for which the quantitative seismicity assessment was performed.

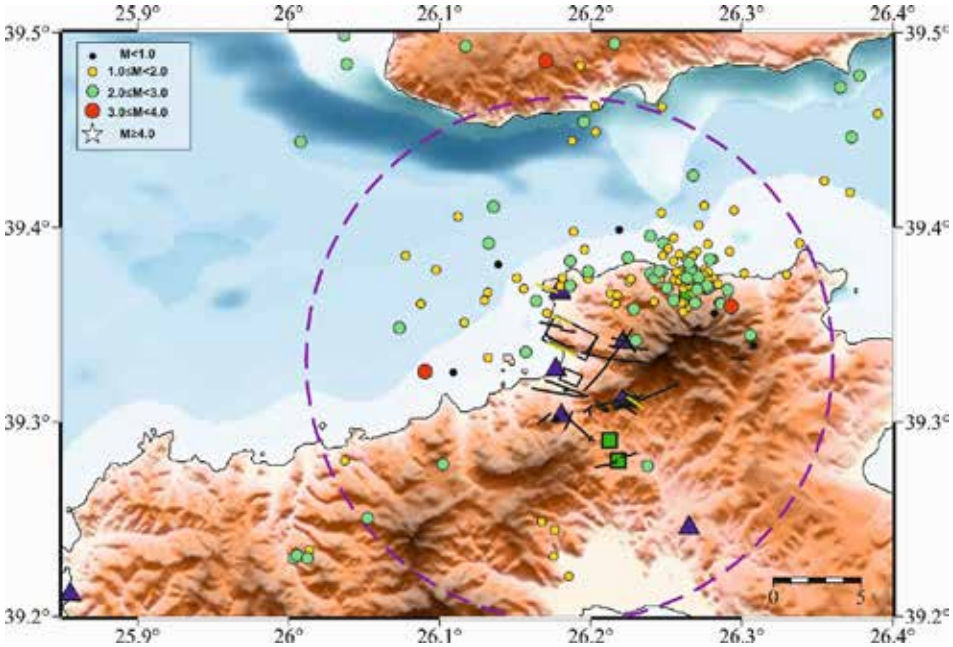

Figure 3. Same as figure 2, depicting the seismicity recorded for the study area by the Hellenic Unified Seismological Network (HUSN).

Figure 4 presents the focal mechanisms which were calculated, whenever possible (clear first motions of P-waves), for earthquakes with magnitudes $M_L \geq 1.9$. Black beach balls represent focal mechanisms associated with normal faults, red beach balls represent focal mechanisms of strike slip faults, while blue beach balls represent focal mechanisms of thrust faulting. The regions of Lepetymnos and Sikaminea are dominated by strike-slip focal mechanisms, while the Efthalou region shows mostly normal focal mechanisms. Focal mechanisms for earthquakes with magnitudes $M_L < 1.9$ were also calculated in some cases but are not shown in the map of Figure 4, as they were prone to very large errors. The largest event recorded with magnitude $M_L = 3.9$, shows a strike-slip fault plane solution, as depicted in the map of Figure 2.3 with the largest red “beach-ball”.

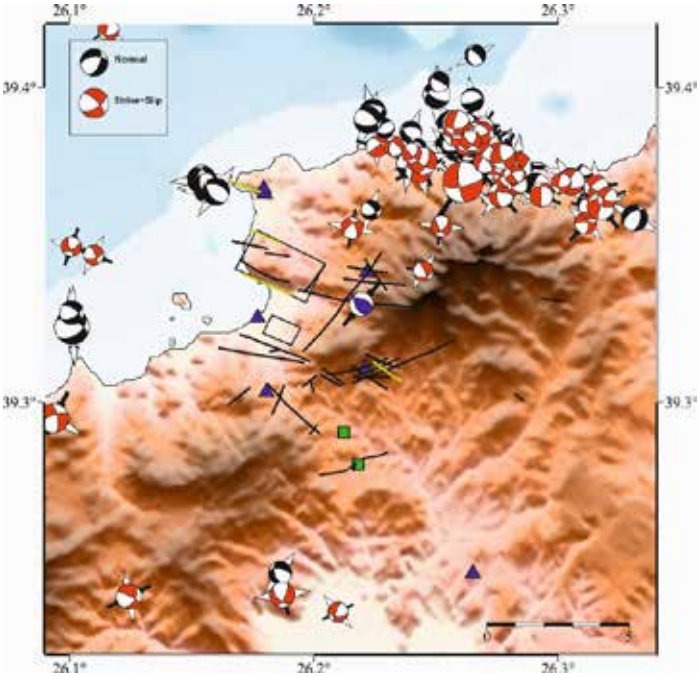

Figure 4. Focal mechanisms calculated for the study area for the 15-month operational period for earthquakes with magnitude M_L≥1.9. Black beach balls depict normal focal mechanisms, blue ones correspond to thrust mechanisms, while red ones indicate strike slip focal mechanisms. All other symbols are the same as in Figure 2.

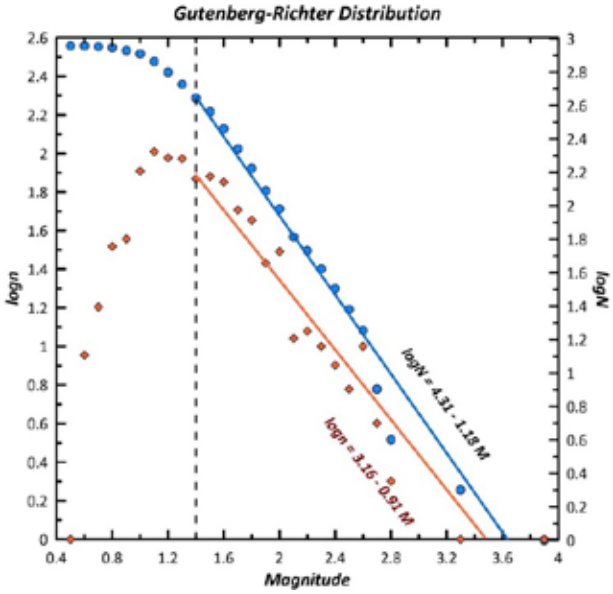

Figure 5. Magnitude distribution of the earthquakes recorded by the local N. Lesvos network within 15km radius from the areas of interest for the time period of 16 October 2023 to 10 January 2025. Red symbols and best-fit line are derived from the number of events recorded at the time period with the corresponding magnitude, M_L, while blue symbols and line depict the cumulative number of earthquakes with magnitude equal or larger than M_L that occurred in the same area. The dashed line indicates the completeness magnitude of the catalogue for the study region (M_L~1.4), while the b value is determined to be ~0.91 (red fonts equation for the number of earthquakes, n, with magnitude, M).

To quantitatively describe the distribution of earthquake magnitudes in this region, the Gutenberg and Richter (1944) distribution was calculated in order to obtain a frequency-magnitude relation of the form:

$$\log N_t = a_t - bM \quad (1)$$

where N_t is the number of events with magnitude M or larger that occurred in a t-years period of time within the examined seismogenic region. a_t and b parameters are calculated by the data, provided that they are homogeneous and complete. We have estimated the Gutenberg-Richter distribution for the 15-month operational period, within a radius of 15km around the areas of interest. Figure 5 presents the G-R graph for the cumulative number of events in N. Lesvos, where $\log N_t$ is plotted against the local earthquake magnitude, M_L. We also present the distribution of **n**, which indicates the number of earthquakes with the same magnitude (rounded to 0.1 magnitude units). The dashed line shows the indicative completeness magnitude for the study area of the 15km radius, which is $M_L \simeq 1.4$. Both considered relationships correspond to equation (1), with the red solid line in Figure 5 denoting the number of earthquakes against magnitude and the black one depicting the cumulative number of earthquakes against magnitude.
Since in our case, no earthquakes of magnitudes larger than M_L=3.9 have occurred, affecting the cumulative magnitude distribution, we consider as more reliable the relationship derived by logn, which is not suffering from the lack of larger events in the (relatively small) time-period examined. For the study area, the b value of the G-R distribution is 0.91 as shown in red in Figure 5 below. This b value is larger than the b value determined by Papazachos (1999) from regional 20th century instrumental data, who calculated a value of b ~0.75-0.83 for the North Aegean region. While b-value variations are often prone to over-interpretation, we believe that thus bias is probably due to the absence of strong seismicity in the study area during the recording period.

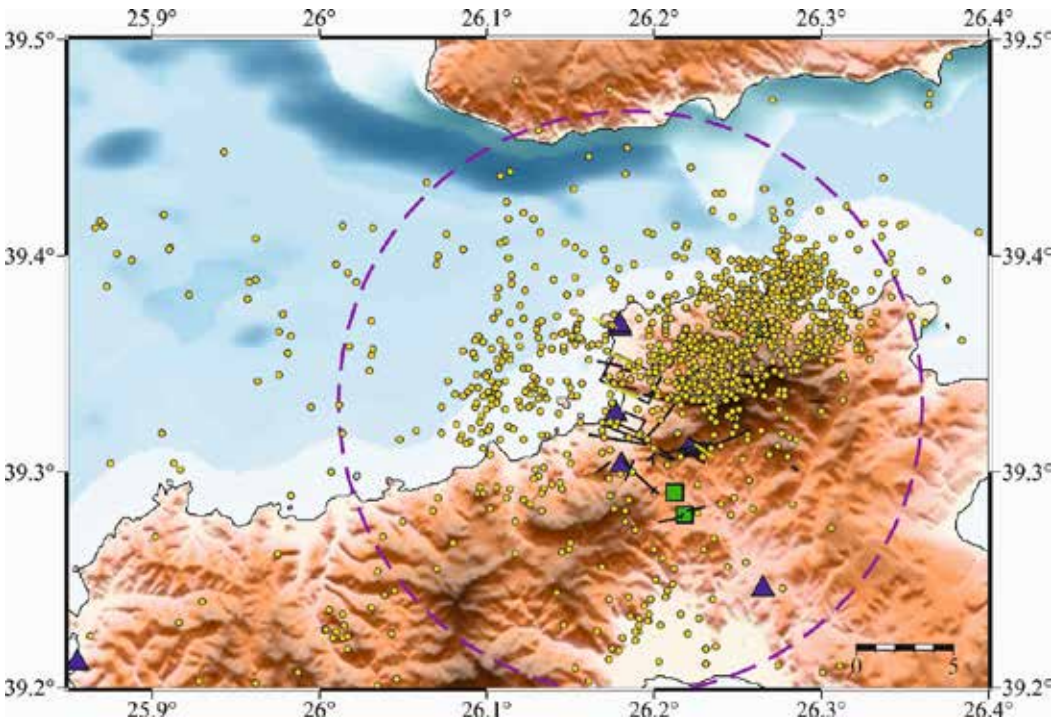

Figure 6. Seismicity distribution using SeisBench toolbox with EQTransformer. Only events with RMS<0.35, ERH<5km and ERZ<10km are shown.

To improve the network detectability, we also employed the SeisBench software, which is an open-source Python toolbox designed to facilitate machine-learning applications in seismology. The interface provided by SeisBench toolbox for accessing seismic datasets and deploying machine learning models makes it easier to integrate advanced algorithms into the seismic analysis workflow (Woollam *et al.*, 2022). More specifically, we have employed EQTransformer, a deep learning model available in SeisBench toolbox, well known for its effectiveness in earthquake detection and phase picking. With an architecture based on a deep neural network with an attention mechanism, EQTransformer has been trained on the global seismic data, to enable detection and picking arrival times simultaneously and efficiently (Mousavi *et al.*, 2020). We modified SeisBench toolbox to include data recorded by the local network and HUSN stations and defined new a seismic event when a minimum number of 10 seismic phases was identified as belonging to the same earthquake. The detected phases were then processed using the HypoInverse (Klein, 2002) software, using the same

local velocity model used in the manual analysis. This process has produced an initial catalog of 6680 seismic events. To ensure improved accuracy, we filtered out the events recorded by fewer than seven stations, with RMS relocation errors larger than 0.35 sec, horizontal location errors (ERH) larger than 5.0 km and vertical location errors (ERZ) more than 10.0 km. After this filtering, the catalogue was reduced to 1214 events. The resulting seismicity distribution is shown in Figure 6. It is interesting to notice that the areas of high seismic activity identified by the manual analysis (Fig. 2), are very similar to the results provided by the SeisBench automated algorithm, which is an encouraging result for both the quality of manual relocations, as well as for the potential to employ automated relocation tools for microseismicity analysis.

Conclusions

In the present study, we demonstrate the critical role of combining dense local seismic networks with modern machine learning techniques for the detailed monitoring microseismic activity. By deploying a local network of high-sensitivity seismographs in the Stypsi geothermal field area, we significantly enhanced the detection and analysis of seismic events compared to regional networks. This underscores the importance of local networks for identifying low-magnitude seismicity, which is essential for understanding the geotectonic setting, as well as studying related phenomena (e.g. induced seismicity events). Integration with SeisBench and EQTransformer allowed the detection of thousands of additional events; however, after applying quality filtering criteria, we obtained a significantly reduced number of events (~20% of the initial automatically located dataset), in good agreement with the spatial pattern of the manually relocated seismicity. This correlation highlights the potential of using machine-learning approaches as supplementing methods to traditional seismic analysis. The spatial and temporal distribution of seismicity, focal mechanisms, and Gutenberg-Richter analysis have provided valuable insight into the stress field and active faulting of the area. These findings underscore the importance of integrating localized seismic monitoring networks, with modern computational techniques for efforts towards mitigating seismic hazard for safe and sustainable exploitation of geothermal resources.

Acknowledgements

The network installation and data analysis were realized within the context of the project “Continuous Microseismic Monitoring of Lesvos” funded by PPC Renewables (contracts PO77001033 and PO77001833). The authors would like to acknowledge the assistance and support of Dr. Nikos Germenis and Geobit SA who provided the instrumentation and assisted in the local network installation.

EXTENDED ABSTRACT 345

Preliminary results on the interseismic deformation of the Argolis Peninsula, Greece

Introduction

Ongoing research highlights that the present-day deformation in eastern part of the onshore areas around the Gulf of Corinth (Corinth area, Perachora Peninsula) is characterized by an average rate of 1 mm/yr, induced by the Corinth rift extension (Evelpidou et al., 2023). Notably, though, the northwest of the Perachora peninsula presents a clear displacement pattern (subsidence), related to the active Pissia fault, according to recent study by Mildon et al. (2024), while the Argolis peninsula displays an overall subsidence pattern. Subsidence patterns are also observed locally, at the area between Kiato and Melissi at the NE coast of the Peloponnese

The inception and evolution of the Corinth rift, since c. 4-3.5 Ma, is associated with the development of the Central Hellenic Shear Zone (Papanikolaou and Royden, 2007) and the roll-back and geometry of the subducting African slab. The rapid N-S extension of the Corinth rift, in the order of 10-15 mm/yr (Briole et al., 2000), is accommodated by E-W normal faults, which provided the depocenters for syn-rift hemi-pelagic sedimentation and extended, massive deltas along its southern margin, which migrated northwards through time (e.g.: Nixon et al., 2016; Gawthorpe et al., 2018). Quaternary uplift of the northern Peloponnese is testified by uplifted flights of marine terraces along the NE coast of the Peloponnese, lying on the hanging-wall of E-W, north-dipping normal faults (Armijo et al., 1996).

The Argolis Peninsula is built of several tectonic units that belong to the Pelagonian and Sub-Pelagonian domains, forming the inherited alpine backbone of the area (Bortolotti et al., 2003). The current deformation in the Argolis Peninsula is influenced by the three neighboring extensional structures, namely the Saronic Gulf, the Argos Gulf, and the Gulf of Corinth. The structure of the Argolis Peninsula that comprises mainly NW-SE normal faults is associated with back-arc extension that started in the Late Miocene, including the Cretan basin (Saronic Gulf and Argos Gulf), induced by the southwestward roll-back of the Hellenic subduction.

Combining fault identification (field reconnaissance, combined with geomorphological and drainage analysis) and geodetic data allows us to understand whether some onshore structures in the Argolis Peninsula are still active, affecting present-day deformation.

Methods

In this preliminary study, we use the Permanent-Scatterer InSAR of the ORTHO dataset from the European Ground Motion Service (EGMS; https://land.copernicus.eu/en/products/european-ground-motion-service) acquired by Sentinel-1 in ascending and descending orbit, during 2019-2023. The time-series provide by the EGMS website cover 2019 to 2023 period. We also use Global Navigation Satellite System (GNSS) data from Briole et al. (2021) with a vertical reference of the ITRF2016 (Altimimi et al., 2016). The permanent GNSS stations in the Argolis Peninsula show a vertical velocity consistent with that of the PS-InSAR data (Fig.1).

Here, we mainly use the vertical component of the available geodesic dataset to identify the present-day deformation of the Argolis Peninsula. The East component from EGMS is similar throughout the study area and the InSAR acquisition method from EGMS does not detect the North component by the line-of-sight (LOS).

The interseismic vertical deformation is compared with the geology and structures of the area. The onshore faults in Argolis Peninsula are determined by geomorphological analysis, then adjusted according to the literature, such as Bortolotti et al. (2003) and Wicker et al. (2024), and the NOAFaults v6.0 dataset. The offshore faults are based on Nixon et al. (2016) for the Gulf of Corinth, Foutrakis and Anastasakis (2020) for the Saronic Gulf, and Papanikolaou et al. (1988) for the Gulf of Argos.

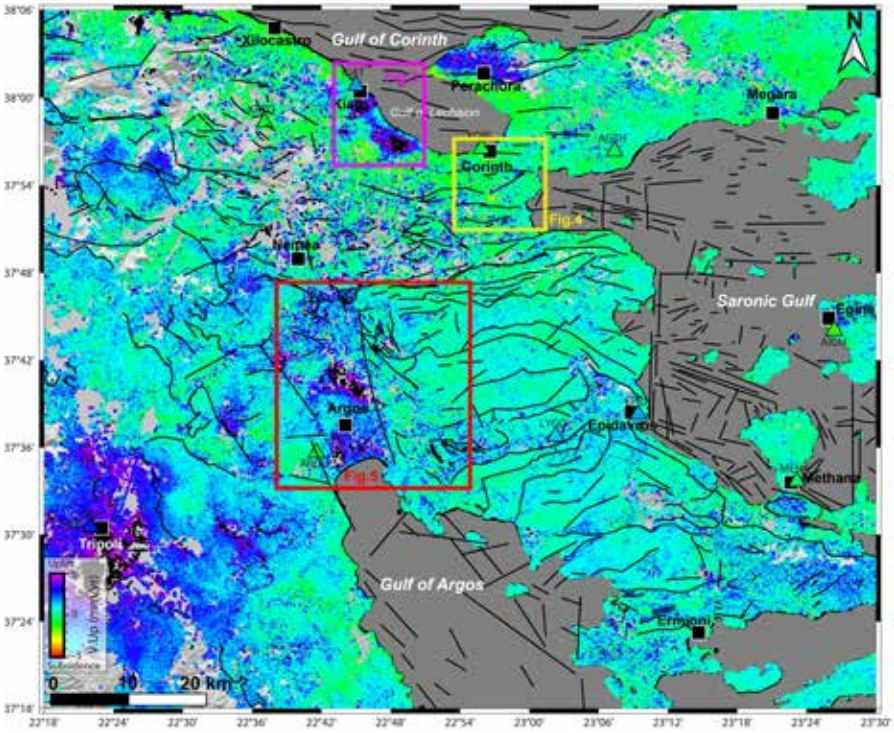

Figure 1: Map of the vertical velocities of Permanent-Scatterer InSAR data (2019-2023) from EGMS (https://land.copernicus.eu/en/products/european-ground-motion-service) and GNSS data from Briole et al. (2021) (represented by triangle) in the Argolis Peninsula.

Results

The PS-InSAR and GNSS data show that the whole of the Argolis Peninsula subsides with an average velocity of -1 ± 0.4 mm/yr for PS-InSAR and -0.5 ± 1 mm/yr for GNSS data inherited with the Corinth rift expansion, even if the Gulf of Lechaion is considered inactive currently. However, we could see at shorter wavelengths that some parts of the peninsula subside or uplift more than the trend of the Argolis Peninsula (Fig.1). Unlike the East component of the PS-InSAR only shows a westward trend averaging -16 ± 0.5 mm/yr at long wavelengths, and the corrected horizontal components from Briole et al. (2021), show a southwestward trend of the Argolis Peninsula for a stable Eurasia plate, averaging -8 ± 0.4 mm/yr for the East component and -12 ± 0.4 mm/yr for the North component (Fig.2).

Subsidence pattern between Kiato and Corinth

At the short-wavelength signal, we observe subsidence with an average of ~3.5 ± 0.3 mm/yr between Kiato and Assos, reaching -10 mm/yr in Assos (Fig.3). We also observe a minor uplift of ~1mm/yr further south of the Assos pattern. Besides, the deformation in Assos and Kiato-Nerantza presents an interesting PS-InSAR time series showing the subsidence increase since April 2021 (Fig. 3a and b). We also observe the same deformation for the slower subsidence, at ~1.5 ± 0.3 mm/yr, between Assos and Nerantza (in pink, Fig.3b). Time-series shows an uplift of 1.4 ± 0.3 mm/yr for the PS-InSAR stacked between Kiato and Nerantza (in red, Fig.3c), and a subsidence of -0.9 ± 0.3 mm/yr for the region of Assos before April 2021 (in yellow, Fig.3a). We also observed the subsidence increases westward since August 2022 (Fig. 3a, b, and c).

This area is a flat alluvial plain with extensive agricultural activity and geographically corresponds to the “gap” of marine terraces in the Northeastern Peloponnese (Armijo et al., 2016). No seismic event is recorded in April 2021 or August 2022. The uplift area corresponds to the New Corinth (49 ka) marine terrace documented by Armijo et al. (2016). Although no faults are known in this location, the uplift could be explained by the general uplift observed on the northeastern coast of the Peloponnese, induced by the E-W normal faults of the Corinth rift. Hence, the subsidence pattern observed could be attributed to sediment compaction, induced by lowering of the water table, which could explain the subsidence range of 3 to 10 ± 0.3 mm/yr, or more if the subsidence is added to the uplift of the northeastern coast.

Uplift pattern in Xilokeriza

At Corinth, the KORI GNSS station and the PS-InSAR show an uplift of ~1 mm/yr related to the Corinth rift extension

(Fig.4). At Xilokeriza, we observe a focused uplift of 1.4 ± 0.4 mm/yr in 1 km of diameter (Fig.4d). The four-year period covered by the PS-InSAR dataset shows a clear seasonality in this area (amplitude of 1 mm), with maximum uplift in spring and maximum subsidence in autumn, related to the local hydrological conditions, which overprints a clear upward trend (Fig.4d). Besides, the area undergoing uplift lies at the possible south-western tip of a presumed NE-SW fault that was identified through geomorphological analysis, but we do not observe any subsidence in the north-dipping hanging-wall of this fault, but an uplift of 1 mm/yr. The time-series of Xilokeriza reveals an uplift of 1.8 mm/yr between August 2019 to August 2020, then a subsidence of -1.7 ±0.4 mm/yr since November 2022. We could also observe a signal between January and August 2019, decreasing at around +0.5 to -2 mm for around eight months, estimating a subsidence of ~1.8 ± 0.4 mm/yr. It is possible that in Xilokeriza there is a seasonal and multi-annual effect, of ± 1.8 mm/yr recorded by PS-InSAR. It is worth noting that uplifted area at Xilokeriza coincides with a marl outcrop surrounded by alluvial deposits.
Further south, we observe subsidence in the hanging-wall of the E-W active Kenchreai normal fault with N-dipping (Koukouvelas et al. 2017), also identified by geomorphological analysis, representing the northern boundary of a Pelagonian Unit faulted block (Fig.4). This fault could extend into the Saronic Gulf according to the seismic reflection analysis of Foutrakis and Anastasakis (2020). However, the other faults in the southern boundary of the horst does not show any deformation. The subsidence between Kiras Vrisa and Corinth corresponds to the highway.

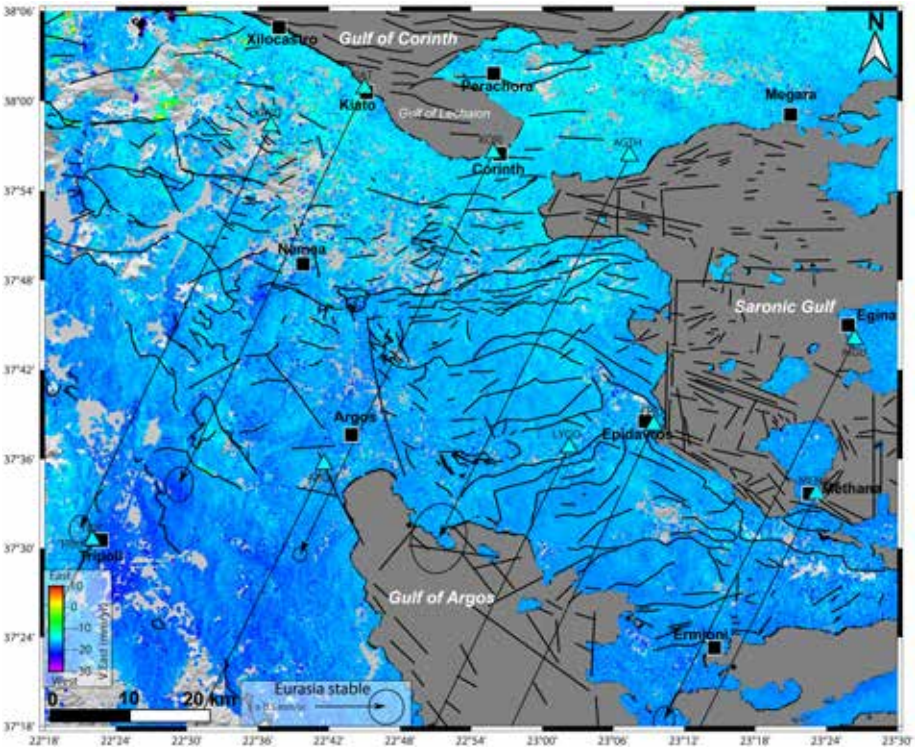

Figure 2: Map of the East-West component of Permanent-Scatterer InSAR data (2019-2023) from EGMS (https://land.copernicus.eu/en/products/european-ground-motion-service) and the horizontal component of GNSS data (represented by triangle) with the Eurasia stable from Briole et al. (2021).

Argos basin

Deformation in the Argos and Nafplion regions may correspond to the main, basin-bounding faults (Fig.5). Indeed, the subsidence is higher along the hanging-wall of NW-SE normal faults formed by the opening of the Cretan Sea and the Gulf of Argos. The PS-InSAR data reveals that the Argos basin has a higher subsidence rate than the whole peninsula, which is in the order of ~2 ± 0.4 mm/yr, reaching a subsidence of -7.5 ± 0.4 mm/yr in the northern part of the basin (Fig.5h). The seasonal variation, common to alluvial plains, is clearly detectable, as well (Fig.5h).
We could identify a difference in PS-InSAR of -1 ± 0.4 mm/yr in the footwall and -2 ± 0.4 mm/yr in the hanging-wall of the southeast-dipping SW-NE normal fault inferred by geomorphological analysis, which marks the boundary between the Pindos unit and the alluvial deposits. The interseismic deformation appears also to be influenced by the overall geological structure, with the Pelagonian and Pindos nappes subsiding slower than the syn/post-rift

sediments.

The northern part of the Argos basin shows an interesting deformation pattern, as the subsidence trend of the basin is ~2 ± 0.4 mm/yr except the southern part of it, which subsides at a rate of ~0.5 ± 0.4 mm/yr, while all the area is characterized by the same post-alpine sediments (conglomerates). Geomorphological analysis in this area, postulates the occurrence of E-W normal faults, with the same geometry as the Mykines fault. These faults may be related to the deposition of conglomerates to the north (potentially a delta in Argos), with the northernmost fault being the more active one. Consequently, the E-W fault delineating the -0.5 ± 0.4 mm/yr subsidence pattern to the north may not have been responsible for the uplift in the footwall, causing a decrease of subsidence.

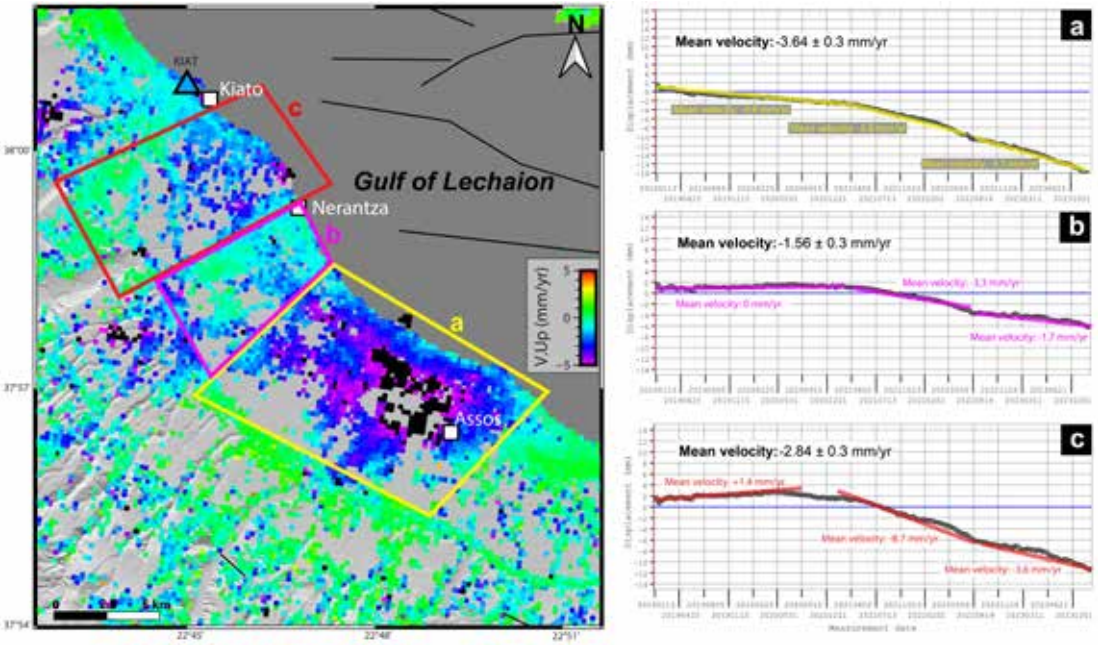

Figure 3: Map of the vertical velocities of Permanent-Scatterer InSAR data (2019-2023) from EGMS and GNSS data (represented by triangle) from Briole et al. (2021). Time-serie of PS-InSAR (2019-2023) from EGMS for a) Assos area (yellow box), b) Nerantza area (pink box), and c) Kiato-Nerantza area (red box) with the mean velocity of each area (in black), and the mean velocity of trend observed in the area (color associated of the area).

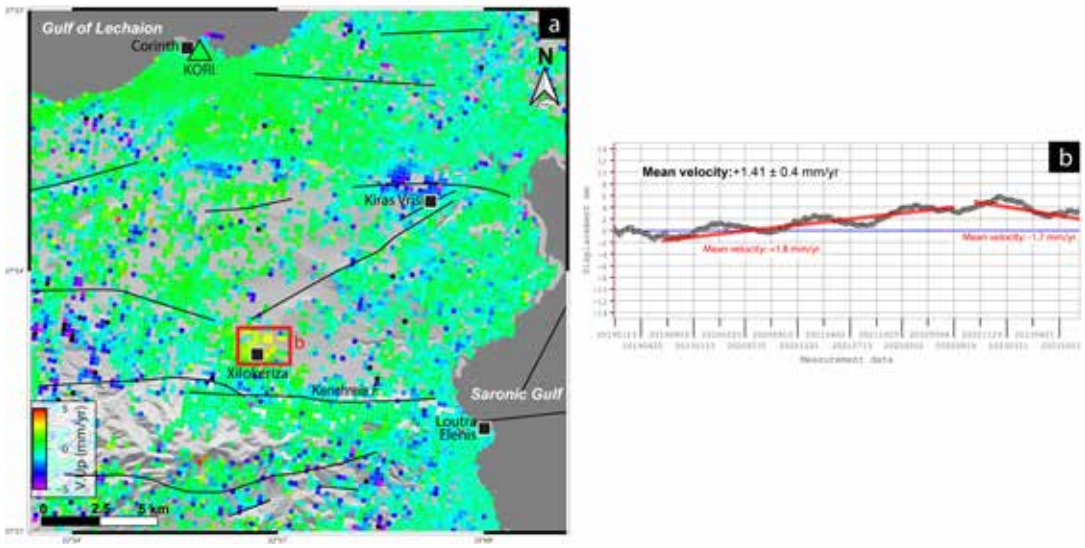

Figure 4: Map of the vertical velocities of Permanent-Scatterer InSAR data (2019-2023) from EGMS and GNSS data (represented by triangle) from Briole et al. (2021). d) Time-series (2019-2023) of PS-InSAR from EGMS of the Xilokeriza area (red rectangle) with the mean velocity of the area (in black), and the mean velocity of trend observed in the area (in red).

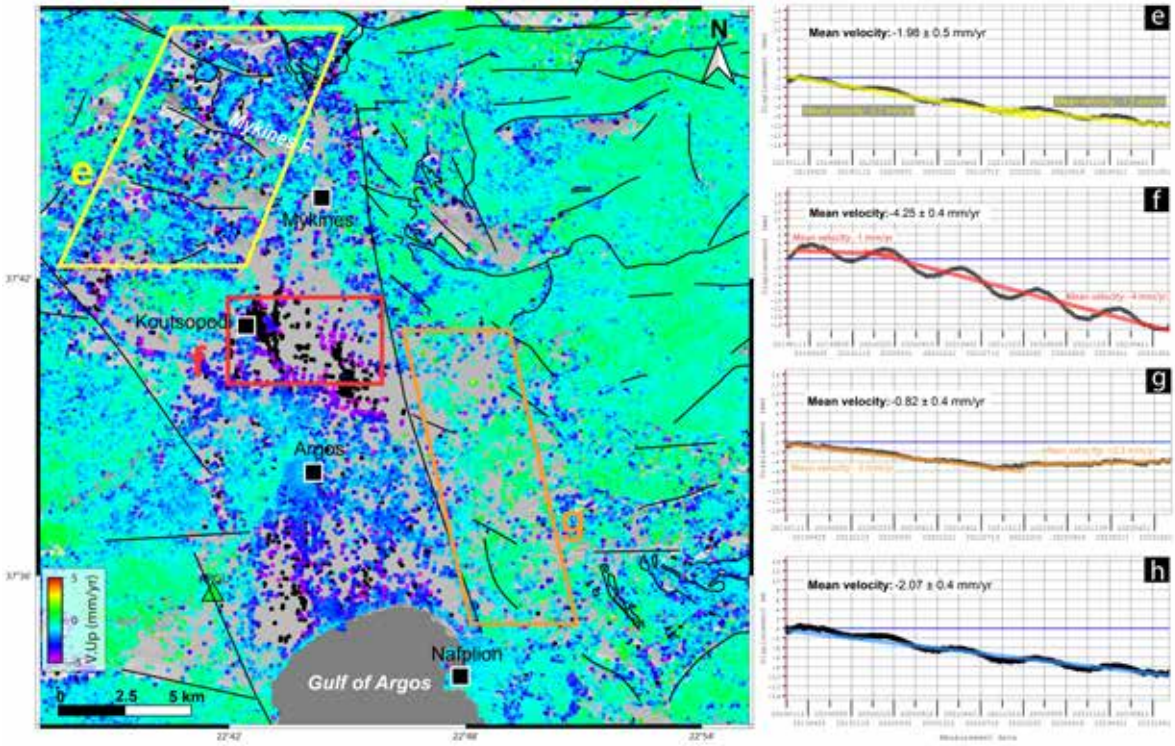

Figure 5: Map of the vertical velocities of Permanent-Scatterer InSAR data (2019-2023) from EGMS and GNSS data (represented by triangle) from Briole et al. (2021) of the Argos Basin. Time-series of vertical velocities of PS-InSAR data (2019-2023) from EGMS of the e) west part of Mykines, f) region of Koutsopodi, g) east part of the eastern boundary of the Argos basin with the mean velocity of each area (in black), and the mean velocity of trend observed in the area (color associated of the area or boxes), and h) whole of Argos basin with a mean velocity represented in black.

We observe three different areas that have different time series in the whole Argos basin, which have a trend with subsidence of ~2 ± 0.4 mm/yr, during the PS-InSAR period from 2019 to 2023 (fig.5g). We observe that the subsidence recorded in western Mykines (~2.7 ± 0.5 mm/yr) becomes less pronounced (-1.5 ± 0.5 mm/yr), since October 2021 (Fig.5e). This area corresponds to the outcrops of conglomerates discussed above.

On the contrary, near Koutsopodi we observe an increase in the subsidence. The time-series of this area shows a subsidence of 1 ± 0.4 mm/yr after an initial uplift until the beginning of the 2020, followed by an average subsidence an of 4 ± 0.4 mm/yr (Fig.5f). Besides, the seasonal effect in this area is important, in the order of 4 mm amplitude, with maximum subsidence in autumn and maximum uplift in spring. The seasonal effect in the Koutsopodi region is higher than that observed in the whole Argos basin or in the eastern part of Mykines that displays a ~1 mm in amplitude. Locally, the Koutsopodi area may have different sediments beneath the alluvium of the Argos Basin that are more influenced by hydrological conditions, explaining this strong seasonal effect, as observed in Xilokeriza.

On the east part of the Argos basin boundary, we observed a -2 ± 0.4 mm/yr subsidence, common in the Argos basin, until October 2021, followed by an uplift of 0.5 ± 0.4 mm/yr (Fig.5g). This area is composed of alluvium, as in the region of Koutsopodi, but the seasonal effect is low (at 0.5 mm in amplitude.) This area lies in the footwall of the west-dipping, NW-SE normal fault dipping and the uplift observed could be explained by a seismic event, but no earthquake was recorded in October 2021. It is worth noting that the 1788 seismic event of M6.2 in Nafplion (NOAFaults v6.0) could be associated with the activity of this NW-SE normal fault.

Conclusions

The present-day deformation of the Argolis Peninsula calls for more investigation, with the view to identifying the deformation observed in the Argos basin, Corinth-Xilokeriza, and Kiato-Assos areas. It will be interesting to investigate the various deformation patterns observed in the Argolis Peninsula, such as the regional subsidence in the Adheres unit (southeastern of Argolis Peninsula, near Methana), the subsidence in northern Ermioni, and the subsidence close to Epidavros. Further work on this, besides detailed structural mapping, includes the comparison of the GNSS dataset and EGMS dataset with another Permanent Scatter approach (Surface motioN mAPPING method

https://docs.terradue.com/geohazards-tep/tutorials/Snapping.html), and the NSBAS approach (Flatsim computation led by the CNES https://flatsim.cnes.fr) which involves using the existing permanent GNSS stations combined with displacement time-series computed from Sentinel-1 satellite data.

EXTENDED ABSTRACT 346

Spatial distribution and deformation of columnar calcite occurred in the high-pressure marbles of Cycladic Massif (Hellenides)

P. Xypolias, N. Gerogiannis, E. Aravadinou, K.A. Tsourtis

Department of Geology, University of Patras, 26500 Patras, Greece; p.xypolias@upatras.gr

Research Highlights

High-pressure (HP) marbles in the Cycladic Massif bear a columnar-shaped calcite microstructure that represents a powerful marker of deformation.

Detailed structural analysis of the columnar calcite microstructure can further refine our knowledge about the exhumation processes of HP terranes.

Objectives

Calcite marbles constitute large parts of the Alpine orogenic system and thus they can be used to study the structural evolution and exhumation processes of HP rocks within subduction zones (e.g., Molli *et al*., 2000; Spanos *et al*., 2015). The presence of a columnar calcite microstructure within marbles of several HP terranes, including the Cycladic Massif of Internal Hellenides, has been reported (Fig. 1a) (Brady *et al*., 2004; Seaton *et al*., 2009; Zulauf *et al*., 2018; Gerogiannis *et al*., 2021, Aravadinou *et al*., 2022; Potočný *et al*., 2023). This microstructure is thought to be formed at static conditions within the stability field of aragonite at the deep subduction levels (HP conditions). The resulted microstructure, after exhumation of the rocks to shallow crustal levels, is interpreted as calcite pseudomorph after aragonite and is defined by coarse-grained calcite crystals oriented at high angles to the pre-existing foliation (e.g., Brady *et al*., 2004; Gerogiannis *et al*., 2021). The columnar microstructure has been used as a marker for the record and quantification of the deformation of rocks within the subduction channel as well as for the identification of spatiotemporal variations in deformation intensity of distinct events during the subduction-exhumation cycle (e.g., Seaton *et al*., 2009; Gerogiannis *et al*., 2021, 2022; Aravadinou *et al*., 2022).

In this work, we combine new and published (Gerogiannis *et al*., 2021, 2022; Aravadinou *et al*., 2022) data about the occurrence and deformation of the columnar calcite microstructure in different areas and structural positions of the Cycladic Massif (Fig. 1b; Basal Unit, Evia Island; Cycladic Blueschist Unit, Evia, Syros, and Ios islands) highlighting their importance on the study of the structural evolution of HP terranes such as the Cyclades area. We show that the columnar calcite microstructure is present in several exposures of HP marbles of the Basal Unit and Cycladic Blueschist Unit, whereas the observed variation in the extent of its preservation/modification indicates that the deformation was highly heterogeneous in space and time within the subduction channel during the exhumation of the HP rocks.

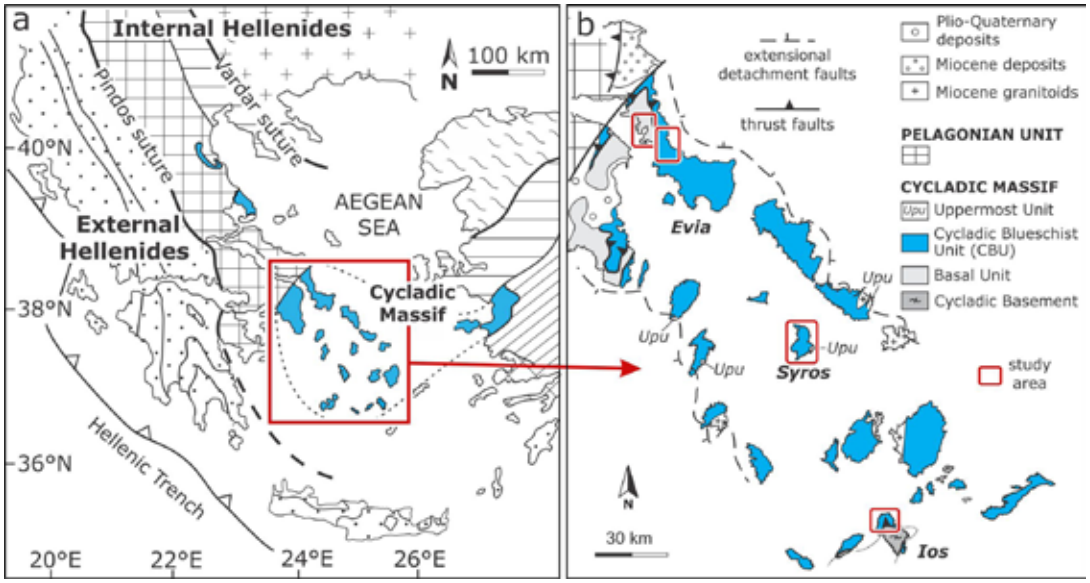

Figure 1. (a) Geological map of the Aegean region showing the position of the Cycladic Massif in the Internal Hellenides. (b) Simplified geological map of the Cycladic Massif indicating the study areas.

Geological framework

The Cycladic Massif is part of the Internal Hellenides and is represented by four metamorphosed units stacked within an Eocene-Oligocene subduction channel during the Hellenides formation (Fig. 1a; Dürr *et al*., 1978). The Cycladic Massif is divided into the Uppermost Unit, the intermediate Cycladic Blueschist Unit (CBU), and the structurally deeper Cycladic Basement and Basal Unit (Fig. 1b). The rarely exposed Uppermost Unit mainly comprises Permo-Mesozoic crystalline rocks, which have not been affected by the Alpine HP/LT metamorphism. The CBU consists of a metamorphosed Mesozoic succession of meta-sedimentary rocks and metabasic bodies, that underwent blueschist to eclogite facies metamorphism during early Eocene. Exhumation initiated under blueschist facies conditions and progressively continued at greenschist facies conditions during Oligocene-Miocene. In south Evia, the CBU subdivided from the lower to upper structural levels into three nappes: a) the Tsaki nappe including various schists with marble intercalations and serpentinitic blocks; b) the Styra nappe, which represents a marble-schist sequence; and c) the Ochi nappe consisting of a meta-volcano-sedimentary sequence interleaved with slices of metaophiolitic rocks. In Syros Island, the CBU is generally composed of marbles, schists, metabasites (blueschists and eclogites) and paragneisses, whereas in Ios Island, it is made up of a marble-schist sequence. The Cycladic Basement crops out on the central and southern Cyclades and comprises mostly deformed Paleozoic granitoids and schists sharing a common metamorphic history with the rocks of the CBU during the Alpine orogeny. Finally, the Basal Unit consists mainly of a Mesozoic carbonate sequence that was affected by HP/LT metamorphism during post-middle Eocene times. In Evia Island, the Basal Unit consists of a thick sequence of Triassic to middle Eocene marbles with local intercalations of schists. The marbles transition upwards to a sequence of quartzites and metapelites (metaflysch).

Results

Microstructural observations in the marbles of Cycladic Massif revealed the presence of columnar calcite in all studied areas (Fig. 2a, b). However, the extent of their preservation and deformation differs from one area to another. Generally, observed calcite microstructure can be subdivided into four groups based on the recrystallization mechanism, grain size, shape, and distribution. The first microstructure (m1) is represented by large columnar calcite (grain size 800 – >3000 μm and aspect ratio >3) with a strong shape preferred orientation (SPO) that forms an angle >60° with the macroscopic foliation. These columnar grains typically present columnar subgrains and associated recrystallized grains indicating recrystallization by subgrain rotation (SGR). The second microstructure (m2) is characterized by inequant (aspect ratios 2–3) calcite grains, with sizes between 200 and 600 μm. These grains display a strong SPO that marks the original columnar calcite forming angles of 30°–60° with macroscopic foliation. All microstructural features indicate that these grains originated by the SGR recrystallization of the larger columnar grains. The third microstructure (m3) is characterized by (sub)equant calcite grains with sizes ranging between ~50 and 500 μm and a weak to well-developed SPO. These grains are typically associated with the presence of subgrains of similar size and shape implying recrystallization through SGR. The fourth microstructure (m4) is represented by small (<70 μm) (sub)equant to elongated calcite grains that have originated by SGR and bulging recrystallization. These grains are typically localized within bands that vary in thickness from <1mm to several centimeters. The density of these bands also varies from meter to millimeter scale.

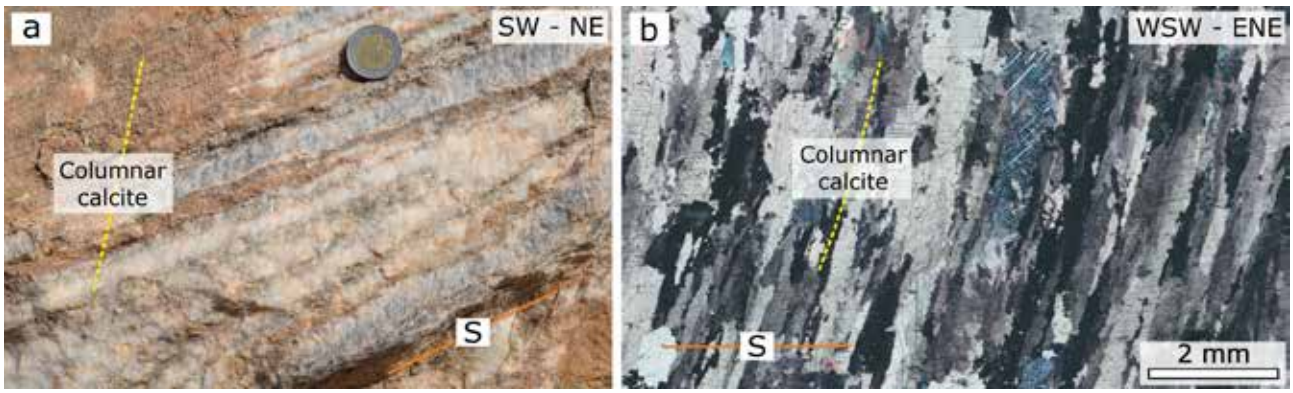

Figure 2. Columnar calcite oriented at high angles to the macroscopic foliation was recorded in outcrop- (a) and micro- (b) scale (a: CBU, Syros Island; b: Basal Unit, Evia Island). S, macroscopic foliation.

In the Basal Unit exposed in Evia Island, m2 is typically the dominant microstructural group within the marbles located

in the eastern part of the unit. However, in several marble outcrops exposed in this area, m1 is present. In turn, in the western part of the unit, and structurally upwards, the marbles are usually characterized by m3, whereas m4 is recorded in specific zones within m3 that are aligned with map-scale shear zones. In the marbles of the CBU (Styra nappe) that overlies the Basal Unit, m2 typically characterizes the marbles that are located in the structurally lower positions of the nappe near the contact with the marbles of the Basal Unit. In these structural levels, m1 was also observed in several marble outcrops. Moving structurally upwards within the Styra nappe (eastwards), marbles are typically associated with the development of m3. Here, m3 is represented by calcite grains with a well-developed SPO.

In marbles of the CBU exposed in Syros Island, the observed microstructures also present a spatial variation. Specifically, in the north part of the island, marbles are clearly dominated by the development of m1. Locally within m1, individual thin bands characterized by m4 are recorded. In turn, in the south part of the island, and moving structurally downwards, the main calcite microstructure recorded within marbles is m3. In this case, m3 is characterized by calcite grains with a weak SPO. Although m3 is dominant in this part of the island, the other three microstructural groups (m1, m2, m4) are also recorded in several marble outcrops.

In the CBU exposed in northern Ios, m1 is recorded in only some marble outcrops located in the northwest part of the island, relatively close to the contact with the underlying Cycaldic Basement. The main calcite microstructural group recorded in the marbles of northern Ios is m3. This microstructure is typically observed near the contact with the Cycladic Basement and generally in the lower structural positions of the CBU. In several outcrops, thin bands characterized by m4 are observed within m3. The marbles located in structurally upper positions of the CBU, near the north coastline of the island, are typically characterized by the presence of m4, that is developed within thick (several centimeters to meter) bands.

Conclusions

HP marbles of the CBU and Basal Unit that belong to the Cycladic Massif of Hellenides are characterized by the occurrence of coarse-grained columnar calcite that is oriented at high angles to the mesoscopic foliation. This columnar calcite microstructure should be formed at deep subduction levels where HP metamorphism was active. The degree of preservation or obliteration of this microstructure in specific positions of the subduction channel provides information about the spatiotemporal variations in deformation conditions during exhumation of the HP rocks.

Combination of new and published data about the occurrence and deformation of the columnar calcite microstructure in the marbles of the CBU and Basal Unit within the Cycladic Massif, showed that this microstructure was initially formed within the marbles of all study areas (i.e., Basal Unit, Evia Island; Blueschist Unit, Evia, Syros, and Ios islands). However, the degree of preservation of this microstructure varies from one area to another. It is noted that preservation and modification / obliteration of the columnar microstructure are linked with absent /weak and intense deformation during exhumation, respectively. Well-preserved columnar microstructure is extensively presented in the marbles of the CBU exposed in northern Syros (upper structural levels). Moreover, well-preserved to partly modified columnar microstructure is observed in the lower structural levels of the Basal Unit and CBU in south Evia. In turn, the columnar microstructure is highly modified or obliterated in the upper structural levels of Basal Unit and CBU in south Evia, as well as in the CBU exposed in south Syros and Ios Island. These results indicate that the intensity of deformation was highly heterogeneous in space and time within the subduction channel during the exhumation of the HP rocks.

Introduction

Expedition DY190 onboard the Royal Research Ship (RRS) Discovery explored the Christiana-Santorini-Kolumbo volcanic field between the 3rd and the 28th March 2025. The primary aim of the expedition was to study the interaction between caldera volcanoes and their hydrothermal systems, to understand the role they play in increasing or decreasing the explosivity of eruptions. However, the expedition was serendipitously scheduled a month after the start of the "Seismic Crisis" in the region and hence provided a unique opportunity to assist in efforts to understand and monitor this seismicity and to assess its impact on both Santorini and Kolumbo volcanoes.

Methods

The data presented here was primarily collected by the Remotely Operated Vehicle (ROV) Isis, during 22 different dives to Santorini and Kolumbo. The ROV is a deep-diving robotic submersible designed for scientific research and exploration owned and operated by the National Oceanography Centre, Southampton (UK) and is capable of diving to depths of 6,500 m. During the expedition the ROV conducted high-definition imaging including detailed underwater video and photography, sample collection of rocks, sediments, seawater and hydrothermal fluids, and operated heat flow and temperature probes.

Additionally, during the expedition an array of 12 broad-band ocean bottom seismometers (OBS) from Dublin Institute of Advance Sciences (DIAS) and 13 ocean bottom nodes (OBX) from the National Oceanography Centre were deployed for a duration of 3 weeks to monitor seismicity and noise associated with hydrothermal circulation. OBSs were manufactured by K.U.M. and feature a120 s broadband seismometer housed in a titanium pressure tube, along with a 100 s hydrophone. Titanium tube also contains the K.U.M. 6D6 four-channel datalogger and batteries. Each tube is integrated within a syntactic foam flotation unit and equipped with a flasher, radio beacon, signal flag, anchor and acoustic release. OBXs were manufactured by Geospace and are equipped with three orthogonal geophones (15 Hz cut off frequency) and one hydrophone (4 Hz cut off frequency) and a tilt sensor. These instruments do not have a floatation or anchoring and are relatively small, which allows for the deployment and recovery by the ROV.

Measurements of CSEM were carried out with two different systems with different depths of investigation: using the transient electromagnetic coincident loop system MARTEMIS, with a shallow investigation depth of several 10s of meters and a relatively localized footprint and a dual dipole transmitter system named CAGEM, which in combination with OBEM receivers offers an investigation depth of up to 500 m below the seafloor.

Gravity cores were collected with a gravity corer (GC), collecting the upper 2 m of the sediment. The GCs were equipped with USBL transponder attached to the winch cable (50 m above the gravity corer) for more precise positioning during deployment. The speed of the final drop of the gravity corer was up to 1.2 m/s.

The deployment locations of all equipment are shown in Figure 1. The expedition also deployed and collected two OBS for GEOMAR, which will extend their array (installed to December) and deployed and recovered instruments for the SANTORY observatory at Kolumbo (Nomikou et al., 2022).

Preliminary observations of the volcanic systems in the wake of the seismic crisis

During the expedition we did not observe evidence of major changes from pre-existing data that could clearly be attributed to the seismic unrest in February and March. We did not observe major bathymetric changes (e.g. associated with landslides, volcanic inflation/deflation, or fault

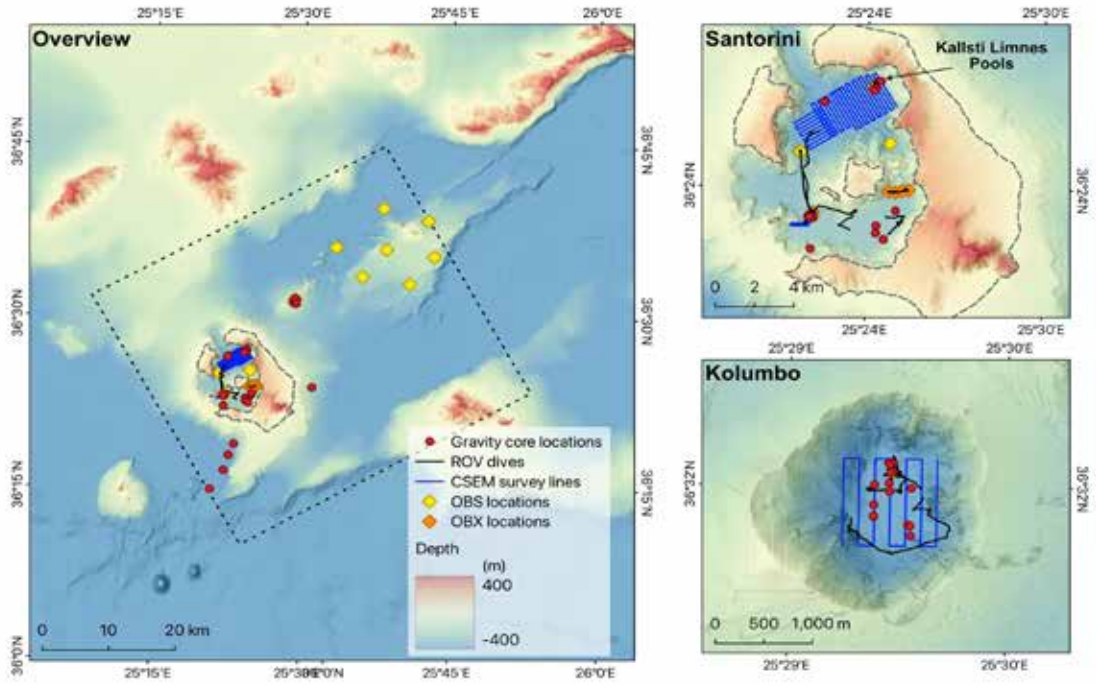

Figure 1. Deployment locations of equipment during expedition DY190.

displacements), however the data remain mostly unprocessed at the time of writing the report, so smaller changes in the bathymetry may exist but be undiscernible from the current unprocessed datasets. We did not find evidence of major landsliding at either Santorini or Kolumbo, nor did we observe evidence of recent turbidity currents in the upper sediments of the cores collected. We did not observe major new cracking or fracturing in the seafloor in the regions we surveyed and we did not find new vent fields in either Santorini or Kolumbo, though we did not cover the entirety of either caldera. Thus, we conclude there is no evidence in the data we collected and have currently analysed for major volcanic unrest or change at either system.

However, there may well be subtler changes in these systems that could be attributed to the seismic unrest, and which might become clearer with further analysis. For example, there may be changes in vent fluid compositions, temperatures and fluxes that will only become apparent with full analysis of the datasets and comparison with previous studies. More detailed processing and interpretation of the bathymetry may highlight smaller changes that are not currently visible. Comparison of the underway measurements made by the ROV may highlight changes in the water column and deep-water properties that are not initially apparent.

There are two differences between our collected data and previous work that we believe can be reliably observed. These are:

1. *Changes in the bacterial coverage in the bottom waters at Kolumbo*

The entire floor of the Kolumbo Caldera was covered in bacterial mats to an extent that had not been previously observed and the turbidity in the water column was very high at depth below 250 m (Figure 1). Professor Nomikou, who has worked inside the Kolumbo caldera many times, observed that both the turbidity and bacterial coverage on the floor of the caldera were higher than she had observed on previous visits, and that these two observations are likely related (the bacteria was extremely light and floccy and easily kicked up into the water column taking a very long time to settle). It is unclear what this means in practice. For example, it may indicate enhanced venting of CO_2 that has accumulated at or near to the seafloor, encouraging the bacterial growth, or increased seeping across the floor of the caldera (though we observe no evidence for this). We highlight, however, that Kolumbo is and will remain

a potentially very dangerous volcano. Measurements of temperatures in the sediments were consistently high in the northern area, and in the venting regions to the east of the main field (so high in one region that we melted the base of a push core, indicating temperatures >100ºC at a depth of just 30-40 cm. Further work is recommended to compare our measurements and observations at Kolumbo with those from previous expeditions, in order to create a time series of data that would make changes and increases in activity clearer than the snapshot measurements presented herein.

2. *Changes in the Kallisti Limnes Pools since December 2024*

Photogrammetric data acquired over the Kallisti Limnes (Pools) in December 2024 was provided by Dr Tom Kwasnitchka at GEOMAR Helmholtz Institute for Ocean Research Kiel, to aid with planning and assessment of the Kallisti Limnes (Pools). This dataset provided an opportunity to assess changes in the degree to which the Kallisti pools were "full" (i.e., amount of cloudy blue fluid within these pools) between December 2024 and March 2025 by comparing the photogrammetry images to ROV dive video. This was accomplished by plotting the ROV dive tracks on the photogrammetry dataset, and identifying pools along the dive track that could also be clearly identified in the photogrammetry. The results of this analysis indicated that, of 22 pools observed in the ROV dives that could also be unambiguously identified in the photogrammetry, only 4 that contained cloudy fluid in December 2024 also contained cloudy fluid in March 2025. The remaining 18 pools that appear full in the photogrammetry did not contain any noticeable cloudy fluid in the ROV video footage. Of the 4 pools that were "full" in both datasets, for at least 1 of the pools, the amount of fluid appears to have diminished since December 2024. Overall, there is a clear reduction in the amount of cloudy fluid that is stored in the pools between December 2024 and March 2025. It is unclear from the datasets if any of the pools that were found to contain cloudy fluid in March were empty in December. It is therefore unclear whether this is a result of the seismic crisis or normal behaviour for the Kallisti Limnes (Pools), as it is currently unknown on what timescales pools fill and empty.

Acknowledgements

We thank the officers and crew or the RRS Discovery for their professionalism and dedication to achieving this expedition. We thank the ROV team, Dave Turner, Russ Locke, Emre Mutlu, Martin Yeomans, Andrea Afonso, Antonio Caldero, Bruno Ramos, and scientific technical team, Dean Cheeseman and Josue Rivero, for their hard work and expertise without which none of the expedition objectives could have been completed. We unreservedly thank the Government and authorities in Greece for allowing us to work in their waters and for their logistical support of activities. We thank the Natural Environmental Research Council (NERC, UK) for funding this research under grant number NE/X01519X/1 and the National Oceanography RISC Scheme for providing the funding for the OBS.

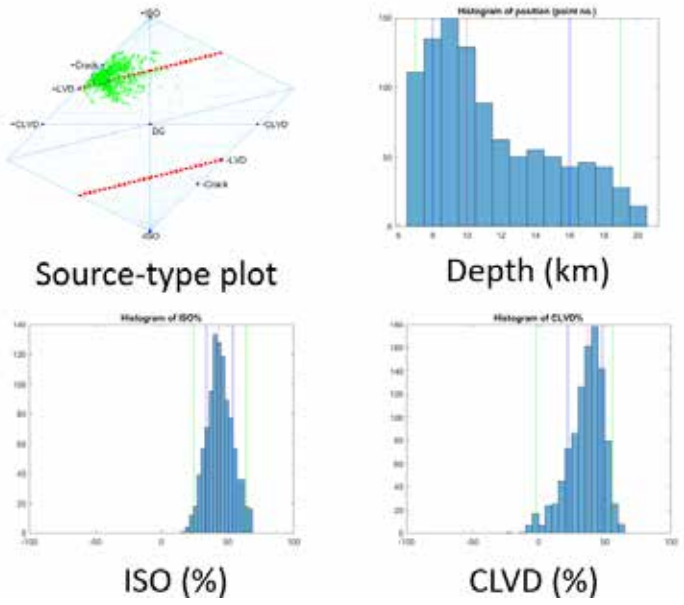
Data, Method, and Results

The 2025 seismic activity near Anydros Island contributes to understanding the relative roles of tectonic and volcanic processes in the Santorini-Amorgos zone (Andinisari et al., 2021a; Heath et al., 2019). Here we report on non-double-couple (non-DC) components of the full moment tensor (MT) analyzed in a probabilistic Bayesian framework. This is a continuation of the study preliminarily reported to EMSC and EarthArXiv in mid-February, during the crisis (Zahradník et al., 2025a). The non-DC components are isotropic ISO (= volumetric, VOL), and compensated-linear-vector-dipole CLVD. Absolute values of these two, and the always positive DC component, sum up to 100%. The six-parameter MT allows for mixed signs of ISO and CLVD in an event. The shear-tensile/compressional model, hereafter STC (Vavryčuk, 2011), allows only the same sign of ISO and CLVD in an event. The STC model enables a phenomenological interpretation of the MT in terms of shear faulting part (strike/dip/rake angles) and angular deviation of the slip vector from the fault plane, ranging from 0° to 90°/-90° for crack opening/closing, respectively. Further, the ISO and CLVD values in the STC model imply the Vp/Vs ratio in the source region which may differ from the values measured from travel times.

We use a semi-automatic station selection, starting from the deviatoric moment-tensor calculation of the Institute of Geodynamics, National Observatory of Athens (NOA) with the software GISOLA (Triantafyllis et al., 2016 and 2022), http://orfeus.gein.noa.gr/gisola/realtime/2025/, and we adopt their pre-processed instrumentally corrected full waveforms. A typical set consists of ~ 8-15 stations of the Hellenic Unified Seismological Network (HUSN; Evangelidis et al. 2021) at epicentral distances from ~40 to ~300 km. Further, we use the manually revised epicenter location by NOA and set the trial source positions below the epicenter. We perform a linear least-squares inversion for the full MT while centroid position and time are grid searched. Four 1D velocity models were tested, i.e., Novotný et al. (2001), Brüstle (2012), Dimitriadis et al. (2010), and a combination of the latter two by Fountoulakis (personal communication). All the tested models provide qualitatively the same results in the typical frequency range of 0.03-0.06 Hz. Results for the latter velocity model are presented below. The full moment tensor was calculated with the ISOLA2024 software (Zahradník and Sokos, 2018 and 2025) and its newer Bayesian bootstrap version (not yet published). By bootstrapping station weights, the method yields a posterior probability density of model parameters, thus enabling calculation of confidence intervals. An example of the processing for two events is shown in Fig. 1, where we demonstrate histograms of source depth, ISO, and CLVD. A suite of ISO-CLVD values of an event, almost equally well-fitting observed waveforms, provides quantification of the uncertainty of the source type (green circles in Hudson's plot of Fig. 1); for reference purposes, each event is also characterized by the median MT (blue circle in Fig. 1). We emphasize a relatively large uncertainty, see Table 1; thus, the representation of an event with confidence intervals is more reliable than with median. Since the non-DC components partly tradeoff with depth (Zahradník et al, 2025a), the optimum solutions are those for which an independent depth constraint is available. Using the NLL-SSST-coherence location results of Lomax (2025), followed by our HypoDD relocation (Waldhauser, 2001; Waldhauser and Ellsworth, 2000), we constrained solutions to depths 7-20 km for events 1-19, while the shallower events 20-25 were inverted in the range of 1-20 km (step 1 km).

Results for the 25 events are presented in Tables 1 and 2 and in Fig. 2. Each blue circle in Fig. 2 is a median MT of an event, analogical to the blue circle in Fig. 1; medians are highlighted in bold in Table 1. As demonstrated in Fig. 2, the waveform inversion unambiguously provides the full MTs with ISO > 0 and CLVD > 0 for most of the investigated events. Note also that blue circles are tightly clustered in Fig. 2. This indicates robustly resolved non-shear faulting, stable across the events. The positive signs of ISO and CLVD point to the shear-tensile source process, i.e., crack opening. Two events (shallower, numbered 20 and 21 in Table 1) represent a shear-compressional process, i.e., crack closing (ISO < 0, CLVD < 0). The DC-part of focal mechanisms of all analyzed events is mostly normal faulting, but strike-slip events were also found.



Discussion

Geodetic measurements indicated a possible dike volume of 3 x 10^6 m^3 (Briole, 2025; Ganas and Tsironi, 2025). We found a typical volume change of a single magnitude 5 event to be 10^5 m^3. An effective model corresponding to the 10^5 m^3 volume change can be, for example, a 1 km x 100 m x 1 m co-seismically opened space (filled with a fluid). Since the MT inversion was performed at low frequencies (shear wavelengths greater than 50 km), a more realistic scenario for this activity would involve a series of smaller, interconnected cracks whose spatial details are not resolvable here. Typical positive ISO and CLVD values of Table 1 and the STC model indicate an opening angle of about 10°-20°. The inferred non-shear faulting in the region is

consistent with submarine volcanism, diffuse seismicity and magmatic intrusions indicated in this region by tomography (Health et al., 2019). Significant ISO and CLVD components have been previously reported near Anydros Island (Fig. 5 of Andinisari et al., 2021b), although with more variability across events than in our study, and without uncertainty assessment. Elevated Vp/Vs ratios 1.77–1.86 calculated from seismic travel times by Andinisari et al. (2021a) were interpreted by them in terms of crack density and fluid saturation.

We used ~60 focal mechanisms of Andinisari et al. (2021b) to calculate the stress field in the region (Vavryčuk, 2014) and obtained a normal friction coefficient ~0.7. Interestingly, when we applied the same approach to the 50 focal mechanisms of NOA retrieved via EMSC for the 2025 Anydros activity, we obtained a much lower friction of ~ 0.2. This is shown in Fig. 2, where all events are cumulating at the top of the Mohr's diagram, and may indicate a co-seismic stress change. Faulting under near-zero friction (Tresca's failure criterion) has been laboratory observed (Rutter et al., 2013), yet it remains debated for real faults.

While non-zero isotropic components have been observed globally, their sign and relation to the tectonic-volcanic process remain ambiguous. Some observations in Iceland, at depths of 2-5 km, reported ISO < 0 for normal events and ISO > 0 for reverse ones (Hrubcová et al., 2021), while others observed ISO > 0 for strike-slip events there (Büyükakpınar et al., 2025). The latter has been interpreted as "an interaction between magmatic intrusions and the derived magmatic gases with shear fractures in the dike damage zone". Cyclic surface motions and seismic activity in Iceland have been explained as due to the migration of deep magmatic fluids and gases (of mantle origin) into upper crustal hydrothermal systems (Flóvenz et al., 2022). Normal faulting correlating with ISO > 0 has been found near injection wells in The Geysers geothermal reservoir, interpreted as tensile opening due to lower differential stresses than in reverse faulting (Martínez-Garzón et al., 2017). Slow magma flow can coexist with the fast spread of earthquakes during the crisis. Fluid-filled cracks do not necessarily need to be created during earthquakes; they may exist in the region and be activated by injections. A fast horizontal expansion of a magma-filled dike can occur, with just a small opening over the dike surface, effectively producing a large ISO > 0 (Dahm and Brandsdóttir, 1997). As a subvertical dike overpressure yields expansion increasing horizontal stress, thus possibly activating nearby reverse faults, subhorizontal sills may possibly trigger nearby normal faults in our transtensional region. Distinguishing between sill-like and pluton-like magma chambers may be difficult under existing measurement errors of geodetic data (Fialko et al., 2001). A 3D finite-element modeling can illuminate the interaction between stress fields due to over-pressurized sills/dikes and tectonic faults in the region (Zhan et al., 2022). Non-DC components represent sensitive parameters, less robust than strike, dip, rake, and moment. We already mentioned a possible tradeoff with depth. Other well-known factors possibly creating wrong non-DC estimates, even under low-noise conditions, are velocity models, station distributions, etc. Here we emphasize the danger of the MT inversion under the deviatoric constraint (assuming ISO=0). This assumption is applied in routine MT calculations by many agencies, e.g. GCMT and NOA. For event No. 1 of this paper, 2025/02/04 13:04:14.56, GCMT reported CLVD = 1%, i.e., DC= 99 %, an almost pure shear faulting. In other words, if an earthquake contains a significant ISO component, and is inverted as deviatoric, it may result in an erroneous CLVD. Thus, under the deviatoric assumption, the detection of non-shear-faulting may completely fail. This issue has been explained through synthetic tests accompanying the previous calculations of non-DC in Santorini region (Křížová et al., 2013 and 2016). That is why we intend to help update the current GISOLA at NOA toward reporting full MTs with uncertainty based on Bayesian bootstrap.

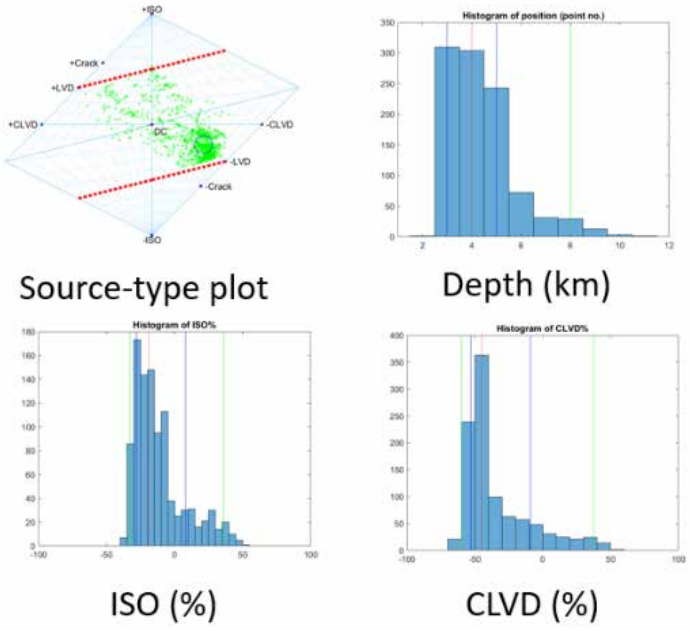


Figure 1. Example of the Bayesian analysis of two earthquakes: (top) No19 of Table 1, 2025/02/11 11:43:54.22, an opening crack, and (bottom) No20 of Table 1, 2025/02/12 01:14:54.63, a closing crack. Percentiles are shown in histograms by vertical lines (median in red).

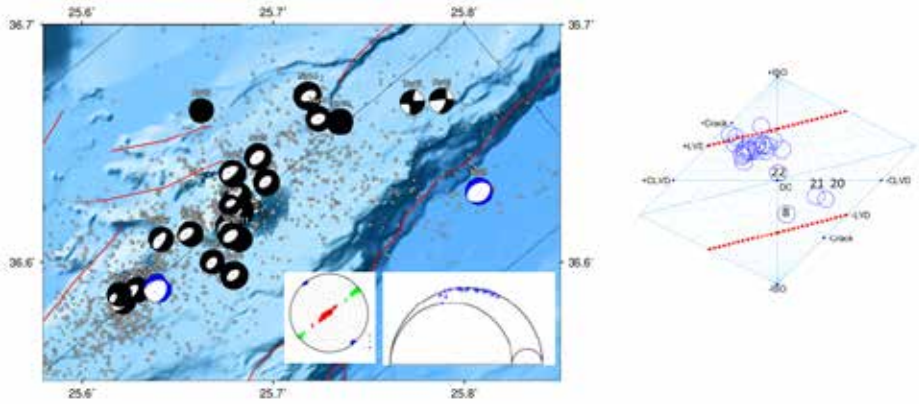

Figure 2. Left: Regional map with "beachballs" for the herein derived full moment tensors. Faults (red lines) are from the NOAFAULTS v5.0 database (Ganas, 2023). In the two insets, the principal stress axes (s_1 red, s_2 green, and s_3 blue) and the Mohr's diagram are shown. Right: Hudson's source type plot of the 25 analyzed earthquakes. No 8 is a poorly resolved event.

Table 1. ISO, CLVD and depth are given with their 15.87%, 50% (median; in bold), and 84.13% percentiles. Mw, and strike/dip/rake angles refer to the median MT. "No" is an internal numbering of events in this study. CLVD with question mark (?) is a value modified by a few percent to have the same sign as ISO, as required in the STC model. Events 1-19 were inverted in depths 7-20 km (step 1 km), events 20-25 in depths 1-20 km (step 1 km). Shaded No. 8 is a poorly resolved event. Shown in red are the two shear-compressional events; all the others are shear-tensional.

Data and Resources

Regional waveform data used in this study were obtained from the Hellenic Unified Seismic Network (HUSN) networks, HL, DOI:10.7914/SN/HL, HC, DOI:10.7914/SN/HC, HP, DOI:10.7914/SN/HP and HA, DOI:10.7914/SN/HA. Data from the HL, HC, HP, and HA networks can be accessed through the National Observatory of Athens (NOA) EIDA node https://eida.gein.noa.gr/ (Evangelidis et al., 2021). The data set of full moment tensors of the present study is archived in Zahradník et al. (2025b). The ISOLA software can be downloaded from https://geo.mff.cuni.cz/~jz/for_ISOLAnews/ and https://github.com/esokos/isola/tree/master (archived in Zahradník et al., 2025c). For Stressinverse code of Vavryčuk (2014), see https://www.ig.cas.cz/en/stress-inverse/. The maps were generated using the Generic Mapping Tools v.6, https://www.generic-mapping-tools.org/download/.

Acknowledgements

The authors would like to thank I. Fountoulakis and C. Evangelidis for valuable discussions and for providing the crustal velocity model. We also thank A. Lomax for sharing his location results. Special thanks to all the Greek colleagues who maintained networks, deployed new and processed all sorts of data during this remarkable sequence. The code sti2MT.m for the STC model and related routines written by V. Vavryčuk were used. J.Z. was supported by the Czech Science Foundation (grant 23-06345S). E.S. was supported by the "TowaRds AdvaNced multidiSciplinary Fault ObseRvatory systeMs²" (TRANSFORM²) project, (101188365 HORIZON-INFRA-2024-DEV-01-01.

(1) Aristotle University of Thessaloniki, Department of Geology, Thessaloniki, Greece, tzanai@geo.auth.gr , (2) University of Patras, Department of Geology, Patras, Greece , (3) University of Patras, Department of Civil Engineering, Patras, Greece

Research Highlights

- Reconstruct the environmental evolution of the Mesolongi lagoon, revealing transitions between freshwater-influenced, brackish, and marine-dominated systems over time.
- Integrated micropaleontological, sedimentological, and geotechnical analysis to uncover ecological dynamics and depositional changes.

Background and Objectives

Coastal lagoons such as Mesolongi lagoon are critical ecosystems that record environmental and climatic changes through their sedimentary archives (Khadraoui et al., 2019). Foraminifera and ostracods, as sensitive bioindicators, provide key insights into these transformations due to their responsiveness to palaeoenvironmental factors such as salinity, oxygen, and sedimentary conditions (Frenzel & Boomer, 2005; Milker et al., 2009; Murray, 2006). This study examines a 21-meter borehole core to reconstruct the Mesolongi lagoon's paleoenvironmental history and identify factors driving its ecological and depositional changes. Geotechnical parameters are also examined to check whether these are affected by ecological and depositional changes and if there is any correlation with micropaleontological parameters.

Figure 1. General satellite view of the study area, showing the borehole sampling exact location, in respect to Mesolongi lagoon, Klisova Lagoon and the Gulf of Patras.

Methods

A multiproxy approach was employed, integrating sedimentological, micropaleontological, and geotechnical analysis. Sedimentological studies characterized lithological variability of the studied sequence, while geotechnical parameters—including plasticity index (PI), undrained shear strength (S_u or q_u), natural moisture content (w), and consolidation parameters—were assessed to interpret substrate physical properties and deformation values. Micropaleontological analysis identified and quantified foraminiferal and ostracod assemblages, with diversity

indices (e.g., species richness, dominance, and evenness) calculated to track ecological shifts. Data was analyzed using Past4.03 software and visualized with Tilia, allowing for stratigraphic interpretation and paleoenvironmental reconstruction.

Results/Discuss

Four stratigraphic units were identified, reflecting distinct environmental phases:

Unit A: Freshwater-Influenced Brackish Lagoon (20.9–15.4 m):

- Dominated by *Ammonia tepida* and *Cyprideis torosa*, indicative of brackish conditions (Altınsaçlı et al., 2015; Debenay et al., 1998; Murray, 2006). However, the presence of freshwater ostracods, such as *Candona* spp., *Fabaeformiscandona* spp., and *Potamocypris fulva*, provides evidence of freshwater inputs influencing the lagoon environment (Altınsaçlı et al., 2015; Frenzel & Boomer, 2005).
- Geotechnical properties revealed a soft to stiff silty-clayey material (CL, ML) with moderate plasticity and undrained shear strength (qu) values which characterize normal consolidated substrate in the depositional environment.

Unit B: Transitional Brackish-Marine Environment (15.4–9.4 m):

- Subunit B1 (15.4–12.8 m): Characterized by an increase in planktonic foraminifera, indicating a stronger marine influence and enhanced water exchange with open sea environments. The dominance of these microfauna reflects a clear shift away from the brackish conditions observed in Unit A.
- Subunit B2 (12.8–9.4 m): Features the notable presence of epiphytic species such as *Rosalina globularis* and *Triloculina trigonula* (Triantaphyllou et al., 2005; Wilson, 2007), which thrive in well-oxygenated environments with vegetation. This subunit also includes localized occurrences of organic material and shells, further suggesting a dynamic interaction between marine and lagoonal conditions.
- Across Unit B, the non-plastic behavior and the decreasing plasticity index (PI) highlight a transition to sandier, less cohesive deposits, such as silty sands (SM) with low oedometric modulus of deformation (Es). These changes correspond to a depositional environment influenced by stronger marine incursions, resulting in reduced clay content and greater permeability.

Unit C: Marine-Dominated Lagoon (9.4–6.1 m):

- This unit reflects a significant marine influence, as evidenced by the high abundance of planktonic foraminifera. The presence of terrestrial material at a depth of 9 meters strongly suggests a washover event, likely caused by storm surges or high-energy waves breaching the lagoon's barrier. This event would have introduced marine water and sediments into the lagoon, altering its ecological and sedimentological dynamics.
- The geotechnical profile highlights the impact of this shift. In the lower part of Unit C, PI and w are relatively low, while Pc (pre-consolidation pressure) and σ'v (effective vertical stress) are moderately high. These characteristics suggest compacted, coarse-grained sediments such as sands and silty sands, deposited under moderately high-energy conditions, likely linked to washover events or barrier breaches introducing marine sediments. In the upper part, a slight increase in PI and w, along with a moderate decrease in Pc and σ'v, indicates a gradual transition to finer-grained, less compacted sediments like silts or clays. This shift reflects reduced depositional energy and overburden stress, corresponding to a more stable and calmer environment as high-energy marine influences diminished overtime.

Unit D: Evolved Lagoonal System (6.1–2.2 m):

Subunit D1 (6.1–4.5 m):

- Represents a stable brackish lagoonal phase, dominated by *Ammonia tepida* and *Cyprideis torosa*, with consistent representation of brackish foraminifera like *Haynesina germanica* and *Quinqueloculina seminulum* (Murray, 2006).
- Geotechnical properties, including moderate PI (Plasticity Index) and w (natural moisture content), reflect cohesive silty clay deposition under stable, moderate-energy conditions that supported a diverse ecosystem.

Subunit D2 (4.5–2.2 m):

- The sharp increase in *Loxoconcha elliptica*, combined with a decline in miliolids, indicates a transition from stable to more stressful environmental conditions. The high abundance of *L. elliptica* suggests the presence of detritus-rich substrates, which support this species (Altınsaçlı et al., 2015). Additionally, the small but notable occurrence of low-oxygen foraminifera points to declining oxygen levels, further reflecting a shift toward environmental stress. These faunal patterns suggest a lagoonal environment experiencing salinity fluctuations, oxygen depletion, and seasonal variations, contributing to ecological instability.
- Increasing PI (Plasticity Index), w (natural moisture content) and eo (voids ratio), alongside decreasing γb (bulk density) and very low oedometric modulus of deformation (Es), indicate the deposition of softer, organic-rich silty clays under lower-energy conditions. These changes in sediment characteristics align with the faunal evidence of a more dynamic and stressful lagoonal phase.

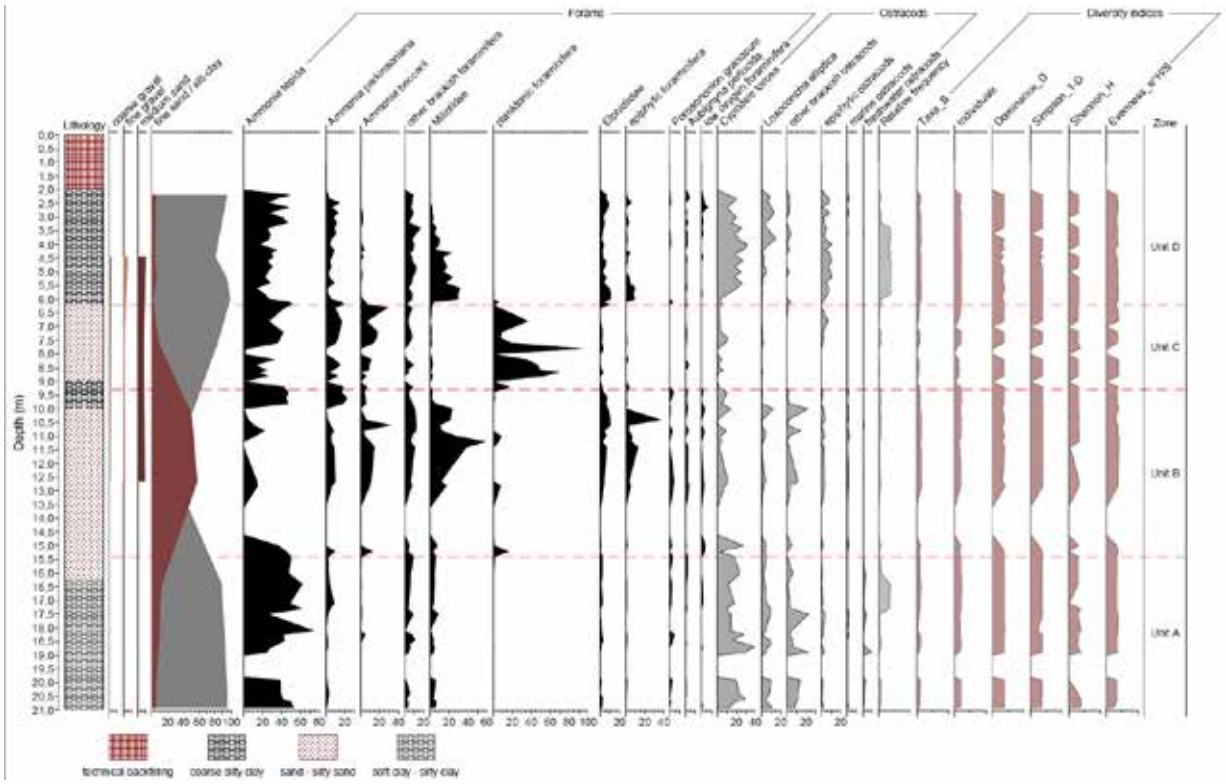

Figure 2. Relative abundances (%) of the identified foraminiferal and ostracod taxa in the samples, alongside log-transformed relative frequency (taxa/g) and diversity indices, integrated with lithology and granulometry.

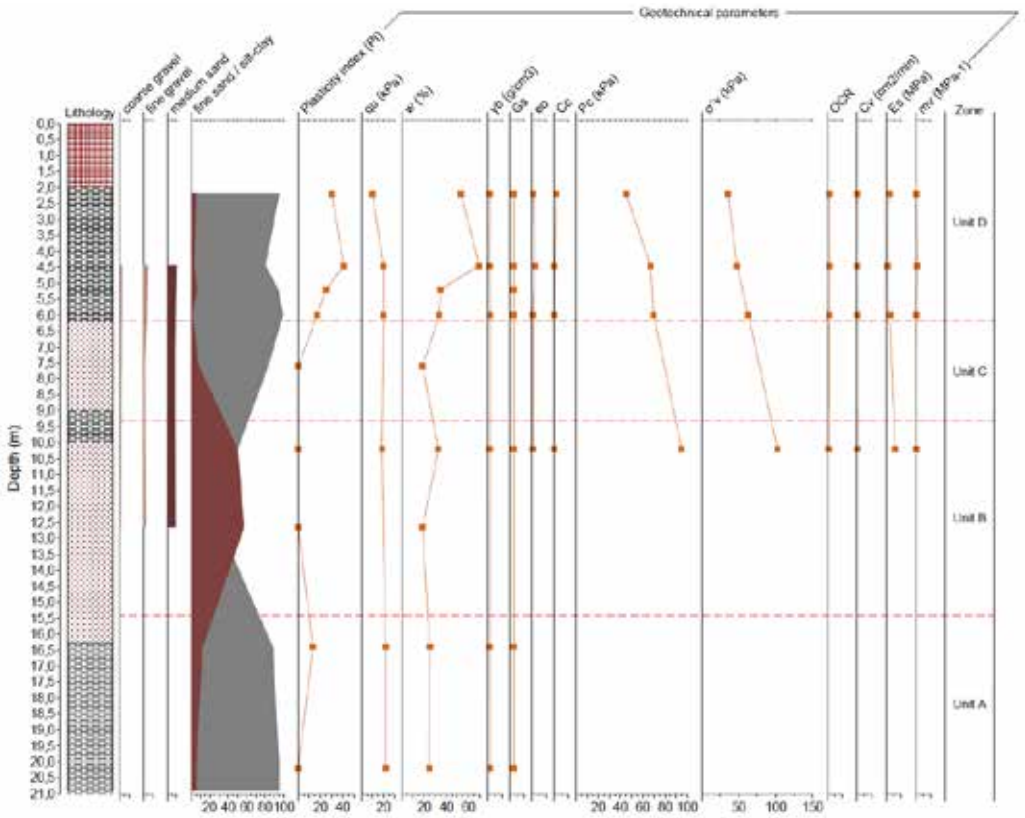

Figure 3. Figure 3 presents the values of the geotechnical parameters throughout the stratigraphic column, except for the consolidation parameters (σ΄v, OCR, Cv, Es,mv), which were examined only within the first 10 meters.

Conclusion

This study demonstrates the integration of sedimentological, micropalaeontological, and geotechnical analyses to reconstruct the palaeoenvironmental evolution of the Mesolongi Lagoon and provides an interesting and rather uncommon correlation between the different datasets. The findings highlight the utility of foraminifera and ostracods as bioindicators for interpreting environmental changes and sediment dynamics. By examining geotechnical parameters throughout the stratigraphic column, alongside lithological and granulometric data, this research provides critical insights into the lagoon's historical environmental conditions and resilience. Further exploration of consolidation parameters in deeper strata could enhance the understanding of sediment behavior and coastal processes in similar lagoon systems. Interestingly, micropalaeontological data and palaeoecological interpretations correlate well with geotechnical data.

Abstract
Southeast Mediterranean is characterized by the presence of nappes that overthrusted the authochonous Plattenkalk series, during Oligocene to early Miocene. South of Crete, the Hellenic Trench (HT) and the Mediterranean Ridge (MR) were developed during the late Miocene. By Messinian time, most of the MR had been already formed and rose above the neighboring abyssal plains. On the elevated portion of the MR, where fields of mud diapirs (volcanoes) have been discovered, the Messinian layer is significantly thinner than on its deeper southern flank. The comparison of western Greece and western Ionian basin with Gythion/Sparta and Crete Island regions with the Plattenkalk series, showed the same depositional conditions, introducing equivalent depositional conditions between Ionian Basin (western part) and the Plattenkalk series, in south Peloponnesus and Crete Island. Therefore, Crete Island could represents the Ionian basin whereas the HT could be the equivalent of the Apulian Platform Margins (APM); whereas the MR could represents a platform, equivalent to the Apulian Platform (AP). During the Oligocene compressional regime, the Crete Island represents the wedge top area, the Hellenic trench the foredeep area and the area of Mediterranean ridge could be the fore bulge area. Later and during the late Miocene migration of compressional regime southwards the MR represents the wedge top, northwards the HT the extensional backstop areas (e.g. Gavdos Trench), and southwards the Sirte abyssal plain the new foredeep. The presence of nappes in SW Peloponnesus, only in Pylos area, shows how the strike-slip faults influence the nappes development. Furthermore, the presence of reefs, according EDDEY in 2018 announcements, reefs must be developed on the MR. The question is if the nappes overstepped the HT (when they were the APM) and covered the MR (when they were the AP)? or the nappes filled up only the HT and therefore the MR now is without any nappe?
Keywords: *Mediterranean Ridge, Apulian Platform, Ionian Basin, Plattenkalk Series, Nappes*

Introduction
Over the last 80 Myr, the Alpine-Himalayan belt represents the most spectacular result of the relative motion between the African and Eurasian plates (Olivet et al., 1982). The MR, which arises from the same plate motion (at a rate in the order of 10 mm/yr), can also be considered as a direct consequence of this plate kinematics (Jackson et al., 1992). The MR, the principal structure in the Eastern Mediterranean, stretches from the Calabrian Rise in the west to the Florence Rise in the east, a distance of 1500 km. Its width changes from about 150 to 300 km, and it has an arcuate southward convex shape, almost parallel to the Hellenic Arc. The average water depth on the MR is about 2.1–2.2 km, varying between 1,200 m and more than 3,000 m. The MR rises 1–2 km above the surrounding seafloor, but because of its large width the general slope, angles rarely exceed 20°. The Ridge is bordered on the north by a number of deep and narrow trenches forming the Hellenic Trench (HT) system (Le Pichon et al., 1982) (Figure 1). Between the Hellenic trench system to the north and the MR crustal domain (chiefly west of the Matapan Trench), a wide area known as the “flat inner zone” (Truffert et al., 1993) extends at 2500–3000 m water depth. South of Crete, particularly south of the island of Gavdos, this flat domain becomes progressively narrower towards the east and the MR central domains appear almost in contact with the Poseidon and Strabo trenches (Leite and Mascle, 1982). The southern boundary of the MR is delineated by a chain of flat abyssal plains adjoin to the African margin. Their depths decrease in general from west to east and they consist of the Messina (Ionian) (4,140 m), the Sirte (4,149 m), and the Herodotus A.P. (3,225 m) abyssal plains. The ridge topography is generally dominated by small, closely spaced depressions and ridges, with a relief of 50–100 m and a wavelength 0.5–2 km, that are mostly parallel to the Ridge trend. These features were attributed both to tectonic deformations displayed in the seafloor relief and to karst forms resulting from dissolution of the shallow lying Messinian evaporites (Belderson et al., 1978). This relief creates hummocky hyperbolic acoustic reflections when using conventional echo sounding devices, and is known as “cobblestone topography “(Hersey, 1965).

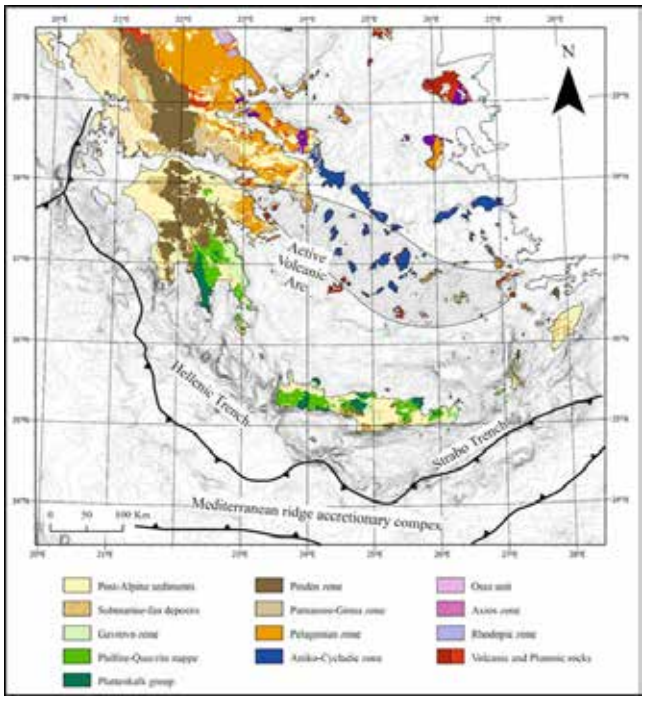

Figure 1. Geological map of southern Greece showing the geotectonic zones and especially the Plattenkalk series, Hellenic Trench and the Mediterranean Ridge (Maravelis et al., 2022).

The MR is characterized by mud diapirs, with the first Mud volcano (MV) identified on the Ridge was named Prometheus and is located southwest of Peloponnesus. MV and mud cones have since been identified and cored (Cita et al., 1989) in three other areas (Prometheus-2; Olimpi, and Pan di Zucchero) also located in the Inner portion of the crustal area of the M.R. accretionary complex. Seismic refraction data and expanding spread seismic reflection experiments, as well as gravity modeling, indicate that the MR consists of a thick (up to 10 km) pile of sediments (Truffert et al., 1993) representing a huge sedimentary accreted wedge (Kastens et al., 1992).

The subduction in the Hellenic trench is complex: in the west, where a frontal subduction takes place in the trench, only the lower level of the sedimentary cover is subducted while the upper one is scrapped off and accumulated in the giant accretionary prism, the M.R., which is under a strong compressional stress. East of 25°E the movement at the plate boundary becomes more of a left lateral displacement. The Pliny Trench, which is also a sinistral shear zone, is treated as the trace of an earlier stage of the subduction zone. Such a pattern of compressional and shear stresses defines the step-like plan shape of the H.T.S. (Huchon et al., 1982). The subduction began about 13 Ma ago in the Late Serravallian (Le Pichon and Angelier, 1979), and as a result, the residual Tethys oceanic basin has been closed completely between Crete and Cyrenaica. M.R. is a large sedimentary wedge involving the upper 4 km of the sedimentary basins. It has also been proposed that the present backstop had been formed in Middle Miocene time by the outward migration of the Hellenic nappes between 20 and 15 Ma (Le Pichon et al., 1982).

The aim of this study is to analyze the geological characteristics of this accretionary wedge system in order to reveal its possibility to be equivalent to the Apulian Platform and to become an important hydrocarbon province and to suggest parts for further research. Undoubtedly, information given in this study is a preliminary approach and further, in-depth research is required to define the petroleum prospectivity of this spectacular feature. Remote sensing, seismic and wireline log data, as well as cores and fluid samples from wells should be integrated to define the exact thickness and lateral extent of the possible seal, reservoir and source rocks, and the trap style.

Geological Setting

Southeast Mediterranean, from Crete Island as far as Libya territory, is characterized by the presence of nappes that overthrusted the authochonous Plattenkalk series, during Oligocene to early Miocene. South of Crete, the Hellenic Trench (HT) and the Mediterranean Ridge (MR) were developed during late Miocene. The MR accretion started at the same time as the HT system subduction began. By Messinian time, most of the MR had been formed already and rose above the neighboring abyssal plains. On the elevated portion of the MR, where fields of mud diapirs (volcanoes) have been discovered, the Messinian layer is significantly thinner than on its deeper southern flank.

The Plattenkalk series represent the autochthonous or para-autochthonous series outcropping in Gythion-Sparta region, south Peloponnesus, and along the Crete Island, and is considered as the equivalent to the Ionian zone. The PS is characterized as

high-pressure low temperature metamorphic series deposits, and comprise generally a carbonate sequence up to 5km thick that deposited in a period of about 300 m.y. The stratigraphy of the Ionian Basin (IB) in western Greece, and especially for the part of upper Triassic to lower Jurassic, consist of Triassic evaporites that pass upwards to Triassic breccia and the Foustapidima limestones and finally to Pantokrator limestones. Under the Triassic evaporites there are the Paleozoic deposits, but they don't outcrop in western Greece. According the literature it seems that the evaporitic breccia and Foustapidima limestones could be or could represent source rocks whereas the Pantokrator limestones represent the reservoirs.

In Gythion-Sparta region, PS consists of dolomites, crystalline limestones and massive marbles, up to 500m thick. These deposits are compared with Pantokrator limestones of western Greece, and rest unconformably over Permian? to lower Triassic Phyllite basement, with up to 500m thick outcropped deposits. The characteristic event for this region is 1. The absence of Triassic evaporites, and 2. The unconformably overlying of upper Triassic to lower Jurassic deposits to Paleozoic (Permian) deposits.

In Crete Island, PS consist of upper Carboniferous-lower Permian to Eocene age deposits. Metamorphic conditions took place during Oligocene to upper Miocene in HP-LT conditions. There are differences from west to east and from north to south. In detail Plattenkalk series consist of dolomites and dolomitic limestones with an outcropped thickness up to 800m (Iraklion and Rethymnon geological sheets). In middle Crete (Perama and Vrisses sheets) of dolomities and dolomitic limestones of upper Triassic to lower Jurassic, with up to 300m thickness, and banded recrystallized dolomitic stromatolites of middle Triassic, up to 150m thick (Perama sheet) or of recrystallized limestones to marbles and dolomites up to 100m thick (Vrysses sheet). In western Crete (Palaeohora sheet) of Upper Triassic variegated formation of schists, recrystallized limestones and quartzite, up to 100m thick, recrystallized limestones and dolomites, up to 300m thick, and Evaporites, with an outcropped thickness up to 300m. The characteristic regime in Crete is the High-pressure low temperature metamorphism of the entire rocks. This metamorphic conditions reduced from west to east of the Island. In Crete Island, there are two different assemblages, the autochthonous Ionian Basin deposits (Plattenkalk series and Phyllite-Quartzite series) and the allochthonous nappes of Tripolitsa, Pindos and Pelagonian zones. The Ionian Basin (IB) comprises Triassic clastic rocks overlain by Mesozoic limestone and late Eocene to Miocene flysch (~35–10 Ma) (Jacobshagen, 1986). The two main nappes making up the Ionian Basin are the P-Q and the underlying Plattenkalk, both of which constitute the high-P belt of the External Hellenides on the Peloponnese and Crete (e.g., Jolivet et al.; Marsellos et al., 2010; Papanikolaou & Vassilakis, 2010). The Cretan Detachment tectonically separates the non-high-P nappes from the underlying, 24–21 Ma high-P rocks of the Ionian Unit (Fassoulas et al., 1994; Jolivet et al., 1996; Kilias et al., 1994; Thomson et al., 1998).

The entire nappe pile has been thrust over the Mediterranean Ridge Accretionary Complex, which started to form at or before 19 Ma and was and still is being underthrust beneath Crete at the leading edge of the overriding plate (Kokinou et al., 2012; Kopf et al., 2003). The present crustal thickness of western Crete is ~ 40–50 km and the bottom 20–30 km of this crust are interpreted to be newly accreted sediments (Knapmeyer & Harjes, 2000). This suggests that high-P rocks are currently forming beneath Crete. Due to its enormous size, M.R. cannot be structured by a unique and stable stratigraphy. It is characterized by the absence of Triassic evaporites in contrast to the external Hellenides.

Several trap styles may be present within the potential M.R. petroleum province, including both structural and stratigraphic traps. Structural Traps may include traps formed by (1) compressive tectonic processes and (2) diapiric processes. Compressive tectonic processes commonly lead to the development of large-scale contractional folds and thrusts. Such contractions are common in convergent plate boundaries (e.g., M.R.) leading to the development of major trap anticlines. Diapiric processes lead to upward movement of both salt and mud can create anticlinal structures that could form petroleum traps. Stratigraphic Traps referred to the Messinian evaporites within the M.R. overly, either directly or unconformably, typical basinal, hemipelagic, pelagic, and turbiditic sediments can lead to the creation of truly massive traps (Maravelis et al., 2015).

Microfacies analysis

From both regions (Sparta-Gythion and Crete) has been selected thirty samples (eighteen samples from Sparta-Gythion and twelve samples from Crete) for micropaleontological analysis. The general description of the thin sections is that the samples are crystalline and metamorphosed and therefore no facies zone identification could be made. Specifically, only two samples from Crete Island have been recognized as evaporitic of brackish and Platform-margin sand shoals facies zones.

Facies analysis showed a platform environment within the Plattenkalk-Ionian basin. Although the evolution of the Ionian basin during the rift stage showed the presence of grabens and highs, until now we have not found any sample showing the platform environment in west Greece. Our explanation is that as normal faults, with east dipping direction, re-activated as thrust faults the platforms overstepped by the accretionally prisms, of the above thrusts, and now are lying under the pelagic limestones of the grabens.

Rock eval analysis

Total selected samples two hundred and five (205) for TOC analysis. Results organized into three different areas: Western Greece, Southwestern Peloponnese and Crete Island. All samples are organized into three-age time span: Paleozoic, Upper Triassic-Lower Jurassic (below Pantokrator limestones) and Upper Jurassic-Eocene.

These results showed in general that samples are poor in TOC content, but taking into account the fact that the Plattenkalk series

is strongly metamorphosed, the presence of at least twenty samples with high TOC content in specific areas lead us to study in detail the above areas.

Approaching the basin evolution

In light of our results two scenarios were build up, the first scenario that is proposed consider that the PS deposits further to the west and south of the Crete Island, if exist, could represent a potentially new source rocks, due to the burial history differences, and furthermore in metamorphic conditions. Hellenic Trench could be the equivalent of the Apulian Platform Margins; whereas Mediterranean Ridge could be a platform, equivalent to the Apulian Platform.

Therefore, the areas west of Sparta-Gythion region and south of Crete Island could represent the equivalent to APM in western Greece, and as a result, the nappes could wedged out or partly overstepped the Platform Margins. The above fact shows different elevation indicating lower metamorphic conditions in the Hellenic Trench and probably without metamorphic conditions in the Mediterranean Ridge.

According to Palamakumbura, et al. (2012), who deals with the Geochemical, sedimentary and micropaleontological evidence for a Late Maastrichtian oceanic seamount within the Pindos Ocean (Arvi Unit, S Crete, Greece), the presence of Apulian Plate is shown south of the existing Ionian Basin (mentioned as Ida-Ionian through) during Cretaceous time.

In the same sense, Accordi et al. (2014) presented in their figure 1a the presence of the African plate west of the Hellenic arc.

Therefore, for this first scenario, the indicated models for deformation – movements presented in figure 2 are: A: for West Greece, B: for Peloponnesus (Pylos area) and C: for west Crete Island).

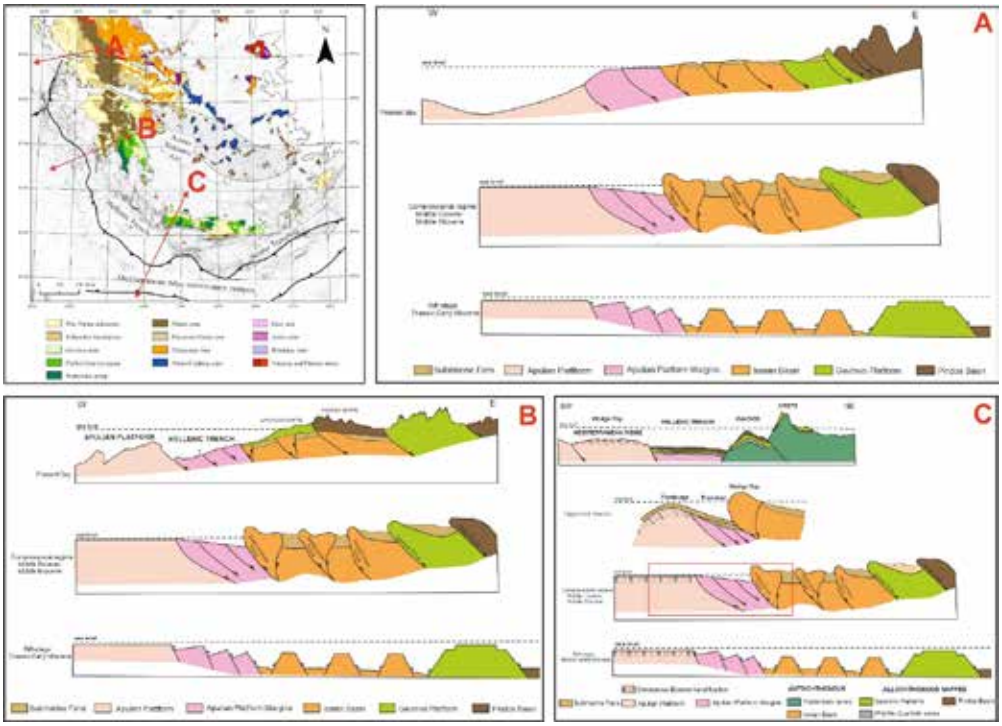

Figure 2. Indicated models for the deformation – nappes movements: A. for West Greece, B for Peloponnesus (Pylos area) and C for west Crete Island).

The application of this scenario for the Pylos region (Figure 3) introduce that parts from Gavrovo platform Pindos unit, must be nappes that moved from east to west and rest now unconformably over the Ionian basin.

The second scenario, supported from few evidences, is that Mediterranean Ridge could corresponds to the external Ionian sub-basin, as this presented for west Greece, and Crete Island the middle Ionian sub-basin (there are not data for Sparta-Gythion areas).

The facts that support this idea are: Crete Island was uplifted during Oligocene as the accretionally prism of a thrust fault, equivalent with middle Ionian sub-basin in western Greece. Therefore, the nowadays-Hellenic Trench could be the foreland basin of the middle Ionian thrust. Later and as the subduction migrated southwards during middle Miocene the MR representing the accretionary prism of this subduction could be equivalent to the external Ionian sub-basin in the west Greece.

The second scenario, supported from few evidences, is that Mediterranean Ridge could corresponds to the external Ionian sub-basin, as this presented for west Greece, and Crete Island the middle Ionian sub-basin (there are not data for Sparta-Gythion

areas).
The facts that support this idea are: Crete Island was uplifted during Oligocene as the accretionally prism of a thrust fault, equivalent with middle Ionian sub-basin in western Greece. Therefore, the nowadays-Hellenic Trench could be the foreland basin of the middle Ionian thrust. Later and as the subduction migrated southwards during middle Miocene the MR representing the accretionary prism of this subduction could be equivalent to the external Ionian sub-basin in the west Greece.

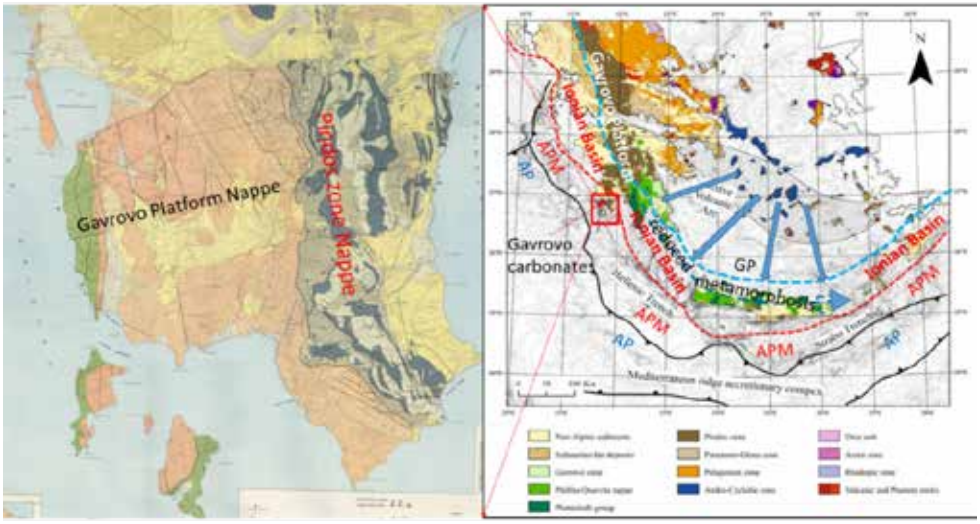

Figure 3. Geological of southwest Peloponnesus (Pylos region), where both Gavrovo and Pindos units overstepped the Ionian unit.

Support to this scenario is the fact that from the only two-studied thin section it seems that Crete Island Mesozoic sequence represents shallow water deposits and not deep-water conditions.
If this scenario will be acceptable then it is clear that:
1. The width of the Ionian basin was at least double in size in Crete in relation with the western Greece, and could be the original width of the Ionian basin.
2. The Ionian basin, during rifting stage was sub-divided into grabens and highs,
2. The nappes in Crete overstepped the Ionian basin without to shorten it and for this reason, some of the Ionian basin highs outcropped in Crete. The explanation of the highs absence in western Greece is that due to thrust activity the highs overstepped and now lies under the accretionary prism, beneath the mountains.

Conclusion.

A. Tethys during upper Triassic to lower Jurassic represent a shallow restricted basin, and analysis of the deposits from southern Peloponnesus and Crete Island, indicate that Tethys in the studied areas was very narrow. It seems that the above studied areas were very close to brackish conditions, where there was a high concentration of organic matter, and for this reason, it shows some differences in the bitumen content from the other areas. During upper Jurassic to Eocene, the basin is characterized by rifting with Ionian Basin sub-division into three sub-basins with characteristics of grabens and highs.
B. The Ionian basin width, in the area of nappe presence, is wider than in the western Greece where the basin shorted due to the compression of the Hellenic orogeny.
C. Plattenkalk series samples are strongly recrystallized, in all regions, although they present different metamorphic influences.
D. Rock-eval analysis, in all studied samples, organized into three different time spans: Paleozoic, Upper Triassic-Lower Jurassic, Jurassic-Eocene, could serve as source rocks. The underlying the metamorphic Plattenkalk series, the Paleozoic deposits, showed that there are many black horizons with high TOC content, in some of them. The fact that many black horizons are poor in TOC content could be related with the metamorphic conditions (high temperature values). The Upper Triassic-Lower Jurassic sequence (as far as Pantokrator limestones) was studied for Triassic breccia and Foustapidima limestones, and showed that there are quite interesting horizons in the studied areas. In detail, in Crete Island the richest deposits referred to the Triassic breccia, in the western part of the Island, and the Foustapidima limestones to the northern part of the Island. The Upper Jurassic-Eocene sequence, was studied for the Jurassic schists with Posidonia and the Cretaceous (Vigla shales), and showed that there are many rich horizons and especially in the areas of probably lower metamorphosis such as the eastern part of Southwestern Peloponnese and the Northern part of Crete Island, probably due to lower metamorphic conditions.
E. As the key points for the MR and the HT are their evolutionary conditions, during the compressional phases, it is very crucial for oil companies (in this case for EXXON and CHEVRON Oil Companies) to understand the depositional conditions of the HT

and MR, both during the syn-rift stage and the compressional phases. The question we tried to answer is about the nappes movements and the areas that they covered. The nappes overstepped the HT (when they were the APM) and covered the MR (when they were the AP) or the nappes stopped in the HT and never covered the MR.
F. Therefore the M.R. could be the equivalent Apulian Platform or could be the external Ionian sub-basin basement, and the Hellenic Trench could be equivalent with Apulian Platform Margins or represents the middle Ionian sub-basin foreland basin during Oligocene.

The trace fossil *Zoophycos* as an indicator for the Apulian Platform Margins evolution during Eocene in Lefkas Island

Zelilidis P.[1], Uchman A.[2], Iliopoulos G.[1], Dalgkitsi P.[3], and Bourli N.[3]

(1) University of Patras, Department of Geology, Laboratory of Paleontology and Stratigraphy 26504, Patras, Greece. zelilidis2001@gmail.com, (2) Faculty of Geography and Geology Institute of Geological Sciences, Jagiellonian University, Gronostajowa 3a, 30-387 Kraków, Poland., (3) University of Patras, Department of Geology, Laboratory of Sedimentology, 26504, Patras, Greece.

The Apulian Platform Margin (APM), situated between the Apulian Platform to the west and the Ionian Basin to the east, are outcropped in Lefkas Island, on the Ionian Sea, and are characterized by the presence of Jurassic to Eocene deposits. During the middle Miocene, the Ionian Thrust activity produced narrow foreland basins between the Ionian Basin and the Apulian Platform, where carbonate sub-marine fan deposits were accumulated. The APM representing the forebulge area of the Ionian foreland was strongly deformed. The studied section with a NE-SW direction is cross cut by many faults. Some of the faults showed synsedimentary activity and were responsible for the deformation within the outcrops. Bedding planes present an eastward dipping direction, up to 70° angle. In the studied Eocene carbonates, up to 400 m total thickness, the facies analysis showed the presence of four different types of deposits, i.e., pelagic calcilutites, calcarenites, and debris flow deposits. All of them accumulated in slope and toe of slope facies zones. Their microfacies point to deep sea conditions. Additionally, there are also breccia with angular clasts, indicating an active tectonics and very close source. The presence of siliceous concretions within the carbonates supports the above suggestion. Small lenses of red granule-size breccia, with abundant calcareous algae indicate also a proximity of a platform source. The trace fossils *Trichichnus*, ?Palaeophycus, *Zoophycos*, crinoids and nummulites in calcarenites were recognized. The *Zoophycos* appearance, with normal and reverse positions led to the sub-division of the sedimentary succession into two parts (both up to 200 m thick), the lower one with the normal position, and the upper one with the reverse position. The upper part probably reversed due to an intense giant slumping event during the sedimentation, indicating that the deformation of the APM started earlier than the middle Miocene, time of the Ionian Thrust activity. Although Eocene was characterized by deep-sea conditions, the normal fault activity produced many tectonic pulses with the development of slumps and slides, close to the Apulian Platform. Due to this fault activity, diverse sedimentary material (e.g., large foraminifers) was transported from the close extended platform to the slope or to the toe of the slope.

Abstract

This paper briefly reports the new results on Miocene gymnosperm fossil wood assemblages from Lesvos, including two families and nine genera: Tsuga, Pseudotsuga, Keteleeria, Larix, Pinus, Lesbosoxylon (Pinaceae), Metasequoia, Sequoia, Taxodium (Cupressaceae). Among them, Pinaceae exhibits the highest taxonomic richness, Pseudotsuga, Keteleeria and Metasequoia were found in Greece for the first time. At present, the Lesvos fossil wood flora is one of the Miocene wood floras with highest diversity found in Greece and even in the Mediterranean, which enriches the fossil record of gymnosperms in the Miocene of Greece. The occurrence of abnormal growth rings and traumatic resin canals in Lesvos fossil woods reflects the short-term climate fluctuations, natural hazards or the interaction between plants and the associated organisms in the forest ecosystem. Further study of this fossil wood flora will provide important evidence for understanding the evolution and development history of modern gymnosperms in the Mediterranean as well as their palaeoenvironment and palaeoclimate background.

Key words: Lesvos Petrified Forest, Miocene, Fossil wood, Gymnosperm, Palaeoenvironment

1 Introduction

Plant fossils constitute exceptional archives for investigating terrestrial ecosystem dynamics and palaeoenvironmental evolution throughout geological history. As durable biogenic structures, they provide critical evidence for reconstructing palaeoclimatic parameters and vegetation responses to environmental shifts (Creber and Francis, 1999; Wang *et al*., 2017). Among various fossil plant remains, fossil wood plays a vital role in exploring the composition characteristics and evolutionary history of fossil floras (Creber and Francis, 1999).

The Lower Miocene petrified forest of Lesvos Island (39°12'N, 26°18'E) (Fig. 1A), preserved within pyroclastic deposits of the North Aegean volcanic province, represents one of the most extensive in situ fossil wood assemblages in the Mediterranean realm (Zouros *et al*., 2004, 2007, 2011; Pe-Piper *et al*., 2019; Zhu *et al*., 2021). This extraordinary preservation event resulted from the rapid burial of standing forests by volcanic ejecta during the Burdigalian (Pe-Piper *et al*., 2019), yielding three-dimensional specimens with intact cellular structures and root systems–a taphonomic phenomenon rarely observed in continental depositional settings.

This study presents a systematic analysis of conifer fossil wood from the new fossil sites along the Kalloni-Sigri road, aiming to: 1) establish taxonomic affinities through quantitative anatomical comparisons, 2) reconstruct the structural composition of Burdigalian forest communities.

2 Geological setting and stratigraphy

The Lesvos Petrified Forest, designated as one of the first 4 European Geoparks in 2000, and a Global Geopark since 2004 preserves one of the world's most remarkable examples of three-dimensional silicified forest ecosystems (Zouros, 2010, 2021). The Lesvos Petrified Forest is the main geological heritage monument of international significance that led to the recognition of Lesvos Island as an UNESCO Global Geopark in 2015. This palaeobotanical Lagerstätte is embedded within the Sigri Pyroclastic Formation (Lower Miocene, ~20–18 Ma), a volcaniclastic succession spanning over 200 m thick that records forest burial events across western Lesvos (i.e. Bali Alonia, Plaka, Nissiopi sites) (Fig. 1B) (Zouros *et al*., 2004, 2007; Zouros, 2004, 2010; Pe-Piper *et al*., 2019). Recent investigations along the Kalloni-Sigri transect have expanded the known spatial extent of fossiliferous outcrops, revealing nine new sublocalities with exceptional stem-root junction preservation (Zouros, 2021; Kafetzidou *et al*., 2022, Zhu, 2024). These discoveries confirm the Sigri Formation as containing the most extensive in situ fossil assemblages in the Aegean region.

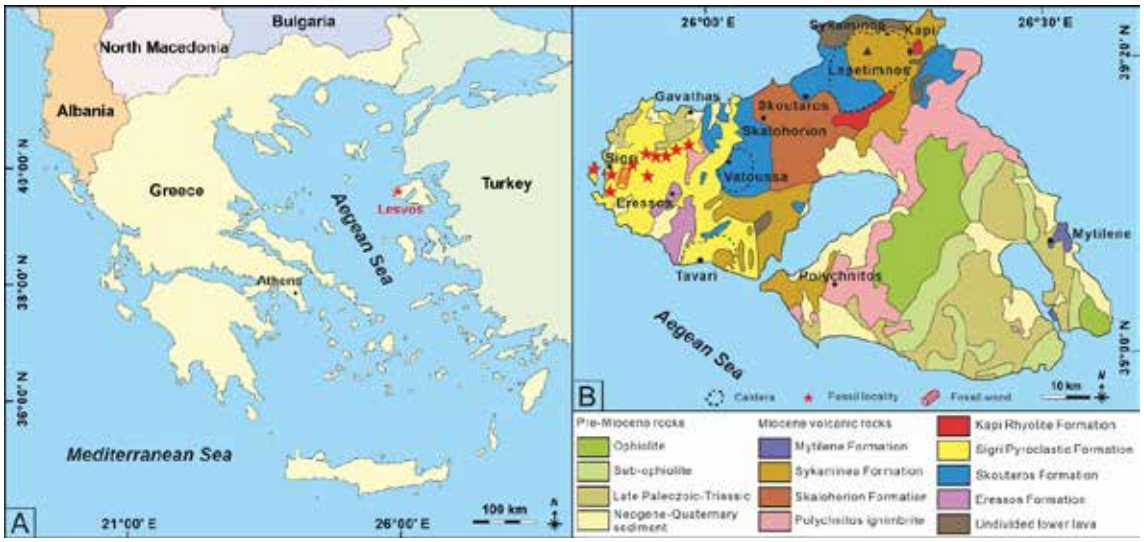

Figure 1. Geographical and geological maps of the fossil locality in Lesvos Island, Greece.
A. Map showing the specific fossil locality within Lesvos Island, Greece (Base map from d-maps (https://d-maps.com)); B. Geological map of the Lesvos Island (Base map modified from Pe-Piper *et al*., 2019).

3 Materials and methods

The fossil woods described in this study were preserved as permineralized wood. They were collected from the Lower Miocene Sigri Pyroclastic Formation in the Lesvos Petrified Forest, Greece. The thin sections in this study were processed by the Natural History Museum of the Lesvos Petrified Forest during the period from 2014 to 2021, and they consist mainly specimens from the fossiliferous sites along the newly excavated Kalloni-Sigri road, this investigation discusses and presents preliminary results for gymnosperms only. Transversely, radially, and tangentially cuts were applied to the investigated petrified wood specimens for preparing thin sections (Hass and Rowe, 1999; Zheng *et al*., 2008). Thin sections were examined under an optical microscope, and photographs were captured based on OPTIKA P20 Pro camera and OPTIKA LITEVIEW software attached to the OPTIKA B-510POL-1 microscope. Anatomical characteristics and geological maps were illustrated and organized with CorelDRAW 2019. All fossil wood and thin sections are housed at the Natural History Museum of the Lesvos Petrified Forest, Lesvos Island, Greece. The descriptive terminology utilized in this study adheres to the recommendations of the International Association of Wood Anatomists (IAWA) Committee (2004).

4 Results

After identification, it can be concluded that the conifer fossil wood assemblages of the Lesvos Petrified Forest contain 9 genera of 2 families: *Tsuga*, *Pseudotsuga*, *Keteleeria*, *Larix*, *Pinus*, *Lesbosoxylon* of the Pinaceae, and *Metasequoia*, *Sequoia*, *Taxodium* of the Cupressaceae.

Systematic Palaeontology

Division: Gymnospermae Prantl, 1831

Family: **Pinaceae** Lindley, 1836

Genus: ***Tsuga*** Carrière, 1855

***Tsuga* sp.**

Description: Specimen number BPY061, Figure 2A–C. Growth ring is distinct, a sharp change from earlywood to latewood, a large number of continuous traumatic resin canals present in the latewood band (Fig. 2A), earlywood tracheids square and polygonal, the latewood band 8–20 cells wide, with a thick, oblong cell wall, with abundant axial parenchyma, tangentially zonate and marginal (Fig. 2A). Earlywood tracheid pitting in radial walls are uniseriate and biseriate, mostly biseriate opposite, crassulae present (Fig. 2B), cross-field pits are cupressoid, also pinoid, 4–6 pits per cross-field (Fig. 2B). Rays uniseriate, ray heights 1–25, mostly 5–18 (Fig. 2C), normal resin canals absent.

Genus: ***Pseudotsuga*** Carrière, 1867

***Pseudotsuga* sp.**

Description: Specimen number TX272, Figure 2D–F. Growth rings are weakly defined, tracheids of the early wood are large and polygonal and thin-walled, axial resin canals are present within the earlywood layer, displaying single distribution along with 8–12 thick-walled epithelial cells (Fig. 2D). The cross-field pit arrangement is piceoid type,

occasionally taxodioid type, the bordered pits on the tracheid walls belong to the abietinean type and are predominantly uniseriate and spaced at a distance (Fig. 2E). Furthermore, longitudinal tracheids show well-developed single and narrowly spaced helical thickenings, with a density of 150–200 coils per millimeter (Fig. 2D, 2E). Rays are uniseriate and fusiform, uniseriate rays in height from 1–13 cells (Fig. 2F).

Genus: ***Keteleeria*** Carrière, 1866

***Keteleeria* sp.**

Description: Specimen number TX302, Figure 2G–I. Growth ring is indistinct with extremely curved abnormal growth ring (Fig. 2G), axial resin canals are present within the earlywood layer, displaying single distribution (Fig. 2G). The cross-field pit arrangement is cupressoid type, occasionally taxodioid type, the bordered pits on the tracheid walls are indistinct (Fig. 2H). Rays are uniseriate in height from 1–30 cells, radial resin canals absent (Fig. 2I).

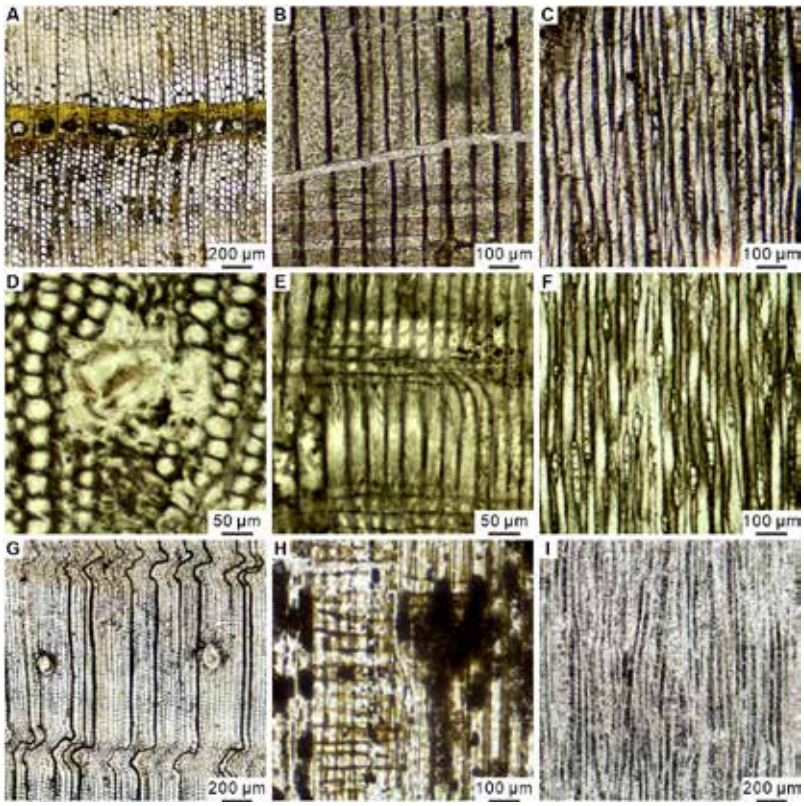

Figure 2. Anatomical characteristics of fossil wood *Tsuga* sp. (A–C, Specimen number BPY061), *Pseudotsuga* sp. (D–F, Specimen number TX272), and *Keteleeria* sp. (G–I, Specimen number TX302) from Lesvos Petrified Forest

Genus: ***Larix*** Miller, 1754

***Larix* sp.**

Description: Specimen number NBA155, Figure 3A–C. Growth rings are distinct, abrupt transition from earlywood to latewood, the presence of a large number of continuous axial resin canals in the latewood band (Fig. 3A), earlywood tracheids square and polygonal, the latewood band 4–8 cells wide, with a thick, oblong cell wall (Fig. 3A). Earlywood tracheid pitting in radial walls are uniseriate and biseriate, mostly biseriate opposite, crassulae present (Fig. 3B), cross-field pits are taxodioid and piceoid, 2–5 pits per cross-field (Fig. 3C). Tangential section absent.

Genus: ***Pinus*** Linné, 1753

***Pinus* sp.**

Description: Specimen number BPY062, Figure 3D–G. Growth rings are distinct, abrupt to gradual transition from earlywood to latewood, axial resin canals present in the latewood band (Fig. 3D), earlywood tracheids are polygonal, the latewood band 4–15 cells wide, with a thick, oblong cell wall (Fig. 3D). Earlywood tracheid pitting in radial walls are predominantly uniseriate, occasionally biseriate, crassulae absent (Fig. 3E, 3F), cross-field pits are window-like, 2–3 pits per cross-field (Fig. 3E). Rays are uniseriate and fusiform with radial resin canals (Fig. 3G).

Genus: ***Lesbosoxylon*** Süss *et* Velitzelos, 2010

***Lesbosoxylon* sp.**

Description: Specimen number TX022, Figure 3H–J. Growth ring is indistinct, earlywood tracheids square-oblong to

polygonal, axially normal resin canals present, resin canals mostly single rounded, scattered in earlywood band (Fig. 3H). Tracheid pitting in radial walls with uniseriate and biseriate, uniseriate detached rounded, biseriate opposite, cross-field pitting commonly pinoid occasionally taxodioid, with a common of 2–6 (2–4) pits per cross-field (Fig. 3I). Rays were mainly uniseriate, fusiform with enlarged secretory cells, and a few fusiform with resin canals (Fig. 3J).

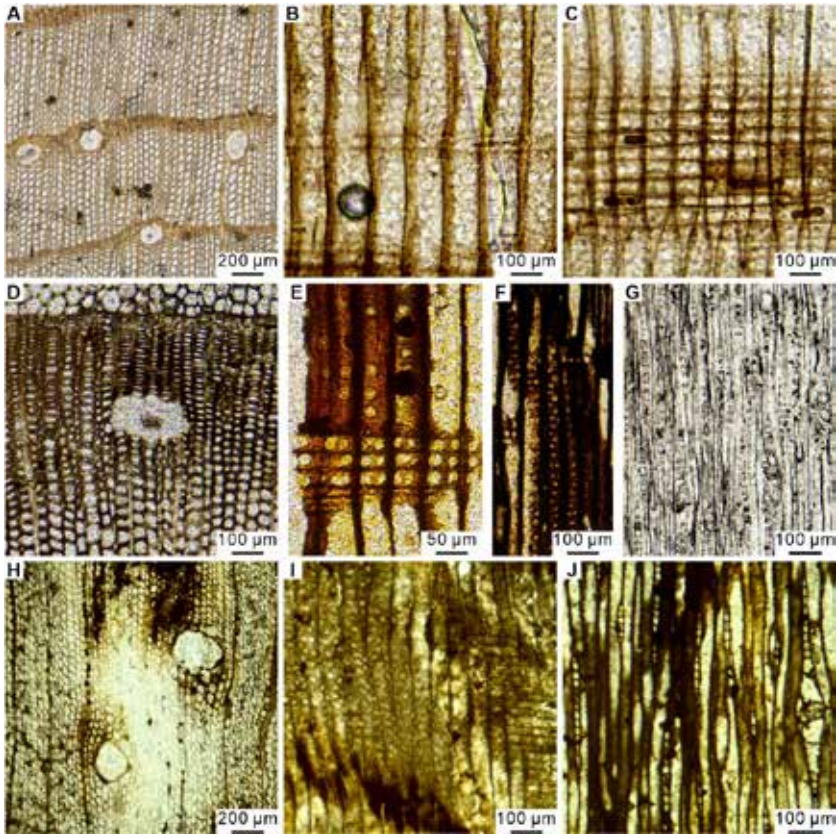

Figure 3. Anatomical characteristics of fossil wood *Larix* sp. (A–C, Specimen number NBA155), *Pinus* sp. (D–G, Specimen number BPY62), and *Lesbosoxylon* sp. (H–J, Specimen number TX022) from Lesvos Petrified Forest

Family: **Cupressaceae** Bartling, 1830

Genus: ***Metasequoia*** Miki ex Hu *et* Cheng, 1941

***Metasequoia* sp.**

Description: Specimen number TX024, Figure 4A–E. Growth ring is obvious and transition from earlywood to latewood is gradual (Fig. 4A). The early wood tracheids are mostly square polygonal, and no resin canals are observed, the late wood band is very narrow, only 1–3 tracheids wide (Fig. 4A). Cross-field pitting taxodioid, 1–6 (mostly 2–3) pits per cross-field (Fig. 4B). The bordered pits on the radial walls in 1–3 seriates, mostly opposite in 2–3 seriates (Fig. 4C, 4D). Rays are mostly uniseriate, 1–60 cells in height, mostly 6-30 cells high (Fig. 4E).

Genus: ***Sequoia*** (David Don) Endlicher, 1847

***Sequoia* sp.**

Description: Specimen number TX047, Figure 4F–I. Growth ring is evident and transition from earlywood to latewood is abrupt (Fig. 4F). The early wood tracheids are mostly square polygonal, axial parenchyma rare, traumatic resin canals present (Fig. 4F). Cross-field pitting is taxodioid, 2–4 pits per cross-field (Fig. 4G). The bordered pits on the radial walls in 1–3 seriates, mostly opposite in 2–3 seriates (Fig. 4H). Rays are mostly uniseriate, 1–50 cells in height, mostly 6-30 cells high, occasionally ray up to 12 cells wide (Fig. 4I).

Genus: ***Taxodium*** Richard, 1810

***Taxodium* sp.**

Description: Specimen number TX301, Figure 4J–M. Growth ring is distinct and transition from earlywood to latewood is abrupt, the early wood tracheids are mostly square and oblong, axial parenchyma abundant, diffuse, and tangentially zonate and marginal (Fig. 4J). Cross-field pitting is taxodioid and piceoid, 2–4 pits per cross-field (Fig. 4K). The bordered pits on the radial walls are uniseriate to triseriate, mostly opposite in 2–3 seriates (Fig. 4L). Rays are mostly uniseriate, 1–40 cells in height, mostly 3–20 cells high (Fig. 4M).

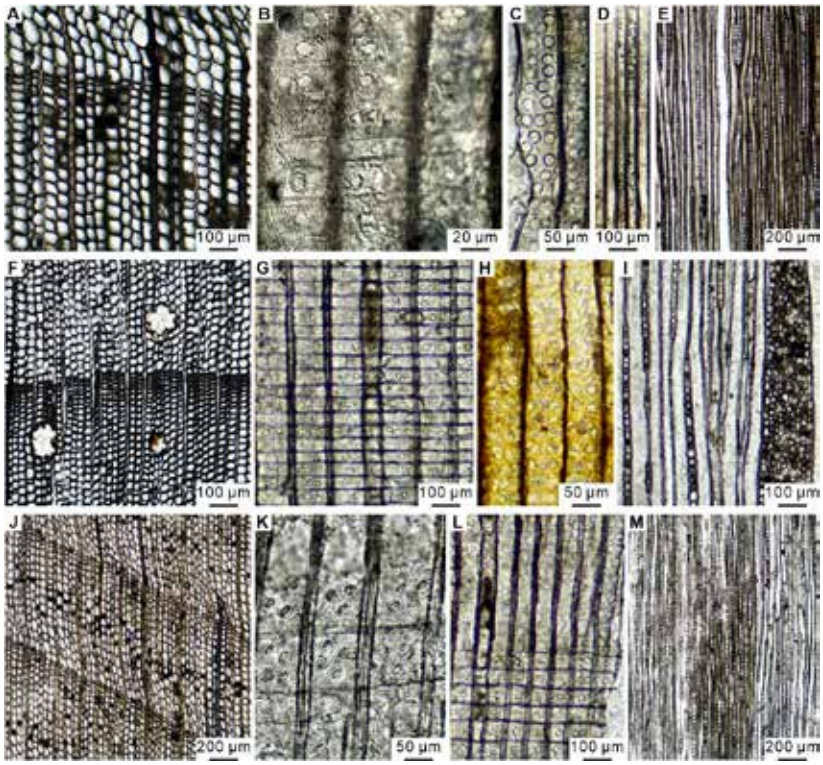

Figure 4. Anatomical characteristics of fossil wood *Metasequoia* sp. (A–E, Specimen number TX024), *Sequoia* sp. (F–I, Specimen number TX047), and *Taxodium* sp. (J–M, Specimen number TX031) from Lesvos Petrified Forest

5 Discussion

5.1 Palaeobiogeographic implications of gymnosperm diversification

The Mediterranean region is one of the Northern Hemisphere regions with the richest fossil records of Cenozoic gymnosperms. In this investigation in the Lesvos Petrified Forest, 9 genera from 2 families of gymnosperms fossil wood were identified, and among of them, *Pseudotsuga*, *Keteleeria*, and *Metasequoia* are first occurrences at Lesvos Petrified Forest. Today, *Pseudotsuga* is discontinuously distributed in western North America and East Asia (Farjon and Filer, 2013; Zhu *et al*., 2025), *Keteleeria* is endemic to East and Southeast Asia (Farjon and Filer, 2013), and *Metasequoia* is a relict genus, distributed only in southwestern China (Farjon and Filer, 2013). The fossil gymnosperm wood assemblage is similar to the modern flora of western North America (Farjon and Filer, 2013).

Current results not only further enrich the biodiversity of the fossil flora in the Petrified Forest of Lesvos, Greece, but also provides insights into the origin and evolutionary trend of the fossil flora. Additionally, it contributes to the fossil record and provides additional evidence for their palaeogeographical distribution range.

5.2 Growth rings of fossil wood and palaeoenvironment

Modern wood anatomy research shows that the appearance of abnormal growth rings is related to climate change and natural disasters (Gou and Feng, 2021; Cheng *et al*., 2023). For example, the occurrence of narrow or missing rings may be associated with wildfires that burn tree crowns and thus interrupt the radial growth of growth rings in the year that the fire occurred (Ortloff, 1996; Cheng *et al*., 2023). The occurrence of extreme drought or insect damage during the growth of trees can lead to the appearance of false growth rings (Creber *et al*., 1984; Cheng *et al*., 2023). Traumatic resin canals (Fig. 2A), abnormal growth rings (Fig. 2G) and traces of arthropod feeding (Fig. 4F) were observed in some fossil wood.

The above phenomenon reflects the impact of climate change, natural disasters, and arthropods in the forest on the growth process of plants during tree growth. This shows that Lesbos Island developed an extremely complicated environment during the Miocene Epoch.

6 Conclusion

Lesvos Petrified Forest is one of the richest Miocene fossil wood assemblages in Greece and even in the Mediterranean. This study enriches the Greek Cenozoic gymnosperm fossil record and provides important evidence for understanding the plant diversity in the Mediterranean region.

The abnormal growth rings, traumatic resin canals and arthropod feeding traces in this fossil wood group provide significant fossil evidence for understanding the palaeoclimate fluctuations, palaeoenvironment and the interaction between organisms in this forest ecosystem during the Miocene.

7 Acknowledgments

We express our gratitude to the Natural History Museum of the Lesvos Petrified Forest for the permission to conduct research activities in the new fossil sites of the Lesvos Petrified Forest, and for the study of the fossils and thin sections of the fossil wood. We also express our sincere thanks to the researchers and technical staff of the Natural History Museum of the Lesvos Petrified Forest for their support and collaboration in the field survey.

EXTENDED ABSTRACT 353

Utilizing ultrasound velocity measurements to estimate physicomechanical properties of carbonate ornamental rocks

Ziazopoulou K.[1], Loupasakis C.[1], Laskaridis K.[2], Patronis M.[2], Arapakou A.[2], Kouseris I.[2]

(1) Laboratory of Engineering Geology and Hydrogeology, School of Mining and Metallurgical Engineering, National Technical University of Athens, Athens, Greece, kziaz24@gmail.com, (2) "Lithos" ornamental stones quality control laboratory, Hellenic Survey of Geology & Mineral Exploration (HSGME), Athens, Greece

Research Highlights

High to very high correlation values have been achieved between the ultrasound velocity and many of the physicomechanical properties, providing substantial information on the application of fast, non-destructive methods for the quality control of the ornamental stones.

Introduction / Background

The quality control of ornamental stones requires the determination of numerous physical and mechanical properties and the conduction of expensive time-consuming tests. Therefore, the development of alternative methods for estimating these properties can be very attractive. This research was conducted to achieve a satisfactory correlation of ultrasound velocity with properties such as Uniaxial Compressive Strength, density, open porosity, water absorption, flexural strength and abrasion resistance of certain samples.

Methods

Thirty eight rock samples, the majority of them from northern Greece, have been tested to correlate the ultrasound velocity with the physicomechanical properties of the ornamental stones. The selected samples were calcitic marbles, dolomitic marbles and limestones. They were shaped cubic (7cm) following the European standards, in which most of the tests are carried out at the Laboratory of ornamental stones "Lithos".

For all the 38 samples, the P-wave and S-wave ultrasound velocity were measured, in all three dimensions, and the mean value was used for the correlations (Figure 1).

Figure 1. ***The ultrasonic velocity measurement procedure for all marble and limestone samples.***

Following, the Uniaxial Compressive Strength (UCS) of every sample was measured by applying the standard destructive method according to the European standard EN 1926 (Figure 2). The ultrasound velocities were measured in m/s and the Uniaxial Compressive Strength was measured in MPa.

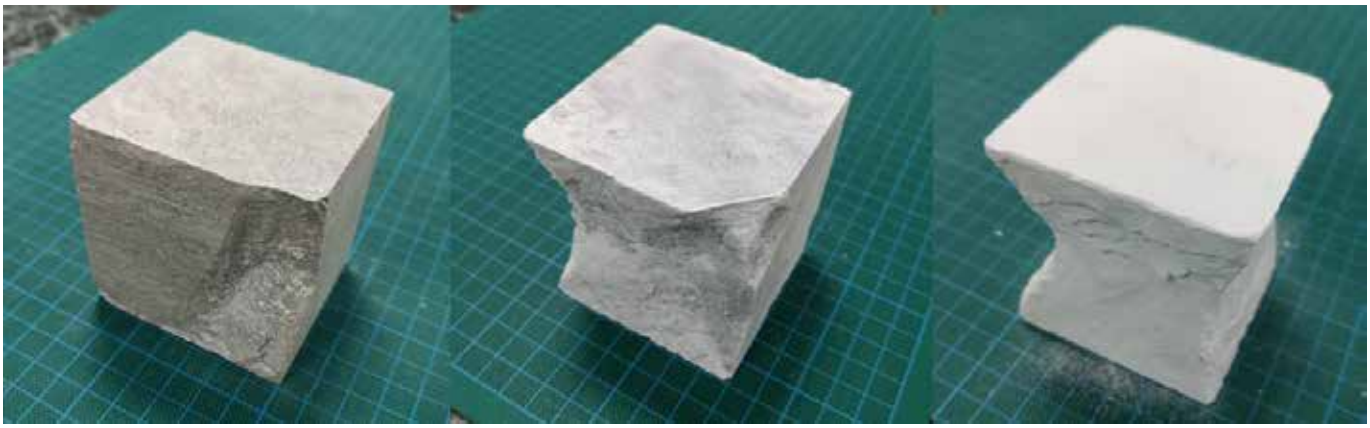

Figure 2. ***The differences of the samples of a limestone, a calcitic marble and a dolomitic marble (from left to right) after the measurement of their Uniaxial Compressive Strength.***

As expected, the correlation between the mean P-wave and S-wave velocity values was very high for all the samples, with a correlation coefficient reaching up to 99%.
The mean values for the density (European standard EN 1936, measured in kg/m^3), open porosity (European standard EN 1936, measured in percent % by volume), water absorption (European standard EN 13755, measured in percent % by mass), flexural strength (European standard EN 12372, measured in MPa) and abrasion resistance (European standard EN 14157, measured in cm^3/(50*cm^2)) were provided by the "Lithos" Laboratory. Following the European standards, those values were calculated by testing 10 samples of the same batch for every rock, within the framework of former contracted projects.

Results

Initially, primary importance was given in the correlation between P-wave velocity and Uniaxial Compressive Strength (UCS) which is, arguably, the most relevant parameter in most fields of applied geosciences, engineering and material science, as it establishes the mechanical response of material under unconfined conditions.
Subsequently, more properties were considered, yielding rewarding results. In particular, the highest correlation coefficients ($R^2 > 0.8$) were obtained for the following pairs of properties:

- P-wave velocity and density for limestones ($R^2 = 0,92$).
- P-wave velocity and flexural strength for limestones ($R^2 = 0,88$).
- P-wave velocity and open porosity for calcitic marbles ($R^2 = 0,86$).
- P-wave velocity and water absorption for all the samples ($R^2 = 0,86$).
- P-wave velocity and water absorption for limestones ($R^2 = 0,81$).
- P-wave velocity and water absorption for all the samples ($R^2 = 0,80$).

Furthermore, sufficient correlation coefficient values ($R^2 > 0,5$) were obtained for the following pairs of properties:

- P-wave velocity and density for all marbles ($R^2 = 0,68$).
- P-wave velocity and open porosity for all the samples ($R^2 = 0,61$).
- P-wave velocity and UCS for all marbles ($R^2 = 0,60$).
- P-wave velocity and open porosity for limestones ($R^2 = 0,60$).
- P-wave velocity and abrasion resistance for dolomitic marbles ($R^2 = 0,60$).
- P-wave velocity and density for all the samples ($R^2 = 0,58$).

In cases where no clear correlation can be established between the ultrasound velocity and the physical and mechanical properties, the datasets were further divided and analyzed considering the rock type. In those cases, the mean values of the physicomechanical properties were correlated with the rock type and the mean values of the ultrasonic velocities (Figure 3). Boxplots were also designed to provide clear information about the range of values, as well as the extreme values (Figure 4).

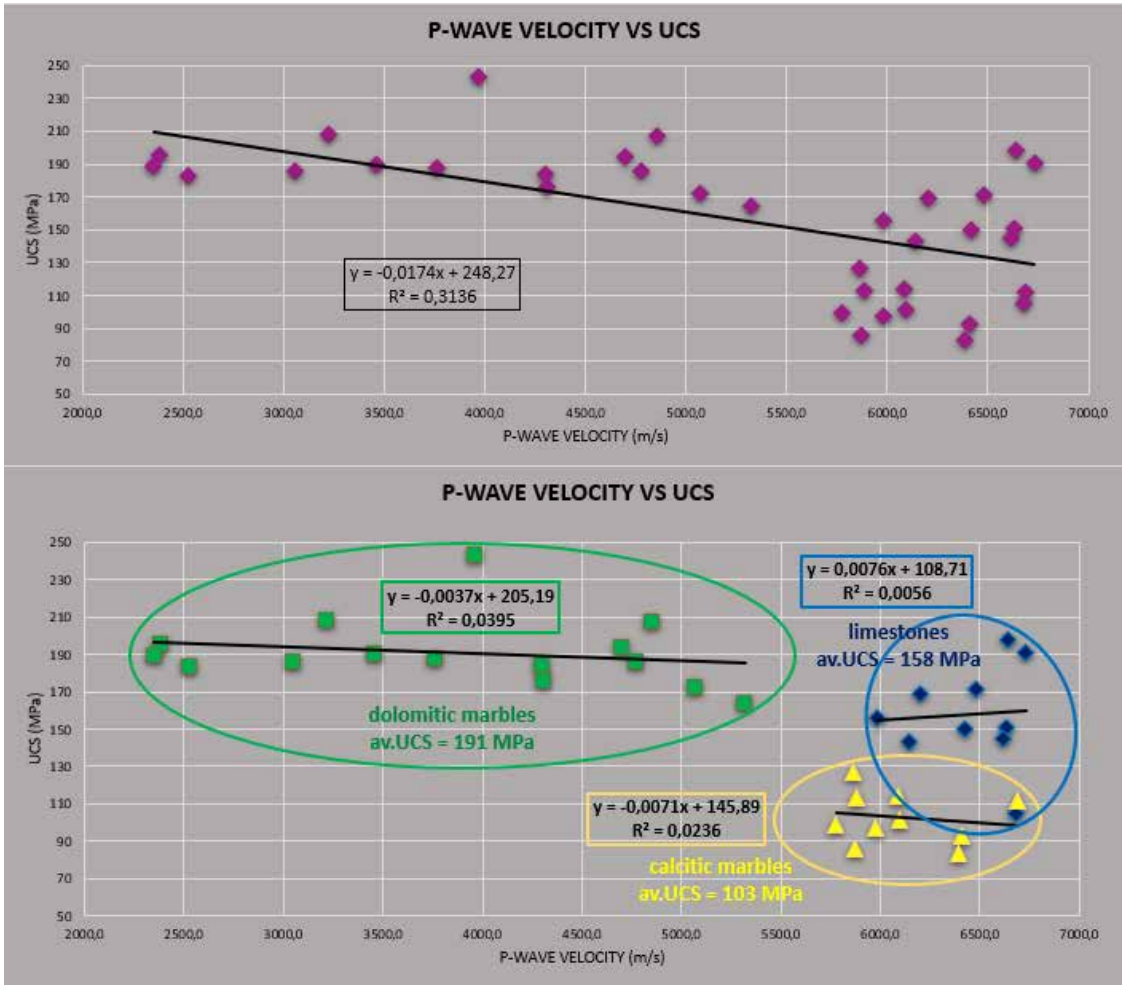

Figure 3. ***In the upper graph it is made clear that the correlation coefficient between P-wave velocity and UCS is not good enough. However, in the graph below, the point areas are showcasing that there can be other conclusions other than just a correlation.***

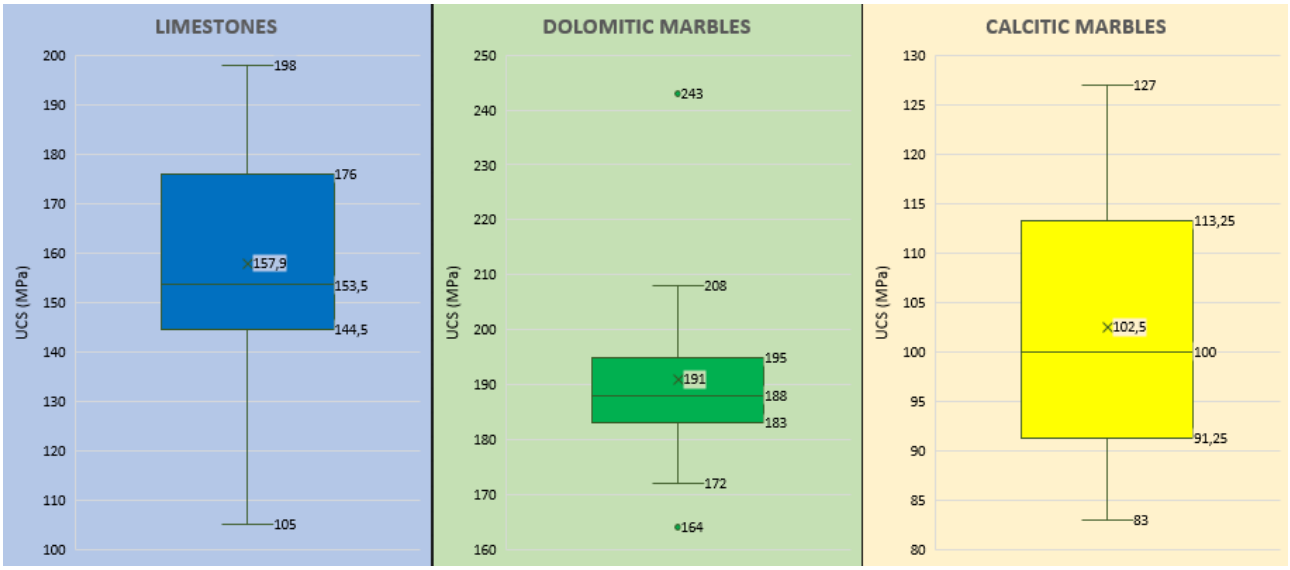

Figure 4. ***Boxplots providing the mean values, as well as the extreme values of the Uniaxial Compressive Strength (UCS) of the three categories of the samples.***

Conclusions

In conclusion, due to the high correlation coefficient values obtained, it seems possible to use ultrasonic velocity measurements as an alternate, non-destructive method to estimate various physical and mechanical properties of ornamental stones.

EXTENDED ABSTRACT 354

Spatial distribution of trace elements in four water districts of Greece during the period 2018-2023. Results from National Groundwater Monitoring Network Program of Greece.

Zorapas V.[1] Chalkiadaki O.[2]

(1) Head of the Department of Hydrogeology and Hydrology, Division of Water Resources and Geothermal Energy, Hellenic Survey of Geology and Mineral Exploration, Athens, Greece, vzorapas@eagme.gr. (1) Department of Analytical Laboratories, Division of Water Resources and Geothermal Energy, Hellenic Survey of Geology and Mineral Exploration, Athens, Greece, ochalkiadaki@eagme.gr

Introduction / Background

According to Directives 2000/60/EC, 2006/118/EC, and 91/676/EEC, Member States are required to establish a National Water Monitoring Network to ensure the systematic monitoring of the qualitative and quantitative characteristics of inland surface, transitional, coastal, and groundwater bodies. The aim is to assess and classify their ecological and chemical status, as well as their quantitative status, and to evaluate long-term changes resulting from human activities, in conjunction with the implementation of the measures set out in River Basin Management Plans.

Given Greece's unique climatic, geological, and physiographic conditions, groundwater resources hold exceptional significance. Unlike Northern European countries that primarily rely on surface water, Greece's water needs are largely met by groundwater. Regions experiencing intensive groundwater use have reported significant quantitative and qualitative degradation, including salinization and nitrate pollution. Prolonged droughts and high temperatures exacerbate these issues, necessitating robust and systematic monitoring of groundwater conditions.

The National Monitoring Network for groundwater, as defined in Government Gazette Issue 5384/B/19-11-2021 "Revision of the National Monitoring Network for the quality and quantity of water with the determination of monitoring stations and the responsible bodies for their operation," consists of 1,896 monitoring stations and covers almost the entire Greek territory, including remote islands. The goal of the project is to provide a coherent and comprehensive overview of the qualitative and quantitative status of the country's groundwater systems. The Network contributes significantly to the rational management and protection of groundwater resources from degradation, as the country is highly dependent on these resources (water supply, irrigation, industry).

The Hellenic Survey of Geology and Mineral Exploration conducted the entire range of tasks (sampling, analysis, evaluation, and results reporting) in a comprehensive manner. A synchronized sampling campaign was conducted annually or semi-annually during the period 2018-2023 in each water district to collect groundwater samples for major and trace element analysis. At the same time, on-site measurements of physicochemical parameters, groundwater level and spring discharge rate, were performed. Water samples were analyzed in HSGME's analytical laboratories (Athens, Preveza, and Xanthi).

The monitoring included:

- Hydrometric measurements such as groundwater level and spring discharge rate.
- Physical – chemical field measurements (pH, electrical conductivity, water temperature, dissolved oxygen)
- Sampling and chemical analysis for major ions (Ca, Mg, Na, K, HCO_3, Cl, SO_4), nitrogenous and phosphorus compounds, trace elements (Cr, Fe, Mn, Hg, Cu, Pb, Zn, Al, Cd, Ni), organic compounds (solvents and pesticides)

The evaluation reports and analysis results were submitted to the Directorate General for Water, the designated national authority for overseeing water management, to inform relevant EU bodies and to be further utilized in the review of RBMPs and the development of management policies.

Groundwater trace element concentrations are governed by complex processes, reflecting the inherent chemical variability of groundwater itself (Farnham *et al*., 2003). Natural factors, including aquifer lithology, recharge water quality, and water-rock interactions, significantly influence trace element composition. However, human activities can disrupt these natural systems, leading to pollution or alterations in the hydrological cycle (Helena *et al*., 2000). Consequently, interpreting trace element data in groundwater necessitates sophisticated analytical techniques.

Study area

This study focuses on four water districts in eastern Greece: EL06 (Attica), EL07 (Eastern Sterea), EL08 (Thessaly), and EL10 (Central Macedonia). Despite their geographic proximity, these areas exhibit significant heterogeneity in terms of geology, anthropogenic pressures, and socio-economic development. Attica and Central Macedonia, hosting Athens and Thessaloniki cities, are characterized as highly urbanized environments with industrial activities, and high population density. In contrast, Eastern Sterea (EL07) is influenced by industrial activities and the geological presence of ophiolitic rocks. Thessaly (EL08), on the other hand, is predominantly an agricultural region. By examining these basins, our research aims to provide a comprehensive understanding of the spatial distribution of trace elements (Cr, Fe, Mn, Hg, Cu, Pb, Al, Cd, Ni) in groundwater, considering the interplay between natural and anthropogenic factors.

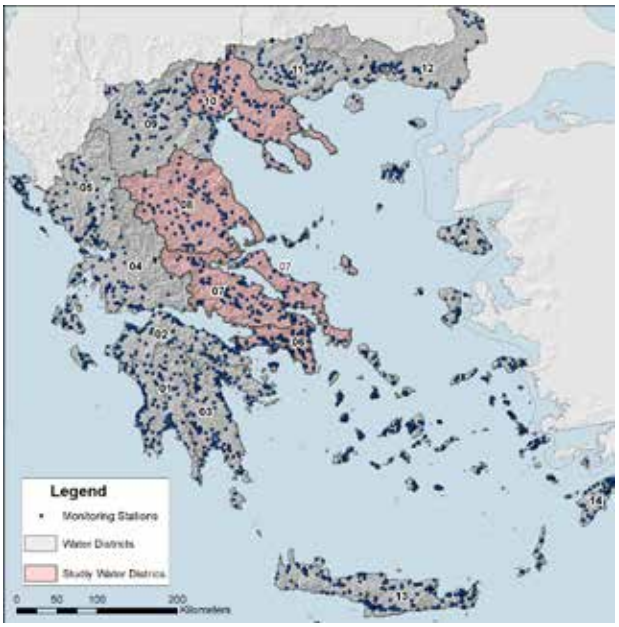

Figure 1. The monitoring network includes 1896 representative monitoring stations (boreholes, wells and springs). Study areas in light red color (Water Districts 06, 07, 08, 10)

Objectives

The objectives of the present work are:

- To investigate the spatial trends of selected trace elements in groundwater across four water districts of Greece, attempting to identify regional variations in groundwater quality and potential sources of contamination.
- To assess the potential impacts of human activities (e.g., agriculture, industry) and natural factors (e.g., geology, climate) on trace element concentrations, providing valuable insights into the factors driving groundwater contamination in different regions.
- To evaluate the effectiveness of existing water management measures in mitigating trace element contamination for future management strategies.
- To contribute to the scientific understanding of trace element occurrence and behavior in groundwater systems in Greece, enhancing the knowledge base for future research and monitoring efforts.

Methods

All groundwater samples were collected from four water districts in Greece (EL06-Attica, EL07-Eastern Sterea, EL08-Thessaly, and EL10-Central Macedonia), from February 2018 to December 2023. The groundwater samples collected using acid pre-washed polyethylene bottles according to the APHA methods (APHA, 2012). Sampling procedure and groundwater analysis followed the APHA guidelines and Mineral and Geosciences Department guidelines (APHA, 2012). Samplers or submersible pumps were used to pump the groundwater samples and the stagnant was removed in 15 to 30 minutes to eliminate the unnecessary substances during the sampling procedures (Appelo and Postma, 2005).

Conductivity and pH were measured upon their arrival at the Analytical Laboratories of HSGME. For trace elements all groundwater samples were filtered in field using Whatman cellulose Nylon-type Millipore filters with a pore size of 0.45 μm. After filtration, samples were acidified using SUPRAPUR® 65% nitric acid. Trace elements (Al, Cr, Mn, Ni, Cu, Fe, As, Cd, and Pb) were analyzed using inductively coupled plasma mass spectrometry (ICP-MS) model ELAN 6100, PE-SCIEX. Major ions (Na, K, Mg, and Ca) were analyzed using inductively coupled plasma optical emission mass spectrometry (ICP-OES) model OPTIMA 5300 DV, PerkinElmer. Bicarbonate and chloride were analyzed using the titration method that was conducted in the laboratory.

Statistical analysis

Multivariate statistical methods were performed using the computer Software SPSS 17.0 in order to investigate the relationships among the trace elements in each geographical area's samples. Correlation analysis was also performed between the trace and major elements and the physicochemical parameters at each of the four water districts in order to establish correlations between every two elements and to explore the strength of such correlations. Boxplots were used to depict the distributions of each of the parameters examined for all the stations of each water district.

Results

SPSS 17.0 was used to perform correlations of the 10 trace elements, and the major elements in all samples of each water district for the sampling period 2018-2023. The sample number analyzed and correlated for each trace element differs for each of the four water districts. For EL06, 509 samples were analyzed, while for EL07, 867 samples, for EL08, 595 samples and for EL10, 712 samples. The difference in trace element concentrations in groundwater is influenced by the activities and types of adjacent areas as well as the characteristics of the aquifer. The main findings are the following:

For Water District EL06:

- Fe: Ranged from 9.9 to 1390 μg/L (mean 62, median 21 μg/L). 31 values out of 509 were above the proposed quality threshold of 200 μg/L, while in 2 out of 93 stations (EL6110609 & EL6160602) the median Fe concentrations throughout the years exceeded the proposed threshold.
- Mn: Ranged from 5.0 to 390 μg/L (mean 15, median 5.0 μg/L). In 14 out of 93 stations one or more values of Mn exceeded the proposed quality threshold of 50 μg/L. In 5 out of 93 stations the median Mn concentrations throughout the years exceeded the proposed quality threshold of 50 μg/L.
- Cu: Ranged from 4.6 to 2500 μg/L (mean 7.6, median 5.0 μg/L). No values were above the National Guideline value, while 32 stations have constant measurements of Cu at LOQ 5μg/L.
- Cr: Ranged from 4.9 to 70 μg/L (mean 7.8, median 5.0 μg/L). Only 9 values were determined above the threshold of 50μg/L, while 14 values were between 25 μg/L (new threshold after 2036) and 50 μg/L. At 2 stations the overall median value throughout the years was equal or above 50 μg/L (EL6010604 and EL6050612)
- Ni: Ranged from 0.5 to 70 μg/L (mean 7.8, median 5.0 μg/L). 49 values out of 509 were measured above or equal to 20μg/L, while in 35 out of 93 stations one or more values of Ni exceeded the proposed limit of 20 μg/L. Moreover, in 2 out of 93 stations the median Ni concentrations throughout the years exceeded the proposed limit of 20μg/L.
- Pb: Ranged from 5.0 to 50 μg/L (mean 5.2, median 5.0 μg/L). Most measurements (501 out of 509) were equal to the LOQ of 5μg/L. In 3 out of 93 stations one or more values of Pb exceeded the proposed limit of 10 μg/L and in 2 stations the future legislative threshold after 2036 of 5 μg/L. There was 1 station (EL6170603, 186038) where the overall median Pb value throughout the years was above 10μg/L (min 16-50, median 23.5μg/L)
- Cd: Ranged from 0.5 to 30 μg/L (mean 0.6, median 0.5 μg/L). 6 values were equal to or above the limit of 5μg/L (in 6 stations) but no station where the overall median Cd value throughout the years was equal to or above 5μg/L. These values were measured in 2 of the systems (EL060806, EL060906) located in Aspropyrgos and Elefsina.
- As: Ranged from 0.5 to 50 μg/L (mean 6.4, median 5.0 μg/L). 46 values out of 509 were above the legislative threshold of 10μg/L. In 19 stations one or more cases the measurement of As exceeded the limit of 10μg/L, in 6 of them the overall median As value throughout the years also exceeded the limit. The water bodies with As with at least one value above the limit of 10μg/L were 11 and only in 1 the overall median As value throughout the years also exceeded the limit.
- Hg: Ranged from 0.5 to 11 μg/L (mean 0.6, median 5.0 μg/L). From the entire dataset of 509 values only 7 exceeded the 1μg/L legislative limit. 502 samples were at the LOQ of 0.5μg/L. The maximum values above 1μg/L were found in 3 stations located in Aspropyrgos.

For Water District EL07:

- Fe: Ranged from 5.0 to 10400 μg/L (mean 219, median 44 μg/L). 184 values out of 867 were above the proposed quality threshold of 200μg/L. In 25 out of 145 stations the median Fe concentrations throughout the years exceeded the proposed quality threshold.
- Mn: Ranged from 4.8 to 1100 μg/L (mean 20, median 5.0 μg/L). 67 out of 867 values were above the proposed quality threshold of 50μg/L, while in 9 out of 145 stations the median Mn concentrations throughout the years exceeded this threshold.
- Cu: Ranged from 1.8 to 630 μg/L (mean 9.9, median 5.0 μg/L). No values were above the National Guideline value, while some stations have constant measurements at LOQ 5μg/L.
- Cr: Ranged from 4.8 to 360 μg/L (mean 15, median 5.0 μg/L). 49 values were determined above the threshold of 50μg/L, while 14 values were between 25 μg/L (new threshold after 2036) and 50 μg/L. In 4 stations the overall median values throughout the years exceeded the limit of 50μg/L, while in 6 stations the overall median values throughout the years exceeded the limit of 25μg/L (threshold after 2036).
- Ni: Ranged from 1.0 to 1800 μg/L (mean 11, median 5.0 μg/L). 38 values out of 865 were measured above or equal to 20μg/L, while in 28 stations there is at least one Ni value above 20μg/L, and only in one of them (7180711) the overall median of all monitoring years is above 20μg/L.
- Pb: Ranged from 5.0 to 105 μg/L (mean 6.1, median 5.0 μg/L). Most measurements (782 out of 866) were equal to the LOQ of 5μg/L. In 51 stations there was at least one Pb value equal to or above 10μg/L and in 7 stations there was at least one Pb value above 5μg/L. There were 4 stations (7090703, 7090712, 7090714, 7320703) where the overall median Pb value throughout the years was equal to or above 10μg/L equal to or above 10μg/L.

- Cd: Ranged from 0.5 to 17 μg/L (mean 0.8, median 0.5 μg/L). 39 values were equal to or above the limit of 5μg/L (in 37 stations).
- As: Ranged from 5.0 to 51.8 μg/L (mean 5.0, median 5.8 μg/L). 38 values were equal to or above are above the legislative threshold of 10μg/L. In 25 stations one or more measurements of As was equal to or above the limit of 10μg/L. In 2 stations (EL7050706 and EL7150702) the overall median As values throughout the years was above 10μg/L.
- Hg: No measurable Hg values were determined. All values were at the LOQ (0.5μg/L).

For Water District EL08:

- Fe: Ranged from 10 to 27000 μg/L (mean 225, median 29 μg/L). 94 values out of 595 were above the proposed quality threshold of 200μg/L. In 55 out of 95 stations one or more values of Fe exceeded the proposed quality threshold. In 6 out of 95 stations the median Fe concentrations throughout the years exceeded 200 μg/L.
- Mn: Ranged from 3.0 to 3458 μg/L (mean 56, median 7.2 μg/L). 120 out of 595 values were above the proposed quality threshold of 50μg/L, while in 18 out of 95 stations the median Mn concentrations throughout the years exceeded this threshold.
- Cu: Ranged from 4.0 to 180 μg/L (mean 7.1, median 5.0 μg/L). No values were above the National Guideline value, while 27 stations have constant measurements at LOQ.
- Cr: Ranged from 4.5 to 75 μg/L (mean 7.3, median 5.0 μg/L). 65 stations have constant measurements of Cr at LOQ 5μg/L. There were 12 values above the future legislative threshold of 25μg/L (2036) and 12 values above the current limit of 50μg/L. In 2 stations the overall median Cr value throughout the years was above 50μg/L (EL8090802 range: 50-75, median 61.3, EL8110806 range: 5-67, median 58.2, Magnesia, Dimos R. Fereou).
- Ni: Ranged from 5.0 to 52 μg/L (mean 6.9, median 5.0 μg/L). 26 values out of 596 were measured above 20μg/L, while in 19 stations there is at least one Ni value above 20μg/L, and only in one of them the overall median of all monitoring years was above 20μg/L (EL8200803, 6 out of 7 values above 20μg/L, Fthiotida, Dimos Domokou, 16.4-39, median 23)
- Pb: Ranged from 0.7 to 690 μg/L (mean 6.5, median 5.0 μg/L). Most measurements (581 out of 596) were equal to the LOQ of 5μg/L. However, there were 8 values above the current legislative threshold of 10μg/L and 6 more values above 5μg/L (future legislative threshold after 2036). In 7 stations there was at least one Pb value equal to or above 10μg/L and in 5 stations there was at least one Pb value above 5μg/L but in none of these stations the overall median Pb value throughout the years did not exceed either limit.
- Cd: Ranged from 0.5 to 2.7 μg/L (mean 0.5, median 0.5 μg/L). Most values (591 out of 596) were measured at the LOQ (0.5μg/L). There were no values above or equal to 5μg/L.
- As: Ranged from 0.2 to 26 μg/L (mean 5.3, median 5.0 μg/L). Most values (558 out of 596, 75 stations) were measured at the LOQ (5μg/L). There were 14 values equal to or above the legislative threshold of 10μg/L. There are 7 stations where in one or more cases the measurement of As was equal to or above the limit of 10μg/L. In 1 station the overall median As values throughout the years were above 10μg/L (EL8280802, 3 out of 5 values, min 7, max 16, median 11.6).
- Hg: No measurable Hg values were determined. All values were at the LOQ (0.5μg/L).

For Water District EL10:

- Fe: Ranged from 6.0 to 23,000 μg/L (mean 495, median 50 μg/L). 153 values out of 712 were above the proposed quality threshold of 200μg/L. In 65 out of 114 stations one or more values of Fe exceeded the proposed quality threshold. In 18 out of 114 stations the median Fe concentrations throughout the years exceeded 200 μg/L.
- Mn: Ranged from 4.6 to 2,500 μg/L (mean 81, median 11 μg/L). 105 out of 712 values were above the proposed quality threshold of 50μg/L, while in 29 out of 114 stations the median Mn concentrations throughout the years exceeded this threshold.
- Cu: Ranged from 5.0 to 295 μg/L (mean 7.4, median 5.0 μg/L). No values were above the National Guideline value, while 49 stations have constant measurements at LOQ.
- Cr: Ranged from 0.5 to 62 μg/L (mean 15, median 5.0 μg/L). Only one value was above the threshold of 50μg/L.
- Ni: Ranged from 1.0 to 480 μg/L (mean 7.0, median 5.0 μg/L). 14 values out of 712 were measured above 20μg/L.
- Pb: Ranged from 0.5 to 25 μg/L (mean 5.0, median 5.0 μg/L). Most measurements were equal to the LOQ of 5μg/L. Only 6 values out of 712 were measured above 5μg/L (future legislative threshold after 2036) and 2 were above the current legislative threshold of 10μg/L.
- Cd: Ranged from 0.5 to 1.0 μg/L (mean 0.7, median 0.5 μg/L). There were no values above or equal to 5μg/L.
- As: Ranged from 0.5 to 390 μg/L (mean 24, median 5.0 μg/L). 94 values are above the legislative threshold of 10μg/L. The 26 stations where in one or more cases the measurement of As exceeded the limit of 10μg/L.
- Hg: Ranged from 0.5 to 5 μg/L (mean 0.5, median 0.5 μg/L). From the entire dataset of 712 values, only 5 exceeded the 1μg/L legislative limit. (702 samples at the LOQ 0.5).

Correlation analysis of trace elements for possible sources of pollution identification and geochemical relationships

Pearson's correlation matrix has been used to evaluate the association between major and trace metals of the groundwater of each water district and to find out the probable factors that control the distribution of trace elements. The positive correlation indicates the metals are from the same origin while the negative significant co-relationship means the sources of metals are different (Hoque *et al,* 2024). Level of significance was set at 0.01.

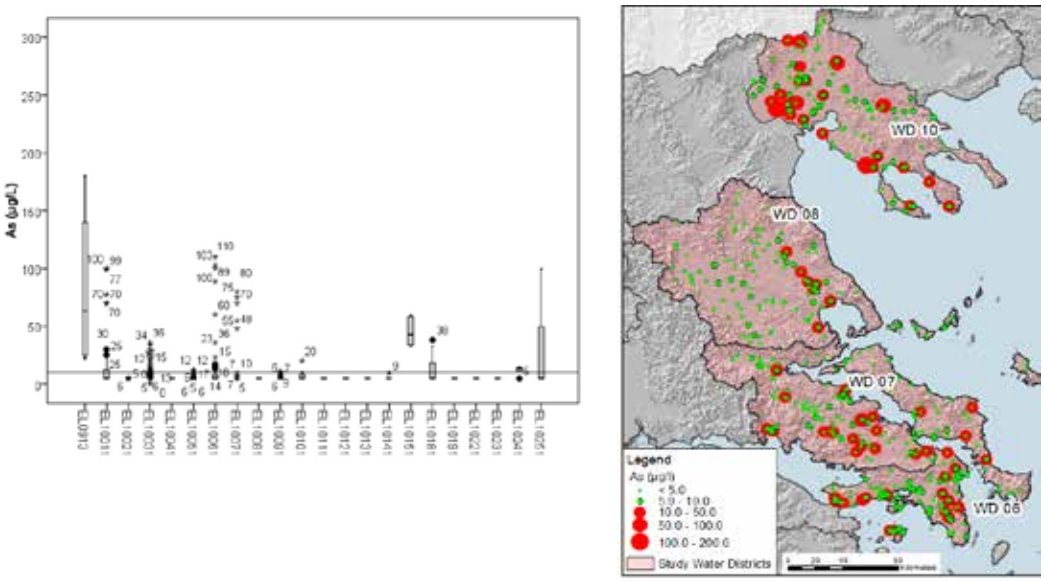

Figure 5. Variation of arsenic (As) boxplot in all groundwater bodies of Water District 10 (with thin line, the legislative limit is depicted) and spatial map of As in the study Water districts (right) showing the geographical distribution pattern of As in the sampling points (As Concentration above the legislative limit depicted in red color).

Table 1. Correlations of physicochemical parameters, major elements and trace elements in the four water districts (level of significance was set at 0.01)

Element	Water District 06	Water District 07	Water District 08	Water District 10
Fe	**+**: Mn, Al, Cond., Mg, Na, K, Cl -: Cr, Cd, Hg	**+**: Mn, Cu, Cr, Ni, pH, Cond., Mg, Na, Al, -: Cd, Pb	+: Mn, Cu, Al, As, Cond., Mg, Na, K, Cl -: pH	+: Mn, Cu, Ni, Al, Cond., Na, Cl -: Cd, Cr
Mn	+: Fe, Ni, Pb -: Cr, pH	+: Fe, Cu, Ni, Pb, Al, As	+: Fe, Cu, Ni, Al, Cond., Mg, Na, K -: Cr	+: Fe, Al, Cond., Na, Cl -: Cr
Cu	+: Ni, Pb, Cd, As, Cond, Ca, Mg, K, Na, Cl -: pH	+: Fe, Mn, Ni, Pb, Al, As, Cond., Ca, Mg, K, Na, Cl	+: Fe, Mn, Ni, Pb, As, Cond., Mg, Na	+: Fe, Ni, Al, As, Cond., Na, Cl
Cr	+: Cd, Hg, pH, Mg, HCO_3 -: Fe, Mn, Ni, Al, Ca	+: pH, Cond., Mg, Na, K Cl -: Fe, Al, Pb, Ca	+: Cond., Mg, Na -: Mn, Ca	+: Fe -: Pb, Mn
Ni	+: Mn, Cu, Al, As, Cond, Ca, Mg, Na, K, HCO_3, Cl -: Cr, Cd, pH	+: Fe, Mn, Cu, Pb, Cd, Al, As, Cond., Ca, Mg, Na, K, Cl -: pH	+: Mn, Cu, Pb, As, Cond., Ca, Mg, Na	+: Fe, Cu, Cd, Cond., Na, Cl
Pb	+: Mn, Cu	+: Mn, Cu, Ni, Cd, Al, As -: Fe, Cr, Cl	+: Cu, Ni, Al	no correlations
Cd	+: Cr, Hg -: Fe, Ni, Al and As	+: Ni, Pb, As, Ca -: Fe, Cr, pH, Na, Cl	no correlations	+: Ni, Pb, As, pH -: Fe, Cr
Al	+: Fe, Ni, As -: Cr, Cd	+: Fe, Mn, Cu, Cr, Ni, Pb, pH, Cond, Mg	+: Fe, Mn, Pb	+: Fe, Mn, Cu, Hg, pH, Na, Cl
As	+: Cu, Ni, Pb, Al, Cond., Ca, Mg, Na, K, Cl -: Cd	+: Mn, Cu, Ni, Pb, Cd, Cond., Mg, Na, K, Cl	+: Fe, Cu, Ni, Cond., Mg, Na, K	+: Cu, Hg, Cond., Na, Cl

Hg	+: Cd, Cond., Ca, Na, K, Cl	no correlations	no correlations	+: Al, As, pH, Na

+ Positive correlation, - Negative correlation

Common Correlations in all water districts:

- **Ca-Mg: This strong positive correlation across all water districts is expected, as these elements often occur together in minerals like calcite and dolomite.**
- **Conductivity - Major Ions: Conductivity is strongly correlated with most major ions (Ca, Mg, Na, K, Cl, HCO3) in all districts, as expected, since these ions contribute significantly to the electrical conductivity of the water.**
- **pH - Conductivity: A negative correlation between pH and Conductivity is observed in most districts, which is generally expected as higher pH values can lead to the precipitation of certain ions, reducing conductivity.**
- **pH - Ca, Mg, Na, K: Negative correlations between pH and these major cations are observed in many districts, suggesting that higher pH values may favor the precipitation of carbonate minerals.**
- **Fe-Mn:** Strong positive correlation observed in all water districts, suggesting a strong association between these elements, likely due to their similar geochemical behavior and common occurrence in iron-bearing minerals.
- **Cu-Ni:** Positive correlation observed in all basins, indicating a potential association between these elements, possibly due to their co-occurrence in sulfide minerals or their similar geochemical behavior.
- **Cu-As:** Positive correlation observed in all basins, suggesting a possible association between these elements, potentially related to their occurrence in organic matter or association with sulfide minerals.
- **Al-Fe:** Positive correlation observed in all basins, indicating a strong association between these elements, likely due to their common occurrence in aluminosilicate minerals.
- **Cr-Fe, Mn, Al:** Cr shows negative correlations with Fe, Mn, Ni, and Al in EL06 and with Fe and Mn in EL07 and EL10. This suggests that Cr may have a different geochemical behavior compared to these elements, possibly due to its redox sensitivity or association with different mineral phases.

Overall, the correlation analysis suggests that the distribution of trace elements in the groundwater of each water district is influenced by a combination of factors, including:

- **Mineralogy:** The presence of specific minerals, such as Fe-oxyhydroxides, sulfides, and clay minerals, can control the distribution of trace elements.
- **Redox conditions:** Redox conditions can influence the mobility and speciation of trace elements.
- **Organic matter:** Organic matter can play a role in the sorption and transport of trace elements.
- **Anthropogenic activities:** Human activities, such as agriculture and industrial processes, can contribute to the presence of trace elements in groundwater.

Conclusions

- The geochemical analysis of groundwater samples at four water districts in Greece revealed that the distribution of trace elements in the studied regions is primarily influenced by geological factors, such as the underlying bedrock and soil types. The presence of specific minerals, such as carbonates and sulfides, significantly influences the concentrations and associations of elements like Ca, Mg, Fe, and Cu.
- Anthropogenic activities, including agriculture and industrial processes, have introduced additional contaminants, leading to localized contamination.
- The presence of chromium, particularly in areas with ophiolitic rocks, suggests the influence of natural geochemical processes.
- The elevated concentrations of arsenic, often associated with volcanic rocks and agricultural practices, highlight the importance of geological and anthropogenic factors in determining groundwater quality.
- The strong correlation between calcium, magnesium, and bicarbonate ions indicates the dominance of carbonate weathering in these regions.
- A thorough understanding of the geological and hydrogeological setting of each basin is essential for a more comprehensive interpretation of the observed correlations.

Acknowledgements

The author gratefully acknowledge the valuable contribution of Ms Helen Gintoni, former Head of the Department of Analytical Laboratories, Hellenic Survey of Geology and Mineral Exploration, Athens, Greece, in the analysis of the samples and the timely delivery of the results, as well as the assistant Dr Vasiliki Paraskevopoulou (Laboratory Teaching Staff, Laboratory of Environmental Chemistry, National and Kapodistrian University of Athens, Department of Chemistry, Athens, Greece) for the statistical analysis of the dataset using SPSS 17.0.

Introduction

The Kefalonia-Ithaca UNESCO Global Geopark (UGGp) consists a distinct geographical area renowned for its remarkable geological features, valuable ecosystems, unique cultural identity, and traditional ways of life. The Kefalonia-Ithaca UGGp is characterised by its intense seismic activity due to its geotectonic setting, which is one of the most tectonically active regions in Europe. Another defining feature of the geopark is the pronounced karstification, caused by water dissolving the limestones that cover large surfaces along the two islands. This unique combination of widespread limestones, tectonic activity, and climatic conditions has led to the formation of numerous karstic features, both underground and surfacial, such as caves, sinkholes, dolines, and poljes. The richness of the natural and cultural heritage of the two islands due to their geological wealth makes the territory of Kefalonia-Ithaca UGGp a unique territory, whose structured approach will strengthen its knowledge, the importance of its functions, and its tourist, heritage, and cultural potential. Kephalonia-Ithaca UGGp constitutes a territory that promotes the sustainable development of its region by leveraging their unique geological heritage, natural landscapes, and cultural traditions. Several actions are specifically designed to highlight the area's rich geological heritage, aligning closely with the United Nations Sustainable Development Goals (SDGs). Below there is an overview of the typical actions Kefalonia-Ithaca UGGp takes to achieve these goals:

Education and Awareness

One of the primary goals of the Kefalonia-Ithaca UGGp is to provide educational programs regarding the different aspects of the natural and anthropogenic environment, aiming to inform, raise awareness, and foster a deeper connection with the region. Particularly there are several educational programs specifically designed to showcase its rich geological heritage. These initiatives play a vital role in advancing the sustainable development of the region. Additionally, the curated exhibitions at the Koutavos Lagoon Information Center and in Anogi village serve as outstanding educational resources, offering engaging and informative experiences to visitors.

The educational programs (Figure 1), which focus on geological heritage, include the following:

- The Kefalonia-Ithaca UGGp has developed a school programme specifically for geodiversity, named "Identification and protection of the geological heritage of the Kefalonia-Ithaca Geopark" for all grade levels.
- A newly developed educational package concerning the fossils of the geoparks. This educational package presents to the children how life, landscapes, and climate have changed over time and how organisms responded/adapted to those changes. The educational package consists of a worksheet, educational games for children of different ages that can be played both indoors and outdoors plus other activities all included in a dedicated museum box containing also real fossils and replicas.
- Caves in Kefalonia-Ithaca UGGp.
- The links Between Biodiversity & Geodiversity in the Aenos National Park.
- Earthquakes in Kefalonia-Ithaca UGGp
- Finally, ten 3-minute videos have been created with the theme of the presentation and interpretation of geological phenomena and structures such as deltas, the geological evolution of Kefalonia, volcanoes, sinkholes, "menirs" (monoliths), earthquakes, caves, Poros gorge, Ithaca "Fjords" and Rudists.

The involvement of the local community is very important. Partnering with schools, universities, and community groups can help foster a deeper appreciation and understanding of local heritage. Such initiatives not only cultivate pride in the community but also strengthen social bonds and contribute to reducing emigration. The Educational programs of Kefalonia-Ithaca UGGp are very well developed. Especially, the high number of visits proves their success. In total, 2,708 pupils and 143 teachers have visited the two environmental centers of Kefalonia-Ithaca geopark, since 2022. The participation of schools and the local community in the educational excursions is also remarkable.

Figure 1 Educational programs in Kefalonia Ithaca UGGp

Research and Innovation

Kephalonia-Ithaca UGGp recognizes the importance of the collaboration with academic institutions for research on geology, biodiversity, and cultural history, in order to achieve the public awareness of understanding the Earth processes, as well as the links among all these themes. For all these reasons, the Geopark collaborates with the local institutions, universities, as well as with the Department of Geology of the University of Patras, in order to develop sustainable practices.

Recent projects have focused on studying and promoting the palaeontological heritage of the Geopark, enhancing scientific understanding and attracting geotourism. For this reason, the Department of Geology of the University of Patras implemented the project “Study and exploitation of the palaeontological heritage of the Geopark of Kefalonia and Ithaca” (Iliopoulos *et al.,* 2024). Another project that the University of Patras has taken over is “The Possibilities of exploitation of clay outcrops for mud therapy” (Botziolis *et a*l., 2024) (Figure 2). Additionally, the University of Patras implemented a geotechnical study on the “Restoration of the Mycenaean Cemeteries in Mazarakata – Lakithra” (Zelilidis *et al*., 2023). It is very important also that the results of the three projects have already been published in international scientific journals.

Another project implemented by the Kefalonia-Ithaca UGGp is “BIO-MEMORY”, a project about the “Memorial Olives and olive trees” including recording, imprinting, dating and promoting them as high valued ecosystems, funded by the Ionian Islands Region. Furthermore, “BIONIAN” is another project which includes actions to protect & promote biodiversity in the Ionian Islands Region, funded also by the Ionian Islands Region and by the Ionian University, supervised also by the Geopark. A different project, “LAERTIS”, consists of an innovative management system for natural disasters management in the Ionian Islands Region funded and implemented by the Ionian Islands Region, the Ionian University, the University of Athens and the Technical chamber and the Geopark. Finally, a recent project that the University of Patras is responsible for concerns the setting up of a proposal for the development of three caves as sheaves in the wider area of the Sami Municipality and their connection to the existing speleological park of the Municipality.

Figure 2 Opening ceremony of the "Palaeontological exhibition" and presentation of the project "The Possibilities of exploitation of outcrops of clay for mud therapy"

Promotion and Visibility actions

The Kephalonia-Ithaca UGGp recognizes the importance of enhancing its promotion and visibility. For this reason, it develops and implements targeted strategies to enhance awareness and visibility of the Kephalonia-Ithaca UGGp, including organisation of conferences and workshops (Figure 3), active participation in the Greek Geopark forum, EGN and GGN, partnerships with local and international stakeholders, and use social media to reach out broader audiences.

Additionally, Kephalonia-Ithaca UGGp develops innovative technologies and strategies to improve visitor experience, while ensuring sustainability. For example, the geopark has developed two visitor centers (one in Kefalonia and one in Ithaca), guided tours, and educational excursion on a systematic basis, which is a very important tool for studying climate change impacts on geological and ecological systems; and develop innovative geotourism strategies to enhance visitor experiences sustainably. Additionally, the Geopark provides presentations and facilitates meaningful discussions with visitors at its information centers.

Kefalonia-Ithaca UGGp has since 2021 organized several events. These events have variable subject topics and include the natural, cultural and intangible heritage of the geopark. The organization of these events avoids the depletion of natural resources, in order to keep an ecological balance that doesn't allow the quality of life of modern societies to decrease.

Some examples of these actions follow below:

- 10 new geosites and three new thematic georoutes to promote sustainable tourism and educate visitors about the importance of preserving natural and cultural heritage were created last year.
- International Festival of Environmental Arts "WE ARE NATURE" at the Ionian center of arts and culture and at Koutavos lagoon geosite
- Wild life photography workshop and bird watching event at Koutavos Lagoon geosite

- Annual informative trip about the aromatic and edible oregano plant in Aenos area
- Geofestival

Additionally, Kephalonia-Ithaca UGGp acknowledges the significance of cooperation by integrating people from local communities, in order to achieve its goals for sustainable development and prosperity, supporting peace and protecting our planet. For this reason, Kefalonia-Ithaca UGGp organizes voluntary actions of Geosites' maintenance as well as educational excursions on a systematic basis, with students of elementary schools in cooperation with Municipalities, in order to awaken ecological awareness.

Furthermore, during the last two years, Kefalonia-Ithaca UGGp in cooperation with the Municipality of Argostoli has created five walking routes for the public in areas where no cars exist. Also, in Ithaca 16 signalized paths that already exist have been added to the geoparks hiking routes. Until now, in Kefalonia-Ithaca UGGp there are almost 30 hiking routes, 13 thematic georoutes and 2 sea georoutes. All of them include geosites with combined value as well as cultural monuments and rich biodiversity.

Finally, the geopark is also responsible for the maintenance of the geosites and the paths in cooperation with the Municipalities of Kefalonia and Ithaca. Additionally, the geopark takes part regularly to the maintenance of several sites in cooperation with other public authorities and within celebration events of Special Days.

Introduction / Background

The Petrified Forest of Lesvos is a unique natural monument located in the western part of Lesvos Island, Greece. It was formed during the Lower Miocene due to intense volcanic activity in the North Eastern Aegean region.

The Lesvos Petrified Forest was declared a protected natural monument in 1985, and its protected area covers 15,000 hectares. In 2000, it became one of the first four European Geoparks. In 2004, it was a founding member of the Global Geoparks Network. Lesvos Island was designated a UNESCO Global Geopark in 2015 by the UNESCO General Conference. The Lesvos Petrified Forest is the primary geological heritage feature of international significance that led to the recognition of Lesvos Island as a UNESCO Global Geopark. Furthermore, it was recognized as one of the first 100 IUGS geological heritage sites by the International Union of Geological Sciences. Thus, the Lesvos Petrified Forest is one of the most important geological heritage sites for research, education, tourism, and sustainable development.

During the last decade, the new road connecting Kalloni with Sigri was constructed, traversing the western peninsula of Lesvos and specifically the protected area of the Lesvos Petrified Forest. During road construction, a large number of remarkable fossil sites with impressive fossilized tree trunks were unearthed, located along the roadside. Consequently, twelve fossiliferous localities along the Kalloni-Sigri road now constitute an open-air park, offering visitors a unique experience within the Lesvos Petrified Forest.

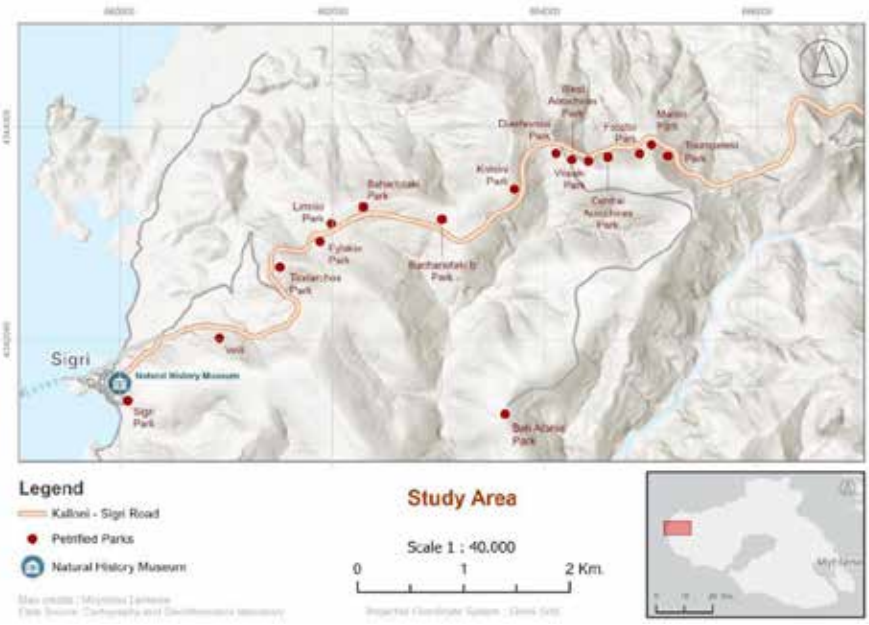

Fig. 1: Location map of the studied area within the Lesvos Island UNESCO Global Geopark, illustrating the 14 fossiliferous localities transformed into open-air parks along the Kalloni-Sigri road.

Geological setting

Lesvos Island is located in the northeastern Aegean Sea. Miocene volcanic rocks dominate western Lesvos and cover the metamorphic basement, which consists of schists and marbles principally of Permian age (Katsikatsos et al., 1982). The oldest Cenozoic rocks overlying the metamorphic basement are lacustrine marls, shales, sandstones, and lignites of the Gavathas Formation (Koufos et al., 2003). The Miocene volcanic sequence of Lesvos comprises andesite, dacite, and basalt lavas, ignimbrites, and a thick pyroclastic sequence (Pe-Piper, 1980; Pe-Piper & Piper, 1993, 2002), which hosts impressive numbers

of silicified tree trunks. The Sigri Pyroclastic Formation consists of several hundred meters of pyroclastic flow tuffs (unwelded ignimbrites) interbedded with fluvial conglomerate and volcaniclastic sandstone. The Sigri Pyroclastic Formation ranges in age from 21.5–22 Ma to younger than 18.4 Ma. Tuffs and fluvial conglomerates in the Sigri Pyroclastic Formation coarsen eastward. Fossiliferous localities with a large number of standing and lying petrified trees, as well as soil horizons, occur throughout the formation (Velitzelos & Zouros, 1997, 1998; Pe-Piper et al., 2019; Zouros et al., 2022).

Research, Excavations and Geoconservation activities in the Lesvos Petrified Forest

The Natural History Museum of the Lesvos Petrified Forest, established in 1995, is a public institution dedicated to the protection and sustainable management of the Lesvos Petrified Forest. Since 1997, the Museum has conducted research activities to identify and map fossiliferous localities in the western peninsula of Lesvos Island. These localities have been identified around Sigri village, in the Tsichliontas river valley, in the Akrocheiras hill range, in the areas of Gavathas and Lapsarna villages, the area north of the Tapsas river valley, the area of Skamiouda, and the area of Eressos village. Systematic excavations have been carried out in the area of Kyria Apolithomeni (Bali Alonia), owned by the Greek state, as well as in areas offered to the Museum by the Greek state, such as the Sigri, Plaka, and Nissiopi Parks (Velitzelos & Zouros, 1997; Zouros et al., 2007; Zouros, 2021). The Museum also conducts rescue excavations within the protected area of the Lesvos Petrified Forest in response to fossil findings during the construction of public and private works.

During the Kalloni-Sigri road construction, the Museum, with support from the Ministry of Public Works, implemented necessary measures, including revisions to the initial road plan, to ensure the protection of fossils and the preservation of significant fossil sites along the road (Zouros et al., 2022).

The Museum implemented a comprehensive geoconservation plan, which included significant challenges: conducting rescue excavations along the Kalloni-Sigri road during road construction, mapping and protecting the newly discovered fossil sites, collecting and conserving the vast number of unearthed fossils, transferring and storing the movable fossils, and protecting and preserving in situ the standing fossil trees and significant lying fossil tree assemblages. This rescue excavation project, which lasted ten years (2004-2014), represents the most extensive paleontological excavation in Greece.

The rescue excavation project was followed by a second project funded by the Operational Programme 2014-2020: North Aegean,.that included a series of interventions to improve accessibility to the fossiliferous sites, provide interpretation and information signage, and develop infrastructure for visitor services. The various fossiliferous sites along the Kalloni-Sigri road are now part of a new, globally unique open-air museum, offering Lesvos Geopark visitors a novel geotourism attraction. In addition to various awareness-raising activities, a new campaign entitled “Walk the Forest” introduces the new petrified forest parks to the public.

Material and Methods

The Museum’s research team monitored the construction work to detect and protect fossils along the new Kalloni-Sigri road. When a new fossiliferous location was encountered, construction work was halted, and the Museum’s excavation team, with the assistance of the Museum’s conservation team, uncovered the fossils from their pyroclastic cover. Detailed cleaning and conservation work took place in situ. Detailed information on the dimensions and stratigraphic location was recorded at 15 fossiliferous locations along the new Kalloni-Sigri road. For all fossils, detailed measurements and location data were taken. The main fossil assemblages, the most prominent fallen tree trunks, and the majority of the standing tree trunks were preserved in their original positions. The removed fossils were secured in plaster casts, and fossil fragments, as well as parts of the respective fossil leaf horizons, were stored in wooden boxes.

Results of the rescue excavations along the Kalloni - Sigri road

The Museum’s research team was monitoring the construction work to detect and protect fossils along the new Kalloni-Sigri road. Fifteen fossiliferous localities have been excavated, revealing numerous fossilized trees and leaves that offer new data on the creation and composition of the Lesvos Petrified Forest.

The **Taxiarchis** locality (Fig. 1) hosts two large conifer tree trunks rooted in tuffs and volcanic conglomerates of the Sigri Pyroclastic Formation, inclined towards the west. In the same locality, two other large conifer trees lie within the volcanic conglomerates, indicating a NNW-SSE tree fall direction.

The **Filakio** locality (Fig. 1) is a significant site hosting three successive paleosol horizons associated with standing tree trunks and extensive root systems. More than 31 standing and lying tree trunks are preserved in their original positions. In this location, six large and medium-sized conifer and angiosperm tree trunks lie within the pyroclastic horizons, indicating a N-S to NNW-SSE tree fall direction.

The **Bachariotaki** locality (Figs. 1, 2) features more than 35 lying and standing tree trunks preserved in their original positions. The majority of the lying tree trunks indicate a N-S to NNW-SSE tree fall direction.

The **Kotsini** locality (Figs. 1, 3) primarily hosts standing tree trunks covered by volcanic conglomerates overlying a very characteristic paleosol horizon. Two lying tree trunks indicate a N-S to NNW-SSE tree fall direction.

Fig. 2. General view of the Bachariotaki fossiliferous locality. N-S to NNW-SSE tree fall direction detected at the site, indicating the moving direction of the pyroclastic flow.

Fig. 3. Petrified tree trunk in Kotsini fossiliferous locality. The roots of the standing tree trunk are diveloped in the silicified paleosoil holizon dividing the lower tuffs with the upper pyroclastic conglomerate.

The **Diastavrosi** locality (Figs. 1, 4) features an intact petrified tree, 19 meters high, with its branches and roots unearthed. The tree was embedded and entombed by the cataclysmic volcanic eruptions of the Vatousa volcano, as the ESE-WNW tree fall direction indicates the moving direction of the pyroclastic flow that transported trees from their original growing location. This is a unique find worldwide. In the same location, two more fossilized trunks have been identified in their natural positions, along with five fossilized trunks, 30 parts of fossilized trunks, and 2,989 fragments of fossiliferous horizons with an abundance of fossilized leaves.

The **West Akrocheiras** locality (Fig. 1) exhibits seven successive paleosol horizons visible between the pyroclastic horizons. Five fossilized tree trunks are rooted in their natural positions. Additionally, 42 fossilized logs or parts of fossilized logs and 6,357 fragments of fossiliferous horizons with an abundance of fossilized leaves are present.

The **Vrysaki** locality (Fig. 1), a continuation of the previous site, also features successive paleosol horizons. Standing and lying tree trunks are embedded in the pyroclastic horizons, including a large standing conifer tree trunk. Ten fossilized trunks are found standing in their original positions. In the same locality, 30 lying fossilized trunks and 2,989 fragments of fossiliferous horizons with an abundance of fossilized leaves are present.

Fig. 4. General view of the Diastavrosi excavation site. 19 meters long tree found intact with its branches and roots with a fall direction towards 113°.

Fig. 5. General view of the Freation fossiliferous locality. E-W and NNW-SSE orientation of the tree fall direction indicate the moving direction of the pyroclastic flow that transported trees from their original site

Fig. 6. The western part of Freation fossiliferous locality. Several excavated tree trunks are covered by plaster cast to avoid damage during excavation works, while others are visible during excavation works

The **Central Akrocheiras** locality (Fig. 1) exhibits successive pyroclastic horizons. Six fossilized tree trunks are rooted in their natural positions. Additionally, 28 fossilized logs or parts of fossilized logs and 2,620 fragments of fossiliferous horizons with an abundance of fossilized leaves are present.

The **Freatio** locality (Figs. 1, 5, 6) is a significant site due to the exceptionally high number of fossilized trunks excavated and preserved on-site. In this locality, 400 silicified tree trunks have been excavated and remain in their excavation positions. Remnants of the trees are found embedded and entombed in pyroclastic flows created by cataclysmic volcanic eruptions from different volcanic centers located east and south of the excavation site. Successive horizons of tuffs are visible, with lying and standing tree trunks preserving evidence of large-scale mudflows. There are also 395 fossilized logs and parts of fossilized logs that have been removed to allow the excavation of the lower fossiliferous horizons. At the same location, 216 selected fragments of fossiliferous horizons with an abundance of fossilized leaves are present. Most of the fossil trunk fragments have been revealed from the Quaternary fluvial conglomerates overlying the pyroclastic tuffs. Three groups of fallen tree trunks are present. The lower group includes tree trunks in the N-S to NNE-SSW (180°-190°) direction, the middle group with an E-W direction (250°), including the longest tree trunks exceeding 25 meters, and the upper group with a NW-SE direction (140°).

Fig. 7: Panoramic view of the I. Toubelekis park fossiliferous locality, where five successive horizons of standing and rooted fossil trunks are visible

Table 1: Fossiliferus localities along the new Kalloni-Sigri road

A/A	Site name	Code	In situ fossils	Removed fossils	Fossil leaves
1	Veili	ΒΕΛ	1	655	
2	Taxiarchis	ΤΧ	2	31	
3	Fylakio	ΦΥ	31	88	
4	Limnio	ΜΡΤ	2	5	
5	Bachariotaki	ΜΠΤ	35	91	
6	Bachariotaki B	ΜΠΤ	4	3	
7	Kotsini	ΜΠΥ	20	2	55
8	Diastavrosi	ΔΜΠ	2	35	2.989
9	West Akrocheiras	ΑΚΥ	5	42	6.357
10	Vrysaki	ΒΡΥ	11	53	3.600
11	Central Akrocheiras	ΒΡΦ	6	28	2.620
12	Freatio	FRE	400	395	216
13	Mantri Toumpeleki	ΤΟΑ	243	0	281
14	I Toumpelekis	ΜΤΟ	127	75	236
15	Moni Ypsiloy	ΑΚΒ ΜΥΒ	2	6	
	Total		**909**	**1.491**	**16.354**

The **Mantri Toumbeleki** locality (Fig. 1) exhibits successive layers of tuffs with lying and standing tree trunks, preserving evidence of large-scale mudflows. The site hosts 243 lying and standing fossilized tree trunks. Additionally, 281 fragments of fossiliferous horizons with an abundance of fossilized leaves are present.
The **I. Toumbelekis** locality (Figs. 1, 7) is a significant site featuring successive layers of tuffs with lying and standing tree trunks. Five successive layers with standing and rooted fossil trunks are visible. The site hosts 127 lying and standing fossilized tree trunks. Furthermore, 395 fossilized logs and parts of fossilized logs have been transported from the site, and 236 fragments of fossiliferous horizons with a plethora of fossilized leaves are present.

Discussion

The excavated localities provide new data regarding the composition of the Lesvos Petrified Forest, its creation, and the stratigraphy of the Sigri Pyroclastic Formation (Zouros et al., 2015; Pe-Piper et al., 2019; Zouros, 2021; Papadopoulou et al., 2025). The vast amount of fossils recovered from the rescue excavation sites along the Kalloni-Sigri road, presented in Table 1, provides a unique archive with significant new data and research results on the composition of the flora, as already published (Zouros et al., 2015, 2022; Zouros, 2021; Kafetzidou et al., 2022; Liapi et al., 2022, 2024; Tsitsou et al., 2022; Zhu et al., 2024). The collected materials will yield further results as they are gradually studied in the coming years.
The rescue excavations along the Kalloni-Sigri road have demonstrated that the Petrified Forest of Lesvos is the result of successive cataclysmic volcanic eruptions that occurred during the period from 21 to 18 million years ago (Pe-Piper et al., 2019). The excavation sections revealed that the formation of the Lesvos Petrified Forest resulted from various eruptive events, leading to the presence of successive pyroclastic horizons hosting standing and rooted petrified trees, separated by paleosol horizons and erosional discontinuities. The collected data are consistent with the suggestion that the pyroclastic materials originated from a southeast-located volcanic center, possibly the one in Messotopos (Pe-Piper et al., 2019).

UNESCO Global Geoparks and Global Geoparks Network : Protecting, promoting and managing Earth heritage - Building Sustainable Communities

Zouros, Nikolaos,[1,2]
(1) Department of Geography, University of the Aegean, Mytilene, Greece (2) Natural History Museum of the Lesvos Petrified Forest, Sigri, Greece nzour@aegean.gr

Introduction / Background

The Geopark concept was introduced at late 90's aiming to protect and promote Earth heritage sites through the sustainable local development of territories containing abiotic nature of significant value.

In June 2000 the first Geoparks Network was formed in Europe by four territories hosting geological heritage sites of international significance. The first four Geoparks in Europe were the Reserve Geologique Haute Provence - France, the VulkanEifer Geopark - Germany, the Petrified Forest of Lesvos - Greece and the Maestrazgo Cultural Park - Spain.

Geoparks adopted a bottom-up process involving all relevant local and regional stakeholders and authorities in the area (e.g. local authorities, heritage managing bodies, national/natural park managers, museums, landowners, community groups, tourism providers, community initiatives, indigenous people, and local associations). This process requires firm commitment by the local communities, a strong local multiple partnership, public and political support.

The European Geoparks Network (EGN) developed quickly including new territories from from the founding countries as well as from UK, Italy, Ireland and Austria offering a new model for the protection and sustainable management of the geological heritage monuments through the sustainable development of the local communities. Geoparks activities gain support of the United Nations Educational, Scientific and Cultural Organization (UNESCO) as part of it's official programme. UNESCO's Division of Earth Sciences supported the EGN development and signed a collaboration agreement in 2001. In 2004 the EGN included 17 members from 8 European countries.

Taking into account the success of the EGN as well as Geopark initiatives in China, UNESCO's Division of Earth Sciences started efforts for the creation of the Global Geoparks Network as a platform of cooperation between areas hosting and managing geological heritage of international significance.

The Global Geoparks Network (GGN) was established in 2004, under the umbrella of UNESCO, including 25 Global Geoparks from Europe and China. The GGN operated initially as an international voluntary network, bringing together protected geological heritage sites management bodies, government agencies, non-governmental organizations, scientists and experts from all countries around the world in a unique worldwide partnership.

Global Geoparks as members of GGN operate to share best practice and exchange know how on various aspects in order to protect, conserve and enhance the value of geological heritage sites, including landscapes and geological formations, which are key witnesses to the evolution of our planet and to promote the sustainable development of their territories through geo-tourism and education activities.

In 2014 after one decade of successful operation as a volunteer network the GGN gained legal personality in order to achieve a major goal, the recognition of the Geopark label, the officialization of it's relationship with UNESCO and the establishment of the third UNESCO site designation. The GGN General Assembly during the 6th International Geoparks Conference in Stonehammer Global Geopark, Canada agreed to the new GGN Statutes and the GGN became an international non-profit international association, subject to French legislation (the 1901 law on associations).

Thus the GGN became an International Association following the ICOM model, including institutional members - Global Geoparks and individual members - Global Geopark professionals. The GGN includes Regional Geopark Networks which foster international co-operation and promotion of the Geopark concept and activities at the regional level.

The 38th UNESCO General Conference on November 17th 2015, ratified the statutes of the new International Geoscience and Geoparks Programme and the UNESCO Global Geoparks Operational Guidelines, introducing the brand UNESCO Global Geopark as a label of excellence for areas that meet certain criteria. The GGN is maintaining formal relations with UNESCO and became the official partner for the operation of the UNESCO Global Geoparks programme under the umbrella of the International Geosciences and Geoparks Programme (IGGP).

21 years after its establishment the GGN includes 213 UNESCO Global Geoparks in 48 countries and during 2025 will add 16 new members, reaching 229 UNESCO Global Geoparks in 50 countries.

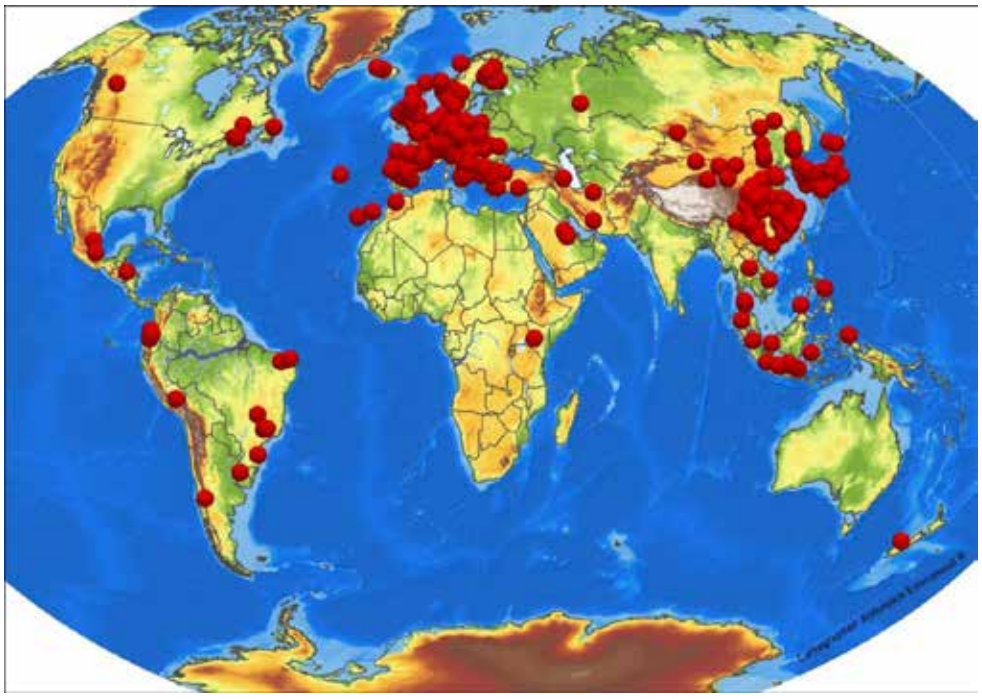

Fig. 1. The Global Geoparks Network includes 229 Geoparks in 50 Countries (2025). List of the UNESCO Global Geoparks at unesco.org

The UNESCO Global Geoparks

The UNESCO's decision introducing under the umbrella of the International Geosciences and Geoparks Programme (IGGP) the UNESCO Global Geoparks Programme (UGGp) together with the existing since 1972 International Geosciences Programme (IGCP) [originally termed the International Geological Correlation Programme], has legally establish the new UNESCO site designation "UNESCO Global Geopark" and endorsed the existing 120 Global Geoparks to become UNESCO Global Geoparks with immediate effect.

The UNESCO Global Geopark branding strongly contributed to raise UNESCO's visibility in Earth Sciences community but also to local communities around the globe in territories hosting exceptional geological heritage sites. The new Programme offer UNESCO a new field of activities and high-quality public outreach on sustainable development in rural territories linked with main global challenges such as the holistic environmental and heritage management, the geodiversity protection and conservation, the geo-hazards mitigation, the climate change adaptation and the sustainable use of natural resources.

Moreover it has been identified that this new UNESCO branding could also be of clear advantage for the development of Global Geoparks in those regions where none currently exist and will be the mechanism to assist countries in the development of Global Geoparks.

UNESCO Global Geoparks according to the Programmes statutes and operational guidelines should fulfill the following basic criteria (UNESCO, 2015):

i. UNESCO Global Geoparks must be single, unified geographical areas where sites and landscapes of international geological significance are managed with a holistic concept of protection, education and sustainable development. The geological heritage sites of international significance should be independently verified by scientific professionals.

ii. UNESCO Global Geoparks should use that heritage, in connection with all other aspects of that area's natural and cultural heritage, to promote awareness of key issues facing society in the context of the dynamic planet we all live on, in particular to increase knowledge and understanding of: geohazards; climate change; the need for the sustainable use of Earth's natural resources; and the empowerment of indigenous peoples.

iii. UNESCO Global Geoparks should be areas with a management body having legal personality recognised under national legislation. The management bodies should be appropriately equipped to adequately address the area of the UNESCO Global Geopark in its entirety.

iv. UNESCO Global Geopark status shall add value by being both independently branded and in synergy with the other designations.

v. UNESCO Global Geoparks should actively involve local communities and indigenous peoples as key stakeholders in the Geopark. In partnership with local communities, a co-management plan needs to be drafted and implemented

that provides for the social and economic needs of local populations, protects the landscape in which they live and conserves their cultural identity.

vi. UNESCO Global Geoparks are encouraged to share their experience and advice and to undertake joint projects within the GGN. Membership of GGN is obligatory.

vii. A UNESCO Global Geopark must respect local and national laws relating to the protection of geological heritage. The defining geological heritage sites within a UNESCO Global Geopark must be legally protected in advance of any application. At the same time, a UNESCO Global Geopark should be used as leverage for promoting the protection of geological heritage locally and nationally. The management body must not participate directly in the sale of geological objects within the UNESCO Global Geopark (regardless of their origin) and should actively discourage unsustainable trade in geological materials.

UNESCO Global Geoparks are evaluated during the initial application by an independent team composed of desk-top advisors and field evaluators.

The justification of the international significance for the geological heritage sites present in an applicant territory is made by experts nominated by the IUGS Geoheritage Commission, through a desk top examination of the geological heritage section of the application. The assessment follows the agreed methodology described by the document Guidelines for the assessment of the international significance of geological heritage in UNESCO Global Geopark applications, which was adopted by the UNESCO Global Geoparks Council. (https://unesdoc.unesco.org/ark:/48223/ pf0000386952)

The evaluation of the Geopark application is made by field evaluators, nominated by the UNESCO Global Geoparks Bureau. The evaluators verify the application in the field using the Checklist to define an aspiring UNESCO Global Geopark (aUGGp). (https://unesdoc.unesco.org/ark:/48223/pf0000383838). The evaluators are submitting their evaluation report and proposal to the UNESCO Global Geoparks Council.

The field evaluators are currying out also the re-validation of the Geoparks operation and activities, submitting their re-validation report and proposal of a green, yellow or red card to the UNESCO Global Geoparks Council. Re-validation missions take place every 4 years (or two years in case of a yellow card).

The UNESO Secretariat in conjunction with the GGN has established and maintains a roster of field evaluators who undertake field evaluations of new applications for aspiring UNESCO Global Geoparks and the revalidations of the already recognized UNESCO Global Geoparks.

The UNESCO Global Geoparks Council, composed by 12 experts and 4 representatives of international bodies supporting Geoparks, is the decision making body for new UNESCO Global Geopark applications and the revalidation of the already recognized Geoparks. The Council takes proposes the new UNESCO Global Geoparks to the UNESCO Executive Board which is the responsible for the nomination of the new UNESCO Global Geoparks. It is also responsible for advising the UNESCO's Director-General on the strategy planning and implementation of the Global Geoparks activity of the IGGP.

During the last 21 years hundreds of Geopark evaluation and re-validations missions have been curried out by Geopark experts. Due to UNESCO's international recognition through Geopark evaluation and revalidation missions outstanding geological heritage sites were protected, conserved and rationally managed.

The Global Geoparks Network

Since its foundation in 2004, the Global Geoparks Networks (GGN) mission is to influence, encourage and assist local communities all over the world to protect and conserve geological heritage sites of international significance, to enhance the integrity and diversity of abiotic and biotic nature and to support economic and cultural development of local communities through the valorisation of their unique heritage and identity.

The GGN established ethical standards which must be adopted and respected by Global Geoparks and Global Geopark professionals.

Every two years the GGN organizes the International Conference on UNESCO Global Geoparks which takes place each time in a different UNESCO Global Geopark selected after a public bid.

The operation of the Global Geoparks Network is based on the active participation of its members through networking at the international, regional, national and local level.

The GGN Members meet every two years at the GGN General Assembly which takes place during the International Conference on UNESCO Global Geoparks, to discuss the GGN activities during the previous years and adopt the strategic action plan for the next biennium. The GGN General Assembly elects the Executive Board which is the decision making body of the Network and responsible to implement the decisions of the General Assembly.

The GGN Advisory Committee consists of the representatives of all the National Geopark Networks and is responsible to advice the GGN on the strategic planning issues. GGN Advisory Committee meets 4 times a year to discuss the implementation of the GGN Strategic Action Plan and to define the GGN Long Term strategy as well as the biannual Strategic Action Plan.

Fig.2. The GGN General Assembly during the 10th International Conference on UNESCO Global Geoparks organized by the M'Goun UNESCO Global Geopark, in Marrakesh, Morocco, September 2023

The GGN Executive Board established several Thematic Working Groups with the participation of GGN Regional Network representatives and Geopark professionals to elaborate proposals and activities in the respected session. The themes of the GGN Working Groups are : a. Geohazards, b. Climate change adaptation, c. Geological heritage and Geodiversity, d. Geodiversity and Biodiversity, e. Sustainable Development Goals, f. Education, g.Tourism, h. Geopark Cultural Heritage, i. Indigenous people, j. Island and coastal areas / Waters / Ocean, k. Gastronomy, l. Communication, m. Geoparks as therapeutic landscapes and n. International Networking.

The GGN Executive Board in order to strengthen the GGN logo visibility and use in activities aiming the promotion of the Geoparks brand, took measures to register and protect the GGN Graphic logo, acronym and the name "Global Geoparks Network" and created a series of combined GGN logos to be used by the different GGN bodies and Regional and National Networks, in order to enhance consistency, efficiency, and flexibility in communication and promotion of the Geopark brand.

GGN Capacity building activities

The GGN advances and disseminates knowledge through capacity building activities organized in collaboration with the UNESCO Secretariat. Capacity building activities include training courses for Geopark managers and staff, on disciplines related to Geopark management, geo-heritage and geo-diversity, geo-conservation, geo-tourism, geo-education and sustainable local development.

The International Intensive Course on UNESCO Global Geoparks is organized every June in Lesvos since 2007 as a join initiative between GGN and UNESCO Secretariat. It is organized by the University of the Aegean and the Natural History Museum with field trips in Lesvos island UNESCO Global Geopark. Since 2001 the UNESCO Chair on Geoparks and the sustainable development of insular and coastal areas at the University of the Aegean is operator for the Course academic programme.

The annual International Training Course on UNESCO Global Geoparks Management and Development has been successfully operated by the China University of Geosciences (Beijing) since 2016. This Course receives full support of UNESCO Global Geoparks Secretariat and Global Geoparks Network, as well as Asia Pacific Geoparks Network and the University of the Aegean. With the close collaboration of Yanqing, Fangshan, Taishan, Songshan, Yimengshan, Zhangye and Xiangxi UNESCO Global Geoparks, the last seven sessions of this Course took place successively in these geoparks, starting with just field lectures and gradually turning into both indoor and field lectures in geoparks.

Fig 3. The international capacity building activities of the Global Geoparks Network in Lesvos, Greece and Beijing, China

The lecturers of the courses are top international Geopark experts and experienced geoscientists and managers from UNESCO Global Geoparks, UNESCO officials, members of the UNESCO Global Geoparks Council and the Global Geoparks Network Executive Board and academic institutions.

Global Geoparks Network facilitates Geopark networking and international collaboration

The GGN encourages and supports co-operation, twinning agreements and exchanges between UNESCO Global Geoparks through common projects, initiatives and activities.
The GGN encourages and supports geopark networking through Geopark conferences, workshops, meetings, common projects and common promotional activities but mainly through the operation of its Regional Geopark Networks and National Geopark Geopark Networks/For a, including all GGN members in each region or country.
The GGN structure includes five regional geopark networks in Europe, Asia Pacific, Latin America and Caribbean, North America and Africa. Regional Networks operate , Thematic Workshops, Meetings and Promotional activities.
Geopark networking facilitates the development and transfer of new methodologies and approaches for the management of Geoparks. The holistic geopark approach in territorial heritage management includes biotic and abiotic factors, landscapes and cultural heritage, holistic nature conservation strategies and action plans, sharing of know-how and new approaches to improve landscape interpretation, awareness raising and public sensitization and the development of educational and touristic activities.
Geopark cooperation provides excellent outcomes and help Geoparks to achieve an effective management and a high level of services and infrastructure. The quick development of Global Geoparks around the globe during the last two decades proves the success of the Geopark concept as a new tool for holistic nature conservation and sustainable rural development through geo-tourism.
The Global Geopark Network seek for international cooperation with other partners on common interests. GGN is a statutory partner of UNESCO for the operation of the UNESCO Global Geoparks programme. GGN has affiliation relationship with the International Union of Geological Sciences (IUGS) and longstanding cooperation with International Union for Nature Conservation (IUCN) to support the Geoparks development. The GGN signed a cooperation agreement with the World Tourism Organization (UNWTO) for the International Year of Sustainable Tourism.

UNESCO Global Geoparks protecting and managing Geological Heritage

A main field of operation for a Geopark is the protection and management of the geological heritage within the Geopark territory. Geopark activities include scientific research, identification and mapping of the geological heritage sites, creation and management of an inventory of geological sites, protection and conservation of geological heritage sites, operation of open air parks, thematic museums and interpretation centers, interpretation and promotion of geological heritage sites, organization of scientific and cultural events.
Through Geoparks operation important geological sites gain worldwide recognition and benefit through the exchange of knowledge, expertise, experience and staff among Geoparks. The new initiative of the IUGS for the first 100 IUGS Geological Heritage Sites (announced in 2022 in Zumaia, Spain) and second 100 IUGS Geological Heritage Sites (announced during the 37th IGC in Busan, Republic of Korea) includes 38 outstanding Geological monuments located in UNESCO Global Geoparks. Among them, the Amonite slab in Digne-les-Bains (Haute Provence Geopark) France, the Lesvos petrified forest, (Lesvos Geopark) Greece, the Holocene Ulmen Maar (Vulkaneifel Geopark) Germany, the alpine superposed buckle folds in Aliaga (Maestrazgo Geopark) Spain, the Dashanpu dinosaus fossil site (Zigong Geopark) China, the Cretaceus-Paleogene Stratigraphic section in Zumaia (Basque Coast Geopark) Spain, the Genbudocave (Sanin Kaigan Geopark) Japan, the Messel Pit fossil site (Bergstrasse-Odenwald Geopark) Germany, the Lower pillow lavas of Troodos ophiolites (Troodos Geopark) Cyprus, the Ngorongoro Crater (Ngorongoro-Lengai Geopark) Tanzania, Shilin Karst (Shilin Geopark) China and Monte Perdito Massif Tectonic structure (Sobrarbe Geopark) Spain.
This recognition shows the value of the geological heritage sites included in UNESCO Global Geoparks as well as the importance of the Geopark label for safeguarding outstanding geological heritage sites, lacking proper management and propmotion.

UNESCO Global Geopark activities and sustainable local development

A broad range of activities combines the main components of a UNESCO Global Geopark operation such as geoconservation, geoeducation, geotourism, and sustainable development.
Geoparks promote themselves as educational territories for sustainability. Geopark educational activities include

a vast range of programmes for all levels of education, from kindengrden and elementary schools, highschools, university students, master courses, vocational training and lifelong learning. Main target group for educational activities in Geoparks are schoolchildren and University students.
Geoparks also promote themselves as ideal destinations for geotourism. Geo-tourism in a form of tourism that sustains, or even enhances, the identity of a place, such as its environment, culture, heritage, and the well-being of its residents.
During the last years Geoparks following the provisions of their management plan implemented a range of actions aimed at the further improvement of its geotourism infrastructure, services, activities and promotion.
The results of the Geopark operation show a significant increase in the number of visitors, the enrichment of their geotourism offer and services to visitors and improvement in geological heritage protection and management..
An important component of the Geopark operation is the support of the local economy. Geoparks create links with local tourist enterprises, restaurants and small hotels in order to provide the necessary infrastructure to meet the needs of the increasing number of park visitors. The majority of visits to the Geopark occur during the summer period, but the aim is to extend the visiting period to the spring and autumn seasons. Geoparks present impressive results in this field. In some cases the number of “Bed and Breakfast” accommodations has doubled over the last few years in order to meet the increasing demand. More importantly, visitors have increased the duration of their visit to the Geopark area. As a result many new enterprises are connected with the activities of the Geopark.
Geoparks support local handicrafts making such as the production of fossil casts and souvenirs by local enterprises. These items are on sale in the Geopark shop along with a variety of other locally made products and the Geopark promotes these products to its visitors.
GGN promotes local gastronomy as an important factor of the Geopark’s identity. Food is reflecting the traditions, history, and values of a territory. In Geoparks, where the conservation of local heritage is paramount, gastronomy serves as a means of celebrating and safeguarding traditional culinary practices, recipes, and food products. By promoting Geopark Gastronomy as a quality brand, local communities can strengthen their cultural identity and promote a sense of pride and belonging among residents and visitors alike. Whether through traditional food festivals, farm-to-table dining experiences, or culinary workshops, Geoparks engage visitors in authentic gastronomic experiences that create lasting memories and foster a deeper connection to the destination. Geoparks collaborate closely with women’s agrotouristic cooperatives and local organic food producers to offer their visitors the opportunity to taste and buy local food products (pasta, organic vegetables, wine, liquors, traditional sweets and marmalades etc). The catering for all Geopark events (conferences, meetings etc.) is supplied using the local traditional food. The Geoparks organize agro-touristic festivals, which promotes quality local products, food and drinks. The event brings local producers and potential customers together. The Women’s agrotouristic cooperative found that this festival provided them with an excellent opportunity to promote their products and their success lead to the creation of similar cooperatives in other villages.

Conclusions

Geoparks contribute significantly to territorial development by directly and indirectly creating new jobs. But what is even more important for the employment in the area is the number of other job opportunities which are created in tourist enterprises, small hotels, guest houses, restaurants and other activities connected with the increase of tourist flow in the Geopark area.
For more than 20 years UNESCO Global Geoparks have campaigned for a holistic understanding of our planet and its evolution, for the protection of Earth heritage and for the sustainable development of their territories. With their initiatives, environmental education and awareness programmes and projects, they place a special emphasis on conveying these natural interrelationships and the impact Man has on these. UNESCO Global Geoparks have been actively pursuing the Global Agenda 2030 with the 17 SDGs for a number of years. Their bottom-up approach with community participation and capacity building, their sustainable regional development activities make the UNESCO Global Geoparks ideal places to understand the relevance of the SDGs and also the responsibility of their implementation. The GGN provides through networking the opportunity for exchanging ideas with partners around the world. Thus the UNESCO Global Geoparks provide ideal model territories for implementing the Agenda 2030. They form the decisive interface between international declarations of intent and concrete on-the-spot activities – which means the transformation from strategy to action.

Introduction / Background

Lemnos Island, located in the northeastern Aegean Sea, is an area rich in a wide variety of geological and geomorphological features, including fossiliferous sites, volcanic geosites, and impressive erosional landforms within sedimentary formations. These features are outstanding representatives of the island's geodiversity.

Geosites are protected under Greek environmental legislation (Law 1650/1986 and Law 3937/2011), as they serve as important witnesses to Earth's geological history. However, the geosites of Lemnos and their geotourism potential remain largely underexplored.

This paper presents the work undertaken to identify, map, and assess the geosites of Lemnos Island, with the aim of selecting the most representative ones—based primarily on their aesthetic value and potential for geotourism development.

The research team on geological heritage and geodiversity from the Department of Geography at the University of the Aegean, in collaboration with the Natural History Museum of the Lesvos Petrified Forest, initiated a project in 2012 to identify and map fossiliferous sites containing fossilized plants on Lemnos. As a result, the Lemnos Petrified Forest was declared a protected natural monument in 2013.

The research has since expanded to include the identification and mapping of a wider variety of geosites across the island. In line with the growing global interest in geotourism, the main objective has been to connect these geosites through thematic geotrails, linking them with other sites of ecological and cultural significance. This approach has the potential to foster greater community interest, engagement, and involvement in their sustainable management.

This initiative is supported by the North Aegean 2014–2020 Regional Operational Program through the action "Creation and Operation of Digital Applications for the Promotion of Geo-monuments of Lemnos." This project, implemented by the Natural History Museum of the Lesvos Petrified Forest in collaboration with the Municipality of Lemnos, focuses on promoting geological monuments, landscapes, and ecologically significant sites, with the aim of encouraging the development of alternative forms of tourism.

Geological setting

The island of Lemnos is the eighth-largest Greek island, covering an area of 476 km² and featuring a coastline of approximately 310 km. The island's morphology is generally smooth, with low relief on the eastern side, while the western part is more hilly. The highest point is Skopia (Vigla) in the northwest, reaching an elevation of 470 meters.

Lemnos lies on the southern margin of the North Aegean Trough, which is associated with the western extension of the North Anatolian Fault Zone. This 1,200 km-long dextral strike-slip fault and its branches that extend into the Aegean Sea facilitate the westward extrusion of the Anatolian Plate. The tectonic structures of Lemnos play a key role in understanding the recent geodynamic evolution of the broader region and the prevailing active transtensional stress regime (Pavlides et al., 1990).

The geological structure of Lemnos is relatively simple compared to other islands in the northeastern Aegean. It consists of two main units: a lower unit composed of sedimentary deposits dating from the Middle Eocene (Lutetian) to the Early Oligocene, and an upper unit of Lower Miocene volcanic rocks.

The lower sedimentary unit (Roussos et al., 1993; Innocenti et al., 1994) consists of conglomerates, sandstones, and claystones, which have been interpreted as deep-water deposits. Petrographic analysis of the sandstones indicates that the detritus is primarily composed of clasts from low- to medium-grade metamorphic and sedimentary rocks, sourced from the Rhodope Massif and the Circum-Rhodope Belt (Innocenti et al., 1994). During the Early Oligocene, these deposits were conformably overlain by shallow marine (shelf) sediments.

Volcanic activity began in the Early Miocene with the eruption of pyroclastic flows, followed by the emplacement of sills, lava flows, and domes. Three volcanic units, along with a small quartz-monzonite intrusion (the Fakos intrusion), cover much of the southwestern part of the island (Davis, 1959; Fytikas et al., 1980; Innocenti et al., 1994). These volcanic rocks include andesite, trachyandesite, trachyte, and dacite, featuring porphyritic plagioclase and alkali feldspar set in a microlitic groundmass composed of plagioclase, alkali feldspar, biotite, and quartz in varying proportions (Roussos et al., 1993).

Secondary mineral phases include micas, calcite, quartz, and clay minerals. Radiometric dating of these volcanic rocks yields ages ranging from 21 to 18.2 million years (Fytikas et al., 1984; Innocenti et al., 1994). The igneous rocks of Lemnos represent the earliest volcanic products in the North Aegean region, where volcanic activity ceased by the Middle Miocene.
The Miocene period concludes with the deposition of conglomerates, marls, and marly sandstones. Locally, Pleistocene porous calcareous and oolitic limestones occur, while Holocene alluvial deposits, coastal sediments, and dunes are also present.

Geosite identification and mapping
Fieldwork conducted between 2013 and 2020 led to the identification of 150 geosites distributed across the entire island of Lemnos.
These geosites were classified into the following categories:
a. fossiliferous sites,
b. volcanic sites,
c. stratigraphic–tectonic sites,
d. geomorphological sites (erosional and depositional),
e. other sites of interest.

The geosites were mapped using traditional field mapping methods. In parallel, Unmanned Aerial Systems (UASs) were employed, allowing for the creation of accurate, high-resolution 3D maps and models at various scales. The main objective of these maps was to promote the rich geological and geomorphological heritage of Lemnos and to effectively communicate geo-scientific concepts.
Additionally, 3D geovisualizations were developed using advanced multimedia techniques and technologies, including augmented reality, 360-degree panoramas, and ultra-high-resolution video.

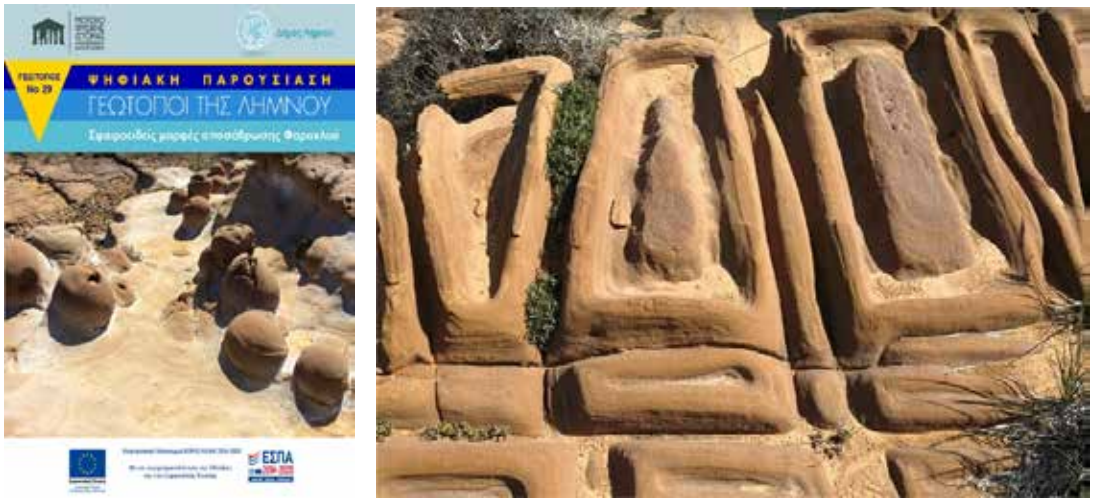

Photo 3 : The spheroidal geoforms at Farakla and Agios Ermolaos

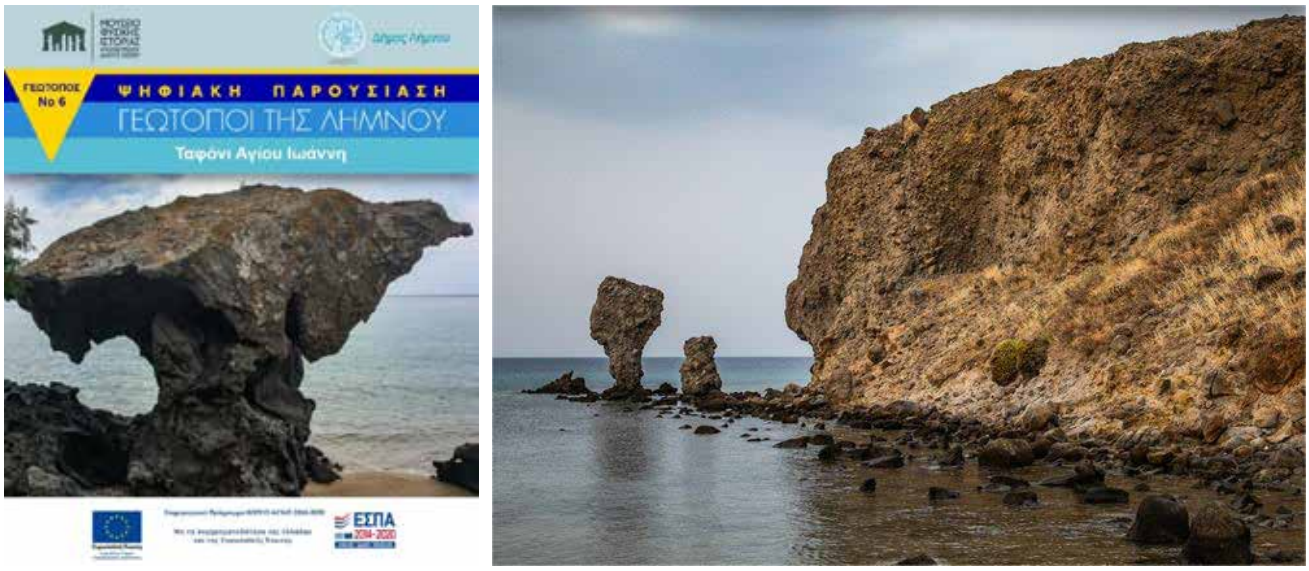

Photo 4 The Agios Ioanis tafoni structure and the sea stacks

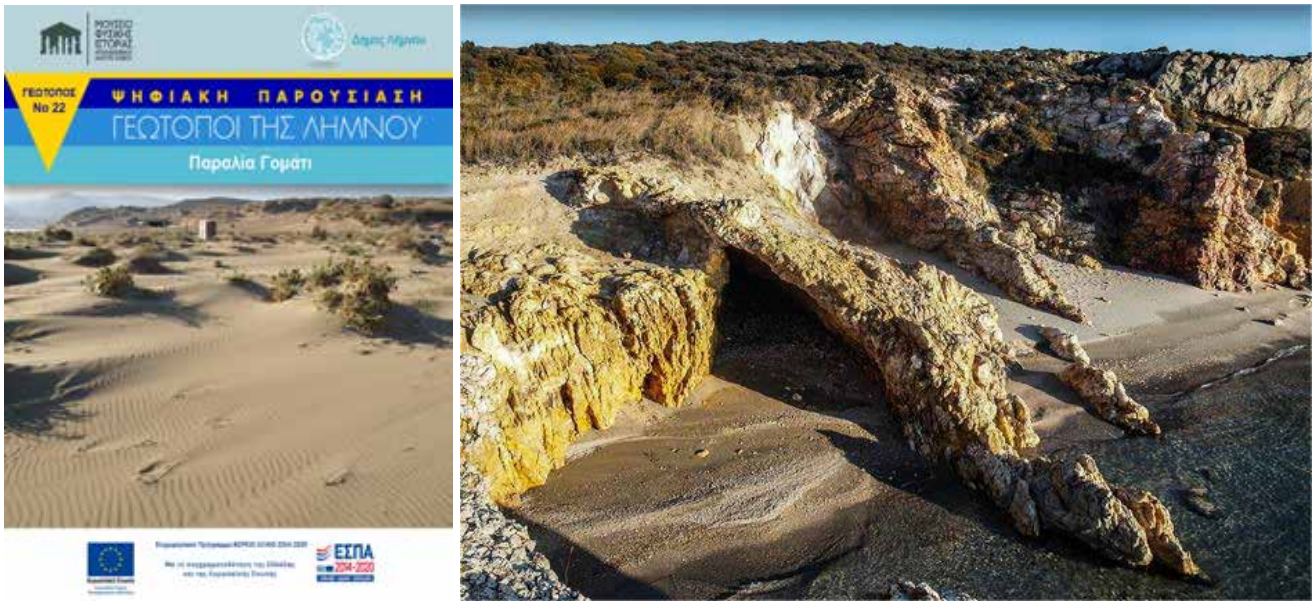

Photo 5 : The dunes at Gomati and the sea caves at Fanaraki

The geological and geomorphological heritage sites were assessed using the methodology proposed for the assessment of geomorphosites (Zouros 2007, 2009).
As a result the selection of the 50 representative geological and geomorphological heritage sites was made. The 50 geosites have been documented for their geoscientific significance. The information for these geosites are taken from field work and literature (Roussos et al., 1993, Innocenti et al.,1994, Maravelis et al. 2007, Chatzipetros et al., 2013).
These geological and geomorphological heritage sites as well as sites of ecological and cultural value, form the basis for the creation of the interpretative geotouristic map of Lemnos island, presenting a balanced proportion of scientific and touristic information.
The sites will be linked alond thematic “geo-tails” which will introduce the visitor to the main geological and geomorphological processes that created the landscapes of Lesmnos.

Interpretation and promotion of the Lemnos geological heritage sites
The promotion of Lemnos’ geological heritage is supported by a variety of tools developed throughout the project.

The geotouristic map of Lemnos is designed to highlight the island's rich geological and geomorphological heritage and to communicate geoscientific themes to a non-specialist audience. It offers the public an opportunity to understand fossils and fossilization processes, geomorphological and geological phenomena, rock types, landforms, and landscapes.
The website www.lemnosgeomonuments.gr was created to consolidate all available information about the island's geological heritage sites. It serves both the general public and visitors to Lemnos, as well as educators in local schools and special interest groups looking to explore the island's natural treasures.
To enhance the on-site user experience, a mobile navigation application was developed for smartphones, featuring visual, audio, and augmented reality (AR) content.
All interpretation and promotional tools were developed using advanced technologies, with a strong focus on user-friendly design and long-term sustainability.
Moreover, the promotion and utilization of this material—when combined with broader efforts to highlight the geoenvironment—can provide a competitive advantage in the development of alternative and sustainable tourism.
Finally, a Digital Information Center for the Petrified Forest and Geosites of Lemnos was established in Roussopouli. This center also serves as an information hub for special forms of tourism, including hiking, rural, geological, agritourism, and educational tourism.

Educational activities

Educational activities on geological heritage sites were designed and implemented using the interpretation and promotional tools developed during the project. Educational programs were offered to students and teachers of primary and secondary schools on Lemnos, focusing on the geological heritage of the island and presenting the main geosites identified, mapped, and recorded by the Natural History Museum of the Lesvos Petrified Forest. These classroom programs were complemented by field visits to key geosites, helping students to deepen their understanding of the significance of Lemnos' geological heritage.
Students, teachers, and parents from the 2nd Primary School of Myrina, the Primary School of Atsiki, the Middle School of Moudros, and the General Lyceum of Moudros participated in these educational activities. Additionally, the principals of primary and secondary schools on Lemnos took part in an educational workshop organized in collaboration with the Regional Directorate of Primary and Secondary Education of the North Aegean, as part of the project "Creation – Operation of Digital Applications for the Promotion of the Geo-Monuments of Lemnos."
During the activities, students had the opportunity to explore the impressive geological monuments and the Petrified Forest of Lemnos, as well as to learn about the geological processes that led to their formation. The students participated actively and enthusiastically, asking insightful questions not only about the Petrified Forest and its origins but also about volcanic activity and volcanic structures on the island.
The students of the 2nd Primary School of Myrina also participated in a model educational activity using newly developed virtual reality (VR) applications, created within the same project by the Natural History Museum of the Petrified Forest of Lesvos.
In addition, special informational sessions were held for teachers of primary and secondary education on Lemnos regarding the possibility of organizing educational visits to Lesvos—recognized by UNESCO as a Global Geopark—and its renowned Petrified Forest. Through a detailed presentation of a proposed three-day educational program and rich photographic material, teachers became familiar with the educational activities available on Lesvos, emphasizing the island's geological, natural, and cultural heritage. Special interest was shown in the educational programs of the Natural History Museum of the Petrified Forest of Lesvos, which are conducted within the protected area of the forest.

Conclusions

The systematic identification, documentation, and promotion of geosites on Lemnos Island have revealed the island's significant geodiversity and its potential as a destination for geotourism and geoscience education. Through fieldwork, geosite mapping, and the development of interpretive materials, 150 geosites were classified and assessed, highlighting fossiliferous areas, volcanic features, tectonic structures, and diverse geomorphological landforms.
Fifty of these sites were selected as the most representative of Lemnos' geological and geomorphological heritage and were integrated into an interpretive geotouristic map. These sites form the foundation for thematic geotrails, aiming to connect geological heritage with ecological and cultural landmarks across the island.
The use of innovative digital tools—including Unmanned Aerial Systems (UASs), high-resolution 3D mapping, augmented reality applications, and virtual reality educational modules—has significantly enhanced the ability to communicate geoscientific information in an accessible and engaging manner. The website www.lemnosgeomonuments.gr, the smartphone navigation app, and the establishment of the Digital Information Center in Roussopouli have created a robust framework for both public engagement and sustainable tourism development.

The educational activities implemented as part of the project have demonstrated strong local interest and participation, fostering greater understanding and appreciation of Lemnos' geological heritage among students, educators, and the broader community. The collaboration with the Regional Directorate of Education and the integration of innovative learning technologies have proven effective in bridging scientific knowledge with experiential learning.

There is a strong potential of Lemnos Island to serve as a model for the promotion of geodiversity through geotourism and education. With continued investment in infrastructure, interpretation, and local engagement, Lemnos can enhance its position as a destination for alternative and sustainable tourism, while preserving and valorizing its unique geological heritage for future generations.

The geomonuments of Lemnos will be used to promote the island's rich geological and geomorphological heritage and to communicate geoscientific themes to a non-specialist audience, offering opportunities to understand fossils and fossilization processes, geomorphological and geological phenomena, rock formations, and the island's recent evolution and ongoing geodynamic processes.
