The total kinetic energy distribution was computed via RocFall software in the middle of the slope profile, at x = 117.3 m, and is presented below (Figure 4). The geological and material characterizes of the rockfall were taken into

account. More specifically, the coefficient of normal restitution (Rt) has a mean value of 0.39 and a standard deviation of 0.04, while the coefficient of tangential restitution (Rn) has a mean of 0.80 with the same standard deviation. The friction angle (Phi) averages 15° (standard deviation 2°), and the mean horizontal velocity reaches 11 m/s (standard deviation 1.1 m/s).

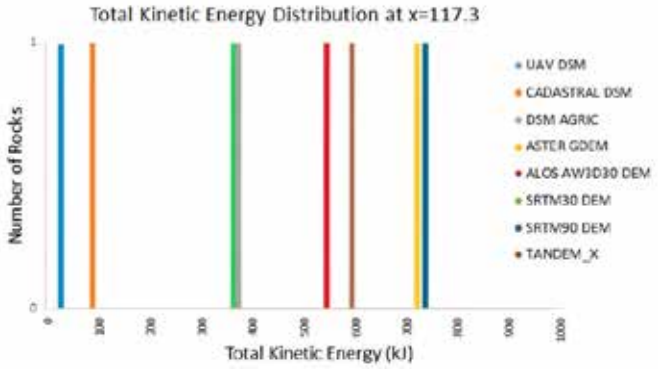

Figure 4. Total kinetic energy distribution at x = 117.3 m for the slope profile via RocFall

Figure 4 illustrates how total kinetic energy—measured at x = 117.3 m along the slope—varies for a single rockfall simulation when using different elevation models in RocFall. Each colored bar corresponds to a specific DSM/DEM, with higher bars positioned farther along the x-axis indicating larger kinetic energies. The UAV DSM and Greek Cadastral DSM (blue and orange bars), which have finer spatial resolutions, yield the lowest kinetic energies (roughly 20–90 kJ). By contrast, the Ministry of Agriculture DSM and SRTM30 DEM (green and grey bars) display moderate energy levels (about 360–380 kJ). The coarsest models, ALOS AW3D30 DEM, ASTER GDEM, SRTM90 DEM, and TanDEM_X (red, yellow, dark-blue, and brown bars) produce the highest energy values (560–730 kJ), since smoothing out the terrain in lower-resolution data allows the rock to accelerate more. Overall, the DSMs with coarser spatial resolution (more than 30 m) flattened the relief; consequently, the rock recorded higher speed than in the other DSMs with high spatial resolution (less than 30 m), which created unsmooth surfaces

- **QProto results**

For examining Platiana rockfall phenomenon and extract maps, in terms of the total weighted kinetic energy (J), QPROTO analysis were accomplished in this section (Figure 5a-5d). The slope and material characteristics which derived from in situ surveys and literature data were defined (Depountis et al., 2010; Sabatakakis et al., 2015; Vagenas, 2020). The energy angle φp is 30°, the forest coverage is dense vegetation in limestones and the propensity index is 1.

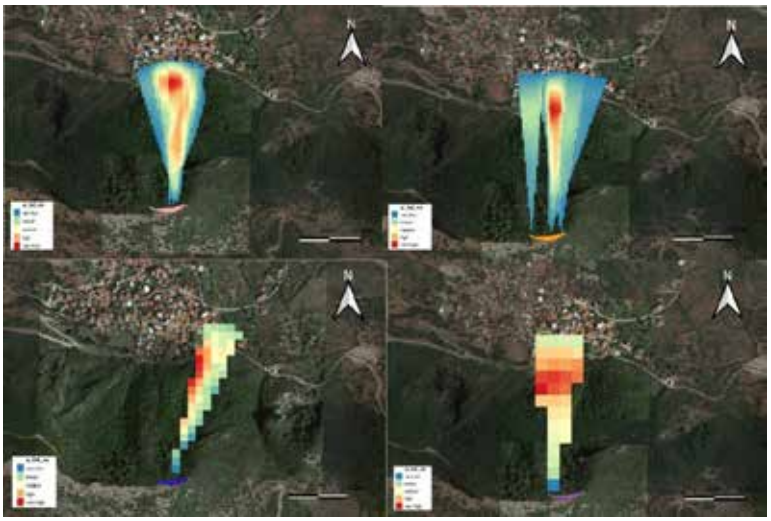

Figure 5. QPROTO results, in terms of total weighted kinetic energy (J), for the site of Platiana. a) UAV DSM, b) Greek Cadastral DEM, c) DSM from the Ministry of Agriculture d) ALOS AW3D30 DEM.

In Figure 5a, the UAV DSM (0.1 m resolution) generated 93,155 source points (pink polygon), necessitating resampling to 5×5 m for faster processing. The QPROTO map shows high to very high total weighted kinetic energies in the slope's center, tapering to very low at the edges, with the northern sector exhibiting the highest values. In Figure 5b, the Greek Cadastral DSM (5 m resolution) yielded just 36 source points (orange polygon), capturing very low to medium energies over two-thirds of the area and higher levels near the slope's end, especially in the north—consistent with in situ observations that place the rock's stopping point in the churchyard, where energies peaked. Although the Greek Cadastral DSM aligns with the UAV DSM, it positions the cone a few meters farther and reveals an exposed block area on the cone's left side. The Ministry of Agriculture DSM (20 m resolution, Figure 5c) produced only two source points (blue region). This analysis shows very low energies in the south, low to medium in the east-north, and high to very high in the west, yet contradicts field data by displaying high values prematurely. Finally, Figure 5d presents the ALOS AW3D30 DEM (30 m resolution) with three source points, indicating low to medium energies over most of the cone, very high in its middle, and an endpoint that stops short of the actual stopping point, rendering this analysis more conservative.

- **HY-STONE results**

For the rockfall analysis, six DEMs were used, covering a resolution range from 5 m to 90 m. The coefficients of restitution E_N and E_T, and the rolling friction coefficient A_T, were back-calibrated on the higher-resolution DEM based on the rockfall event (Table 1). The masonry stone walls were simulated with low values of E_N and E_T and high values of A_T, similarly to buildings. Given that HY-STONE operates on a stochastic model, simulations were performed with 1000 rocks to provide a more accurate representation of rockfall dynamics. The following data presents the maximum translational kinetic energies for the Platiana rockfall, expressed in kJ (Figure 6).

Table 1. Coefficients of restitution and rolling friction in Platiana rockfall, calibrated on the Greek Cadastral DEM

Description	E_N	E_T	A_T
Houses	0.20	0.20	1.00
Road- asphalt	0.55	0.70	0.25
Debris well vegetated	0.35	0.60	0.42
Debris without vegetation	0.40	0.65	0.35
Stone wall	0.20	0.20	1.00

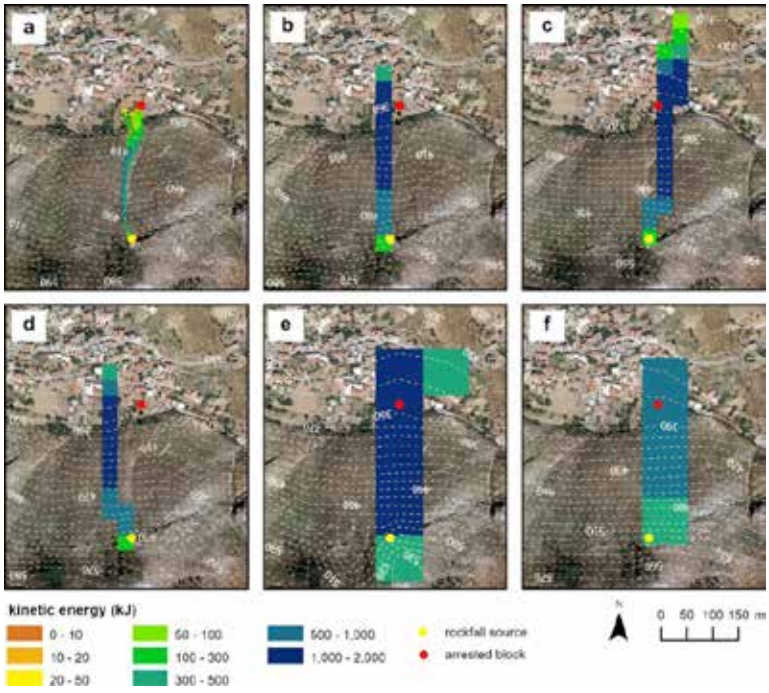

Figure 6. HY-STONE results, in terms of in terms of the maximum translation kinetic energy for the site of Platiana. a) Greek Cadastral DEM, b) ALOS AW3D30 DEM, c) ASTER GDEM, d) SRTM30 DEM, e) SRTM90 DEM and f)TanDEM_X.

In Figure 6, the Greek Cadastral DEM (a) shows high to very high kinetic energies (0–1,500 kJ) near the rockfall source and centrally, then decreasing to very low at the slope's end; the ALOS AW3D30 DEM (b) starts with low energies near the source, rises to high in mid-path, and declines with medium energies at the end; the ASTER GDEM and SRTM30 DEMs (c, d) depict multiple paths with low energies (0–1 kJ) at the source, high energies (100–1,500 kJ) in the middle, and medium levels (0.1–100 kJ) in residential areas—extending beyond the actual endpoint; the SRTM90 DEM (e) generates two paths showing very high energies (500–1,500 kJ) at the endpoint and low energies (0.2–1 kJ) near the source; and TanDEM_X (f) presents a single trajectory transitioning from medium to high, then very high, and finally back to medium and low energies, likewise extending past the real endpoint.

Conclusions

The findings of this study highlight the importance of DSM resolution in rockfall simulations. The area of interest has been extensively observed since the occurrence of the rockfall events. Therefore, a plethora of in situ measurements and observations have been recorded and many geo-data sets have been collected. These data significantly contribute towards the extraction of a reliable 2D rockfall simulation, with relatively small discrepancies from the observations of the real event.

1. DSMs from UAV data with sub-decimeter spatial resolution proved to be the most accurate for a rockfall simulation.
2. The UAV offers a significantly different pathway among different rock paths, whereas the other DSMs have a simplified path of the fallen blocks.
3. The DSMs can be classified into three categories according to their accuracy in rock-fall simulation. In particular:

(i) High accuracy, which corresponds to DSMs with spatial resolution less than 5 m, such as UAV DSM and DSM from the Greek Cadastral. The processing of these DSMs in RocFall software extracted results similar to in situ observations.

(ii) Medium accuracy which corresponds to DSMs with spatial resolutions ranging from 20 m to 30 m, such as DSM derived from the Ministry of Agriculture, ALOS AW3D30 DEM, ASTER GDEM and SRTM30 DEM. Against all these DSMs, only DSM of the Ministry of Agriculture and ALOS AW3D30 DEM offered rockfall illustration relatively close to the real event.

(iii) Low accuracy, which corresponds to DSMs with spatial resolution of 90 m, such as SRTM90 DEM and TanDEM_X, and led to rockfall conclusions that abstain from the reality.

4. The existence of vegetation plays an important role in the simulation of the rockfalls and a recent and very accurate DSM from UAV can represent the real height of the vegetation in contrast to the free available DSMs, such as SRTM 30DEM or ASTER DEM that were created few years ago.
5. The coarse resolution of SRTM 90DEM and TanDEM_X may lead to the inaccurate slope profiles and to the erroneous calculations of the rock kinetic energy. Previous rockfall simulation studies based on SRTM90 or TanDEM_X DSMs should be re-evaluated.

Acknowledgements

The authors would like to thank Prof. Paolo Frattini from the University of Bicocca, Milan, for providing access to the HY-STONE software and for his valuable contributions.

The late Ruscinian leporid *Trischizolagus* (Leporidae, Lagomorpha) from Megalo Emvolon (Thessaloniki, Greece)

Christina N. Kalaitzi[1], Dimitris S. Kostopoulos[1]
(1) Laboratory of Geology and Palaeontology, School of Geology, Aristotle University of Thessaloniki, 54124 Thessaloniki, Greece

Introduction – Fossiliferous site

Since 2017, ongoing field campaigns at Megalo Emvolon have led to the discovery of a new fossil site, Megalo Emvolon-4 (MVL), which has yielded, inter alia, an abundance of lagomorph fossils. This paper introduces the newly discovered leporid collection (Leporidae, Mammalia) at MVL, featuring exceptionally well-preserved cranial, postcranial, and dental fossil remains. All specimens are attributed to *Trischizolagus dumitrescuae*, the most prevalent and widespread species of the genus during the Early Pliocene (Ruscinian) in Europe. Originally discovered in Romania, *Trischizolagus dumitrescuae* has since been identified at more than fifteen fossil sites across Eurasia (Averianov and Tesakov, 1997; Čermák and Wagner, 2013; Čermák *et al.,* 2021; and others).

The sediments in the Megalo Emvolon area are part of the Gonia Formation (Fm) and are indicative of a fluvio-lacustrine depositional environment with frequent river discharges and shallow lakes (Syrides, 1990). Alternating lenses and intercalated beds of clays, silts, marls, sands, sandstones, massive marly limestones, and gravels constitute the sedimentary sequence in the Megalo Emvolon area. Small pockets or spots, ranging from 0.5 to 3 meters in length, typically concentrate fossils at the site, scattered across various stratigraphic levels. Koufos *et al.* (1991) identified three fossil horizons within the Megalo-Emvolon section, with MVL either correlated with the basal or middle fossiliferous level (MEV, MEM) or situated in between both levels. The Megalo Emvolon fauna is dated to the Late Ruscinian, MN 15 (Koufos *et al*., 1991; Koufos, 2006) (about 4.2–3.2 Ma, according to http://paleobiodb.org).

The MVL *T. dumitrescuae*

Overall, the leporid material of this study is in excellent condition, with only a few incomplete specimens or fragments. The MVL material comprises 383 specimens, out of which 26 are cranial, 212 are dental (146 upper and 66 lower), and 145 are postcranial (11 bone groups), all in outstanding condition (Fig 1). Significantly, this study presents the first discovery of well-preserved skulls of *T. dumitrescuae* at Megalo Emvolon, providing unprecedented insights into its cranial morphology. The identification of *T. dumitrescuae* is solely based on the morphology of p3 and is strongly supported by comparisons with Romanian samples among other localities, alongside a detailed analysis of several morphometrical traits. The p3 exhibits the typical tetralobed trigonid form, a well-developed mesoflexid and hypoflexid, and a 1:2 size ratio between the length of the trigonid and the talonid. Moreover, the so-called "*Alilepus* pattern" is the predominant morphotype across all MVL material. Regarding the cranial anatomy, *T. dumitrescuae* has a large and acute cranium that is highly fenestrated, especially in the premaxillary, maxillary, and frontal regions, and exhibits a set of supraorbital processes that are not so well developed. Regarding the postcranial material, the forelimb features a scapula with a broad neck and a narrow coracoid process positioned close to the glenoid cavity. The humerus is characterized by a prominent deltoid crest. In the hindlimb, the femur's proximal trochanters are closely spaced, while the pelvis displays a robust ilium and a wide ischial tuberosity. Additionally, the calcaneus has an elongated body.

Conclusions

The material from MVL significantly expands upon earlier records from the site (Koufos and Koliadimou, 1993), providing valuable new insights into the previously unknown cranial morphology of *T. dumitrescuae*, its intraspecific dental variability, and locomotive tendencies, while also refining the genus and species diagnostic characteristics, correcting earlier misconceptions, and establishing intraspecific variation in comparison to other European records. The description of the cranium of *T. dumitrescuae* reveals a unique combination of *Lepus*- and *Oryctolagus*-like features that differentiate it from both the Eurasian *Alilepus* and the African *Serengetilagus*. The dental shape and size of MVL are consistent with those of dental remains from Megalo Emvolon-1 (Koliadimou and Koufos, 1993), as well as those of *T. dumitrescuae* from the type locality in Măluşteni, Romania. Lastly, preliminary ecomorphological analysis based on limb and skull morphology of *T. dumitrescuae* in MVL reflects adaptations for swift movement, high jumping, and capability for digging.

Figure 1. Craniodental and postcranial material of *T. dumitrescuae* in MVL.

Acknowledgements

The authors express their sincere gratitude to Dr. Lars von den Hoek Ostende and Pepijn Kamminga, MSc, of the Naturalis Biodiversity Center, for providing recent leporid specimens essential to the comparative study. Special thanks are also extended to Dr. Georgios Konidaris and Stylianos Koutalis, MSc, from the Department of Geosciences, Palaeoanthropology section, at Eberhard Karls Universität Tübingen, for their assistance with 3D scanning. Finally, we deeply appreciate Dr. Stanislav Čermák for generously sharing raw data on the *Trischizolagus* p3.

EXTENDED ABSTRACT 124

Multiscale Geo-visualization Dashboard of Persistent Scatterer Interferometry SAR Data, Lesvos Island, Greece

Panagiotis Kalaitzis[1], Michael Foumelis[2], Antonios Mouratidis[2] and Nikolaos Soulakellis[1]
(1) Department of Geography, University of the Aegean, Mytilene, Greece, p.kalaitzis@geo.aegean.gr
(2) Department of Physical and Environmental Geography, Aristotle University of Thessaloniki, Thessaloniki, Greece

Research Highlights

This study emphasizes the importance of effective visualization for Persistent Scatterer Interferometry (PSI) data, particularly in capturing the dynamic and spatiotemporal aspects of ground displacement. A novel multiscale generalization algorithm was developed to optimize PSI dataset visualization across eight predefined cartographic scales, ensuring suitability in each cartographic scale. An interactive dashboard was designed to properly visualize PSI data of different geographic, cartographic, spatial, and temporal scales, combined with auxiliary geospatial data, addressing the need for intuitive cartographic tools. The results highlight the importance of visualizing and studying PSI data through interactive dashboards, applying the classic principles of cartography. This approach underscores their role as innovative tools for understanding and monitoring the dynamic behavior of surface motion.

Introduction / Background

The rapid increase in the availability of earth observation (EO) data has introduced a critical demand for precise, user-friendly, and interactive dashboards that facilitate the thorough analysis of these vast and complex datasets (Gehlot & Hanssen, 2008). Despite significant advancements, the interpretation of EO data remains a challenging endeavor due to their spatial and temporal intricacies. Advances in geospatial data visualization have provided efficient, low-cost methodologies for analyzing and interpreting geospatial information (Kraak & Ormeling, 2020). Among these, Persistent Scatterer Interferometry (PSI) has emerged as a highly effective technique for monitoring ground deformation and instability phenomena. Utilizing spaceborne synthetic-aperture radar (SAR) imagery, PSI achieves millimeter-level precision in detecting surface motion over extensive spatial domains, serving as a key tool in geosciences, urban planning, and environmental disciplines (Crosetto *et al.*, 2016).

PSI data provide valuable insights into a broad spectrum of dynamic processes, including land subsidence, landslides, volcanic activity, and infrastructure stability. However, the technique is inherently dependent on persistent scatterers (PS), which exhibit consistent radar reflectivity over time. The spatial density of PS can be limited in non-urban environments where suitable targets are sparse. To overcome this limitation, distributed scatterers (DS)—targets with consistent scattering behavior within radar resolution cells—are integrated with PS measurements, significantly enhancing spatial coverage. The combined PS/DS solution enables more detailed analyses by increasing point density, particularly in densely vegetated or sparsely built-up areas (Foumelis *et al.*, 2022).

Recently, algorithms for performing multi-temporal interferometric analysis have been seamlessly integrated into cloud platforms, providing users with operational and automated services. This integration significantly reduces the need for extensive data storage, computational resources, and specialized expertise in executing complex processing chains. An example of such a service is the surface motion mapping (SNAPPING) service integrated on the Geohazards Exploitation Platform (GEP). SNAPPING is a PSI chain designed specifically for the Copernicus Sentinel-1 mission, capable of generating average motion and corresponding displacement time-series at various spatial resolutions.

However, effective visualization of PSI data remains a challenge, particularly at multiple scales and resolutions. The spatial and temporal complexity of PSI data necessitates the development of innovative visualization methods to support comprehensive analysis. Generalization techniques, such as point aggregation and elimination, are employed to adapt datasets to predefined cartographic scales while mitigating challenges posed by overlapping points in high-density areas (Kalaitzis *et al.*, 2023; Poncoş *et al.*, 2022).

Existing platforms, such as the European Ground Motion Service and national services in Germany, Norway and the Netherlands, demonstrate the utility of PSI web applications in monitoring ground motion. The dashboard employs a cohesive, interactive design centered around a web map that serves as a primary visualization element. Complementing this, key performance indicators (KPIs) provide high-level insights, while dynamic graphs depict trends and relationships in the data. Accompanying these are structured **lists** that offer detailed tabular information.

All components are interconnected: any selection or interaction within one-such as clicking on a map region, a data point in a graph, or a list item-immediately updates the other components, ensuring a synchronized and contextualized user experience. This architecture enables seamless data exploration and decision-making (Bach *et al*., 2022).
Interactive dashboards offer dynamic tools for visualizing and exploring PSI datasets. Providing tools such as data filtering, time-series graphs creation and comparison with auxiliary geospatial data, dashboards enable both expert and novice users to interact with and interpret ground deformation data effectively. By combining original and generalized datasets in areas with varying densities, dashboards help manage cartographic challenges and offer insights into intricate geospatial information.
This study introduces a novel approach to address the challenges of visualizing and exploring PSI datasets of different spatial resolutions, in predefined cartographic scales. This approach is based on the development of a standalone dashboard, providing interactive cartographic tools designed to optimize the visualization and exploration of PSI datasets. The dashboard represents a low-cost solution that can be tailored with any generic PSI dataset, in order to offer users invaluable insights into such intricate geospatial information.

Methods

The methodology of this study is represented by the flowchart in Figure 1, consisting of three main steps.

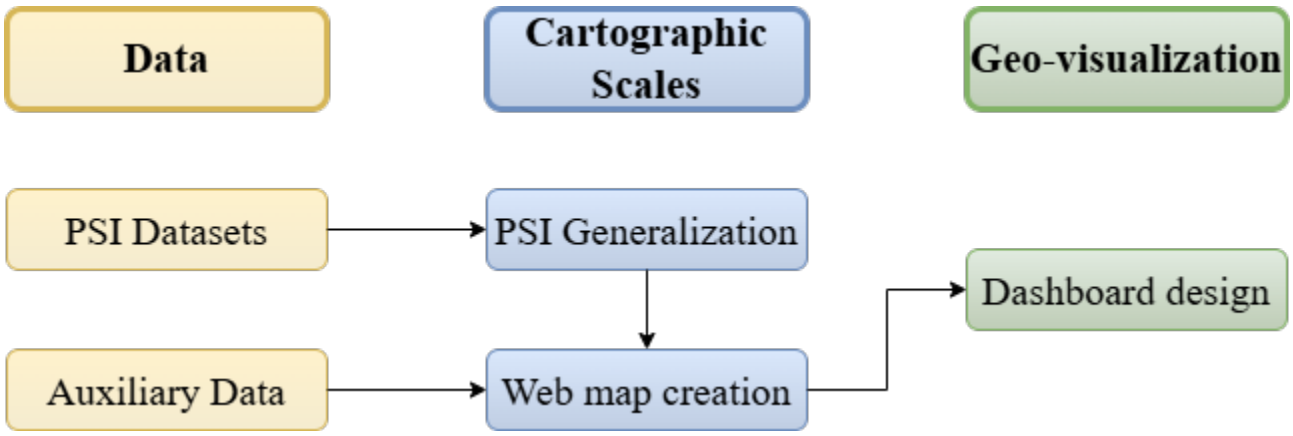

Figure 1: Overall workflow chart of the methodology followed for the integration of the research

1. Data: Describing all the PSI datasets generated and the auxiliary data used for the needs of the current study, as well as for visualization.

   PSI Data

   The processing of Sentinel-1 SAR data is performed using the SNAPPING service on GEP, where PSI services are available at different spatial resolutions. For this study, two resolution datasets (PSI Med and PSI Full) were utilized. SNAPPING offers three distinct services: the SNAPPING IFG service, which generates interferometric stacks, and the SNAPPING PSI Med (i) and SNAPPING PSI Full (ii) services, which conduct PSI analyses at medium and full resolutions, respectively. Additionally, SNAPPING provides a PSI time-series analysis service for both resolutions (Foumelis et al., 2022).
   PSI processing focused on PS/DS (iii) scatterers was carried out using the infrastructure of Aristotle University of Thessaloniki (AUTh), utilizing the SNAPPING IFG outputs, including differential interferograms and auxiliary data, previously generated on GEP. To ensure measurement consistency, common processing parameters were applied to all solutions, with adjustments made for deviations caused by different references.
   According to specific criteria, the detected Persistent Scatterer (PS) targets from the SNAPPING PSI Med dataset were initially merged within a 100-meter search radius, reducing the number of targets in areas with high point density. For SNAPPING PSI Full, no merging of neighbouring PS targets was performed, preserving the original sensor resolution. Compared to PS-InSAR, DS-InSAR results significantly enhance the spatial distribution density of point targets, particularly in regions with lower coherence (Foumelis *et al*., 2022).
   PSI Med and Full resolution datasets consist of 45,749 and 283,419 PSs respectively, geolocated in the broader area of Lesvos Island, for the period between 2015–2020. PS/DS dataset consists of 11,169 points for the period between 2019-2021 and located in the broader area of Bali Alonia Park.

   Auxiliary data

PSI data are integrated with auxiliary datasets to meet visualization requirements and enable enhanced utilization. The auxiliary datasets include: A geology layer, digitized from the freely available geological map of Greece (1:500,000), provided by the Hellenic Geological and Mining Research Authority (E.A.G.M.E) and ESA Land Cover 2020 dataset, with a spatial resolution of 10 meters.

2. Cartographic scales: Based on previous studies (Kalaitzis *et al*., 2023; Poncoş *et al*., 2022), the necessity for PSI interpretation aligned with pre-specified scales becomes evident. By combining the coverage area of each PSI dataset with various geographic scales (e.g., regional scale, local scale), eight predefined cartographic scales are derived:

- 1:1,000,000
- 1:500,000
- 1:200,000
- 1:100,000
- 1:50,000
- 1:20,000
- 1:10,000
- 1:5,000

An algorithm for generalizing PSI datasets was developed, in order to avoid point overlapping especially on smaller cartographic scales (Kalaitzis *et al*., 2024). More extensively, based on the visual acuity of the human eye in each predefined cartographic scale, eight grids with corresponding cell sizes were created, as presented in Table 1.

Table1: Predefined cartographic scales used for visualization, followed by the PSI dataset visualized in each case. For generalization needs, a grid was created for each cartographic scale, with the corresponding cell size. For each cartographic scale, a dataset (either generalized or not) is generated with the corresponding number of points and point density.

Cartographic Scale	Cell Size (m)	PSI Dataset	No. of Points	Point Density (points/km^2)
1:1,000,000	250	PSI Med	14,348	15
1:500,000	125	PSI Med	31,189	66
1:200,000	50	PSI Med	45,749	99
1:100,000	25	PSI Full	158,030	376
1:50,000	12,5	PSI Full	231,166	507
1:20,000	5	PSI Full	283,419	580
1:10,000	2,5	PS/DS	11,169	9422
1:5,000	1,25	PS/DS	11,169	9422

After applying a generalization algorithm to all available PSI datasets, it is derived that each original PSI dataset is best visualized at a specific cartographic scale, determined by the point density of the dataset. In every other cartographic scale, generalized datasets are used for visualization.

After this procedure, all PSI datasets were joined with auxiliary data and uploaded on a server provided by ArcGIS Enterprise™ platform. Through this platform a web map, consisting of all available data, was created.

3. Geo-visualization: Based on the web map created, an interactive dashboard was created consisting of the basic viewer of the application (web map), combined with several cartographic tools, providing crucial information about each points' attributes (mean v
4. elocity, velocity uncertainty, temporal coherence, cumulative deformation, time-series, geology and land use).

Results

An interactive dashboard developed, contributing in proper visualization and exploration of different resolution PSI datasets in multiple cartographic scales. The main component of this platform, is the web map, providing visualization of mean velocities of PSI datasets and exploration through the study area. Navigation along the study area, is also enhanced by predefined bookmarks, zooming in specific areas of Lesvos Island. A base map list is also available, allowing users to customize it according to their preferences. The map is combined with four different indicators about mean velocity, temporal coherence, velocity uncertainty and cumulative deformation. Time-series graph, presenting ground deformation of points through time, is also available. The time-series graph tool allows users to zoom in on shorter time periods within the graph using a scrollbar. The indicators and the time-series graph display the mean values of the attributes they represent. Lists of geology and land use of points, are also provided as tools. Each one of the tools is linked with the map, so every adjustment by the users (selection, pan, zoom) affects both the map

and the tools. Selection of single or multiple points from the map, also updates indicators, time-series graph and lists. Dashboard is accessible by the link: Multiscale Geo-visualization Dashboard for PSI Measurements, Lesvos A preview of the dashboard is presented in Figure 2.

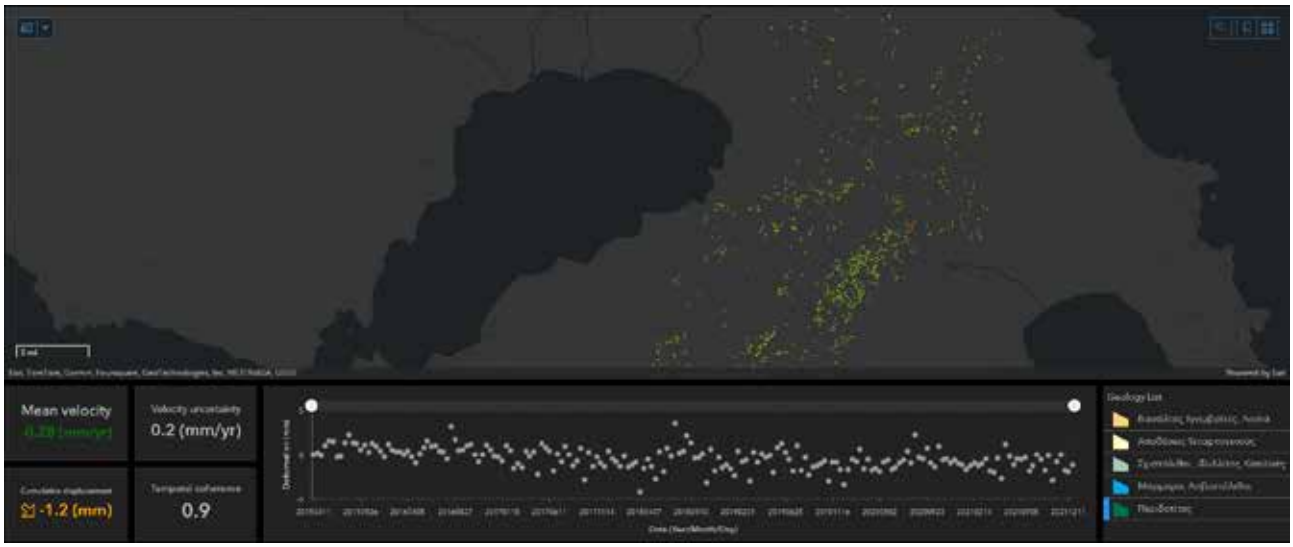

Figure2: A preview of the dashboard, visualizing mean velocities of PSI med resolution dataset, in scale 1:200.000. Only points referring to peridotites are filtered and displayed; cartographic tools are adjusted accordingly. Mean velocity of filtered points is -0.28mm/yr with a velocity uncertainty of 0.2mm/yr, cumulative deformation is -1.2mm and temporal coherence is 0.9.

Limitations mainly refer in the availability of cartographic tools, which may not cover all user needs for advanced data analysis or visualization. Customization options for the tools are restricted, making it challenging to tailor the dashboard to specific workflows or preferences. While functional, the dashboard's tools are constrained by its simplified design, prioritizing ease of use over extensive configurability. Another limitation arises concerning the application of generalization algorithm on PSI datasets. More specifically, during the generalization process, the number of points in each generalized dataset is reduced compared to the original. In the cartographic scales where generalized datasets are used, information regarding individual ground displacement values per date is absent. Consequently, time-series analysis is not feasible at these cartographic scales. To address this limitation, time-series graphs are exclusively generated for the original datasets at their corresponding cartographic scales.

Conclusions

The utilization of the multiscale geo-visualization dashboard facilitates the effective exploration of various PSI datasets, enabling easier extraction of ground motion information and valuable insights into the prevailing conditions. The integration and seamless interaction between the web map and the cartographic components result in an accessible and fully operational tool for interactive data visualization applicable to any generic PSI dataset and individual case studies.

Generalized PSI datasets enable accurate and effective visualization of measurements across multiple cartographic scales, facilitating qualitative data interpretation. Each original PSI dataset is optimally visualized at a specific cartographic scale, dictated by the dataset's point density. Visualizing original datasets at their corresponding optimal cartographic scales not only ensures precise depiction of ground displacement but also enables comprehensive qualitative and quantitative spatiotemporal analyses, such as time-series graphs generation.

By visualizing mean velocities of different resolution PSI datasets, via the multiscale geo-visualization dashboard, reveals that Lesvos Island is not characterized by significant ground deformation. Negative velocity rates between -5 mm/year and -8 mm/year, indicative of land subsidence, are observed in the eastern part of the island near Lampou Mili village. Conversely, positive velocity rates indicating uplift, reaching up to 2 mm/year, are concentrated in the northern region, between Mythimna and Efthalou.

Research Highlights
The aim of the present article is to investigate the factors that affect the cave mapping. This investigation is based on comparisons of topographical diagrams of a given space made by different surveys of the same stations. A classroom of a known topography has been used for that purpose. The used traverses are the circumference survey, splay shots, zig-zagging survey and radial survey (after Dasher 1994). The comparisons concern the shape, the area and the direction of the cave map as well as the time that is needed for the survey and the affect of errors in certain station to the general topography of a map. The results are summarized and the significance of reference in the used methodology in any cave surveying is concluded. Among the different traverses the radial one and the splay shots are considered as the most accurate.

Introduction to Cave Mapping
Cave mapping is a crucial aspect of speleology. Due to the complex nature of caves, the perception of distances often does not align with reality. A well-drawn map allows speleologists to assess the cave's size, identify hazardous areas, anticipate challenges during exploration, and determine the necessary equipment. Furthermore, the systematic study of caves requires detailed and reliable mapping in a suitable format and scale, addressing various geoscience disciplines such as geology, speleology, and paleontology (Pagounis et al., 2004; Doggouris et al., 1986). Cave mapping is complicated by numerous factors, the two most prominent being the non-ideal conditions explorers face due to the challenging environment (Doggouris et al., 1986), which makes the mapping process arduous, and the cave's inherent complexity. This often requires documenting points located at vastly different elevations, necessitating a comprehensive representation of a three-dimensional space.
The first stage of cave mapping involves collecting data to create the map, which includes measurements taken by a mapping team. Ideally, this team consists of 3-4 members to optimize time, particularly in large caves, though a two-person team often exhibits better coordination (Judson, 1974). The team leader determines the locations of the measurement stations, records data in a logbook, sketches the cave, and typically designs the map, as they are most familiar with the notes. The other team members operate the instruments and relay measurements to the leader (Savvaidis et al., 2007).
The mapping process begins by establishing a station (which may or may not have pre-defined coordinates relative to a reference system). Subsequent stations are positioned to accurately depict the cave's shape. For each new station, the distance from the previous one, the azimuth, and the elevation difference (or slope) are measured and recorded. With these data, the stations can be drawn to scale and oriented on paper. This process is repeated as needed for all required stations.
The measurements collected form a path within the cave, known as a traverse, which can be either open or closed. In a closed traverse, the start and end points coincide, while in an open traverse, they do not. Closed traverses provide greater accuracy in mapping, as they allow the mapper to detect potential errors (Dasher, 1994). There are four types of traverses: central, radial, circular, and zig-zag, each suited to different cave shapes and sizes.

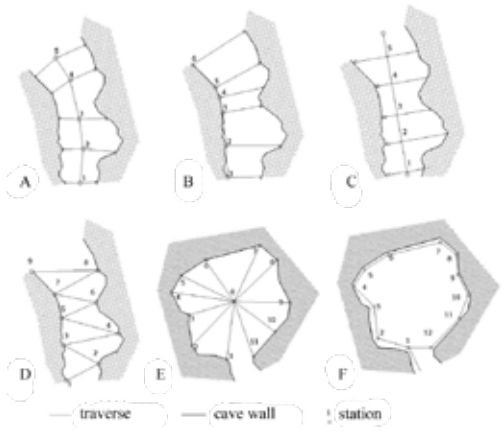

Figure 1. Illustrates various types of traverses: (a) central traverse, (b) central traverse with the main line along the wall, (c) central traverse with vertical measurements from the main line, (d) zig-zag traverse, (e) radial traverse, and (f) circular traverse.

- In a central traverse, a central line of stations is established down the middle of the cave passage, and the distance to the

cave walls is measured from each station on both sides (Judson, 1974). Lateral measurements always include azimuth readings (Fig. 1a). When the cave's morphology permits, the central line can run along one wall, with measurements taken only toward that wall (Dasher, 1994; Fig. 1b). In some cases, a straight central line is used, and wall distances are measured perpendicular to this line without needing azimuth readings (Fig. 1c; Savvaidis et al., 2007).

- In a zig-zag traverse, measurements alternate between the left and right sides of a narrow passage, creating a zig-zag path (Fig. 1d). This method provides more detail about each cave wall. Some explorers believe this technique distorts the cave's length, but it offers more comprehensive information for the final map (Dasher, 1994).
- In a radial traverse, measurements are taken from a central station (usually in a chamber) toward the boundaries of the area being mapped. The subsequent stations are radially arranged around the central station. This method is ideal for chambers that are roughly circular, allowing a clear line of sight from all stations to the center (Fig. 1e).
- In a circular traverse, measurements follow the perimeter of the mapped area. In this case, the traverse's shape matches that of the mapped space (Fig. 1f). This method is commonly used in circular chambers, where completing the traverse by taking measurements from the last station back to the first helps identify potential errors during map creation (Dasher, 1994).

Mapping Instruments

The primary instruments used in cave mapping are tape measures and laser meters for distance measurement, compasses for azimuth readings, and clinometers for slope measurements (Tarsoly, 2006).

Tape measures are the standard tool for direct distance measurement. They are made from various materials (metal, plastic, linen, or plastic) and typically come in lengths of 20, 25, 30, and 50 meters. Their accuracy is approximately 2-3 cm per 100 meters under standard tension (marked on the tape) and at 20°C. Proper care should be taken when rewinding the tape into its case, as mud and dirt in caves can jam the tape, rendering it unusable (Savvaidis et al., 2007).

Laser meters, which use electromagnetic waves to measure distance, are particularly useful in large caves. Many laser meters can also measure slope (Doggouris et al., 1986).

For angle measurements, a magnetic compass is used to measure the azimuth, or the angle between the target and magnetic north, which differs from true north. Compasses can be divided in several ways, with the most common being a 0–360° system providing a clockwise azimuth relative to north. Other systems include quadrant-based systems, military mils (6400 divisions), and grads (400 divisions) (Dasher, 1994). More precise angle measurements can be made using theodolites or total stations, though their size can make them cumbersome in caves. 3D scanners, which capture real-time three-dimensional coordinates to generate a 3D model, are another tool used in cave mapping (Pagounis et al., 2004).

A clinometer measures ground slope to calculate elevation differences. Simple clinometers consist of a protractor and a plumb line and can sometimes be integrated with a compass. Geometrical leveling is another method for measuring elevations, though it is difficult to apply in steep environments (Doggouris et al., 1986).

Error Correction and Map Drawing

After data collection, the next step is to correct for measurement errors (Tarsoly, 2006). Errors during mapping can distort the final result, deviating from reality. These errors fall into several categories:

- **Random errors**, such as deviations from a straight line, horizontal position, or recording inaccuracies (Savvaidis et al., 2007).
- **Systematic errors** caused by instrument imperfections, differences from the standard, or incorrect tension applied to the tape measure. Tape sag due to weight is another common source of error. Calibrating the instruments outside the cave to account for these errors is a recommended procedure (Savvaidis et al., 2007).
- **Blunders**, the most critical type of error, arise from human factors such as inexperience or extreme fatigue, making them unpredictable.

The final stage of mapping is creating the map based on the corrected measurements. It is crucial that the cave map is aligned with the country's triangulation network (or other reference systems) (Tarsoly, 2006).

Different mapping techniques can yield slightly varied results for the same cave. This study examines the case of mapping a specific space while keeping parameters like stations, team composition, and instruments constant but varying the traverse technique.

Mapping of a Room with Different Survey Routes

To compare different mapping techniques, a room and its antechamber from the Department of Geology at Aristotle University of Thessaloniki (AUTH) were selected for mapping. This choice was made because the shape of the space was already known, and a topographic plan existed, allowing for a comparison of each route's results with the topographic model (Fig. 2).

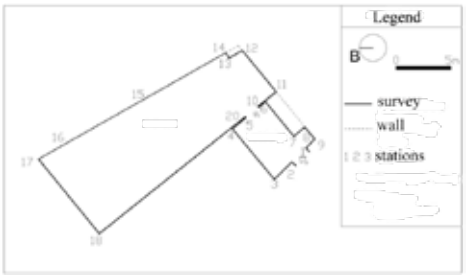

Figure 2. Topographic plan of the chamber mapped in this study, showing the locations and numbering of the stations used.

Instruments Used and Stations

The instruments used included a laser meter, a measuring tape, and a Suunto compass with a clinometer. A total of 21 stations were defined, remaining the same for each survey route to ensure accurate comparison of results, even in specific points. Additionally, on the eastern side, stations 15 and 16 were marked along with stations 14 and 17 to examine the deformation caused by redundant stations.

It was noted that the length of each measurement should be as large as possible to limit the number of stations, as suggested by Judson (1974).

Different Mapping Routes

The mapping was repeated, keeping the same instruments and team composition, but changing the route. The routes used were:

1. Radial route: Measurements were taken from three central stations (0, 21, 19).
2. Circular and zigzag routes: Mapping started from station 1, located at the entrance of the antechamber.
3.Central route: Measurements were taken perpendicularly from two central lines (19-21 and 21-22) toward the walls.

After collecting the data, four different maps of the same area were produced without any error correction (Fig. 3).

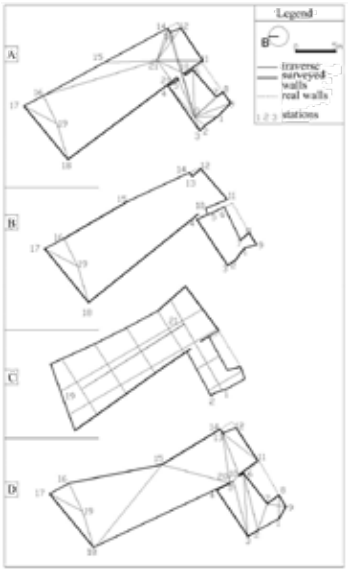

Figure 3. Topographic diagrams in "speleological style" of the chamber with different traverses: a) radial traverse, b) circular traverse, c) central traverse, d) zigzag traverse.

Discussion and conlusions

Radial Route Map (Fig. 3a, Table 1): This map closely aligns with the topographic plan of the room. The measured area matches the actual size (171 m²). Points 15, 16, and 17 are on the same straight line, with only minor deformations in some spots, such as the turn of the antechamber, which do not affect the overall shape of the room.

Circular Route Map (Fig. 3b, Table 1): This map shows deformation compared to the room's topographic plan, affecting the calculated area, which is smaller than the actual size by 7 m². Significant deformations were observed at the corners, which influence the overall shape. However, the advantage of the circular route is that there is a direct relationship between the measurement and the area represented.

Central Route Map (Fig. 3c, Table 1): This map presents minor deformations and a good overall correlation with the topographic plan. The measured area deviates slightly from the actual size (by 3 m²), with stations 15, 16, and 17 aligning correctly. The corners are also accurate. The central route, especially when measurements are taken at right angles, yields very good results but is time-consuming (Savvaidis et al., 2007).
Zigzag Route Map (Fig. 3d, Table 1): This map exhibits significant deformation compared to the actual shape. A notable discrepancy was found in the length of the room, which is a known issue with this route (Dasher, 1994). This also affects the area, which is calculated larger than the actual size by 15 m². Additionally, a slight shift in the map's orientation relative to the north was observed. Although the zigzag route requires less time for measurements compared to other routes, a single error can greatly distort the overall shape of the map and, with it, many important data points such as area and length.

Table 1. Summary description of the results of each traverse and evaluation regarding the main characteristics of cave mapping.

Type of Traverse	**Radial**	**Circular**	**Central**	**Zigzag**	**Type of Traverse**
Deformation	Minimal	Considerable	Minimal	Considerable	Deformation
Area Accuracy	Very good	Shows deviation	Relatively good	Shows significant deviation	Area Accuracy
Retention of Straight Lines	Yes	Yes	Yes	No	Retention of Straight Lines
Effect of an Error on Subsequent Measurements	Small to minimal	Significant	Small to minimal	Very large	Effect of an Error on Subsequent Measurements
Mapping Speed	Fast	Fast	Time-consuming process*	Fast	Mapping Speed
Deviation from Actual Orientation	No	No	No	Slight angle	Deviation from Actual Orientation

Dermitzakis & Dikaioulia (1981) emphasize the importance of a unified methodology in cave mapping. This study highlights the significance of:
a) the chosen survey route (Table 1),
b) the number of stations, and
c) the location of those stations in the mapping process.
As a result, maps produced using different methodologies are not directly comparable. Although references to the specific mapping methodology used are rarely found in the literature, it is deemed essential that each map be accompanied by these details for clarity and accuracy.

EXTENDED ABSTRACT 126

Geoeducational and Geotourism values of geological resources as novel path for Geosciences Education

Introduction

The modern trends of nowadays force us to adapt more and more to them in order to achieve the European as well as the international goals of smooth and sustainable development. Specifically, the evolution of data in Greece reveals that we are increasingly moving towards a new model of overtourism, where, in addition to the increase of revenue from an economic perspective, we must also identify any other ways to use these visitors from the geosciences viewpoint. This will indirectly help us to create a more conscientious audience capable of receiving any additional information regarding environmental protection in a more fruitful manner.

The only way to balance the strong relationship between human and nature is the sustainable development as it will solve problems between the increasing demands for resources and the environment. Living in a world where the climate change is increasingly apparent, the risk of depletion of mineral resources as well as the environmental pollution is becoming our daily routine, it is imperative as geo-scientists to reconsider our views and our actions in order to promote a more sustainable development model for a more sustainable society. Nowadays, the general public awareness of daily environmental challenges and sustainable development is low. Young people are by nature receptive to learn, while at the same time, they are also the key drivers of change in a society. In order to play a such role, they need to become environmentally aware. In this way, they could devise action programs to solve problems as they considered as active citizens and also exploited their relationship with all social media. Environmental education and geo-education, "which is promoted as the new educational trend that will make learning more comprehensive, more effective, more conscious and based on the research-scientific method of collecting, processing, presenting and utilizing information" will contribute to addressing this necessity. Thus, the purpose of knowledge of the environment is not the domination of man over nature but, in the context of the total environment, the relation of competition and domination are transformed into relations of complicity, cooperation and creation, where man must lead and follow the nature (Zouros *et al.*, 2004). In fact, at the 1977 International Conference in Tbilisi, Georgia, participants agreed that environmental education should be regarded as a separate scientific field of crucial significance. It is worth mentioning that UNESCO never gave up on the concept and initiative of environmental education. Following the above philosophy, UNESCO started to demarcate some areas with important geocultural monuments and designate them as UNESCO geoparks after strict geotope parameter controls (Iliopoulos *et al.*, 2024).

Geoturism has created techniques for geoeducation that enable geo-interpretation and the attainment of cognitive objectives by the audience, i.e., a broad education in geology, in order to promote awareness of geoheritage values, mainly in geoparks and geosites (and in Greece, in legal forms of protection – reserves of geoheritage and documentation sites or monuments of geoheritage).

This study aims to investigate the perception and the cognitive level of Tourists in Kefalonia Island (Greece) as one of the famous Geoparks in Europe. To achieve the main objective of improving the knowledge about geosites, mineral raw materials, and geological heritage, a targeted public outreach took place based in a hotel in Argostoli (Kefalonia) within one of designated UNESCO Geoparks focusing on teaching and rapid learning about the basic principles of geoeducation, when at the same time is giving emphasis in the importance of sustainable environmental practices about the mineral raw materials by increasing geoethical awareness and education. Through this type of study, it is possible to identify immediately and interactively the cognitive gaps for a better and sustainable society.

Geological setting of studied area

Kefalonia Island, one of the biggest Ionian Islands, is mainly separated through alpine formations (Paxoi and Ionian geotectonic units) and Plio–Quaternary sediments (Underhill 1989, Lekkas *et al.*, 2001). The Paxoi unit composed of Triassic–Middle Miocene carbonates and clay-clastic sequence of flysch from the Middle Miocene–Early Pliocene, including alternations of marls, clays and mudstones, while the Ionia unit composed of Triassic evaporitic series and Jurassic–Cretaceous limestones and slates (Lekkas *et al.*, 2001). Pliocene–Calabrian and Middle-Upper Pleistocene–Holocene series make up the Plio–Quaternary sediments, which characterized through the presence of a marine sequence, yellowish marls with siltstones, sandstones, sands

and coarse calcarenites. Pliocene–Calabrian series prevail in the Lixouri area, where the marine sequence is observed as an uplifted coastal zone with 2 to 10 km width range. Such formations have a thickness variation between 200 and 500 m and are developed transgressively over Paxoi unit (Figure 1) (Lekkas *et al.*, 2001).

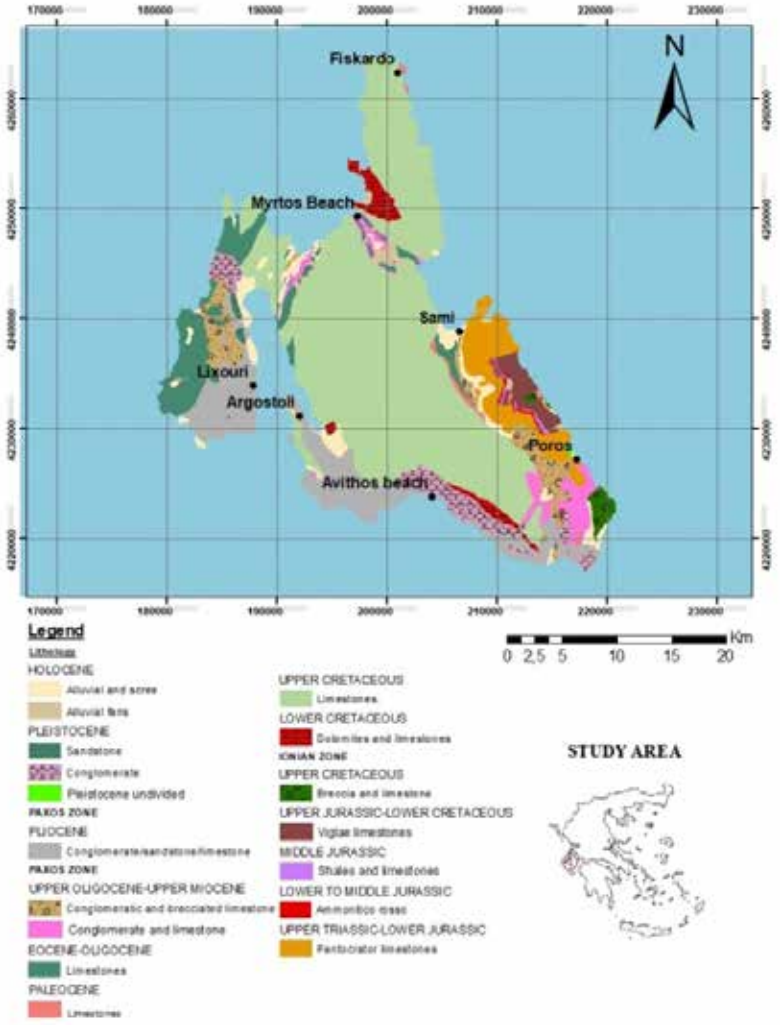

Figure 1. Geological map of Kefalonia (after IGME) (Lampropoulou *et al.*, 2023).

Analytical methods

In order to investigate how informed the European citizens about Geosites, geology, petrology and raw materials issues are, as well as whether they agree with the necessity of geoeducation to the general public, a number of questions accompanied by a geological map were given to a variety of European citizens. For this reason, a random sample of visitors was selected from May 25 to June 25, 2024, which is a peak period, and 300 European citizens coming from various European countries were selected in order to obtain a representative statistical sample. The questions were given in visitors of a hotel located in Kefalonia Island, which constitutes one of the most famous European tourist destinations and now has air connection with almost all European countries. Moreover, this hotel was chosen as it contains a geological stand which has a display case of rocks of various types and provides explanatory information about each one as well as at the reception the employees are geology graduates. The island of Kefalonia was strategically chosen, as in 2021, it was included in the UNESCO Geoparks, as a result of which it attracts many European citizens who visit the island to discover the natural beauty of the geopark. All the answers were statistically analyzed in order to draw important conclusions.

Questionnaire

In order to investigate how informed European citizens are about geoparks and more specifically about the Kefalonia-Ithaca Geopark, a series of questions were given in a preliminary survey stage to 300 European citizens/visitors in

order to obtain a representative statistical sample. The design of the questionnaire was based on determining the elements necessary for the research and then the questions were screened and the most representative ones were selected, following all European standards. The questionnaires were distributed/given to the partner hotel from 25 May to 25 June of 2024 and at this point the questionnaires were purely diagnostic in nature and statistically analyzed in order to draw significant conclusions. In the context of this study, we present a part of the overall questionnaire that was given to the guests of the hotel as well as the wider research that was conducted.

Below, the questions used in the questionnaire are listed:

1. What is your academic backround?
2. Have you visited another Geopark or Geo-invastigation in the current/last year? (yes, no)
3. Do you have any special interests about geosciences as a subject at school?
4. Have you ever encountered the term geotourism? (yes, no)
5. What do you think about the mineral raw materials in our life, are they very important? (yes, no)
6. Do you think geoheritage sites (specific rocks, caves as Melisani Lake) can be an important tourist attraction? (yes, no)
7. Does the school, universities, or public teams, organize field trips or lessons in your country/ region to the geoheritage sites? (yes, no)

At this point, representative Geologist in collaboration with the hotel's reception service informed and educated the tourists about the concept of Geopark and the geology of Kefalonia island, while they also guided them how to navigate in the geopark so they could better understand the geological history of the area. Actually, through this way, we pursued to achieve the reconnection of human society, at all levels, with the planet known as home. However, extremely important was to make them understand and also to accept that our planet and its 4,600 million of years history have shaped every aspect of our lives and our societies. As a result, the aim was to strengthen the feeling of respect of the environment and the preservation of this natural heritage.

The way to achieve what was mentioned above was to organize short trips through the georoutes map of the geopark (Figure 2). Along with the selected and suggested geo-routes for exploration, all the necessary instructions and information relative to what they were going to visit was given to the guests. The aim of this step was the tourists to see in depth the geological history reflected in each geosite and to become a part of the history and geological processes.

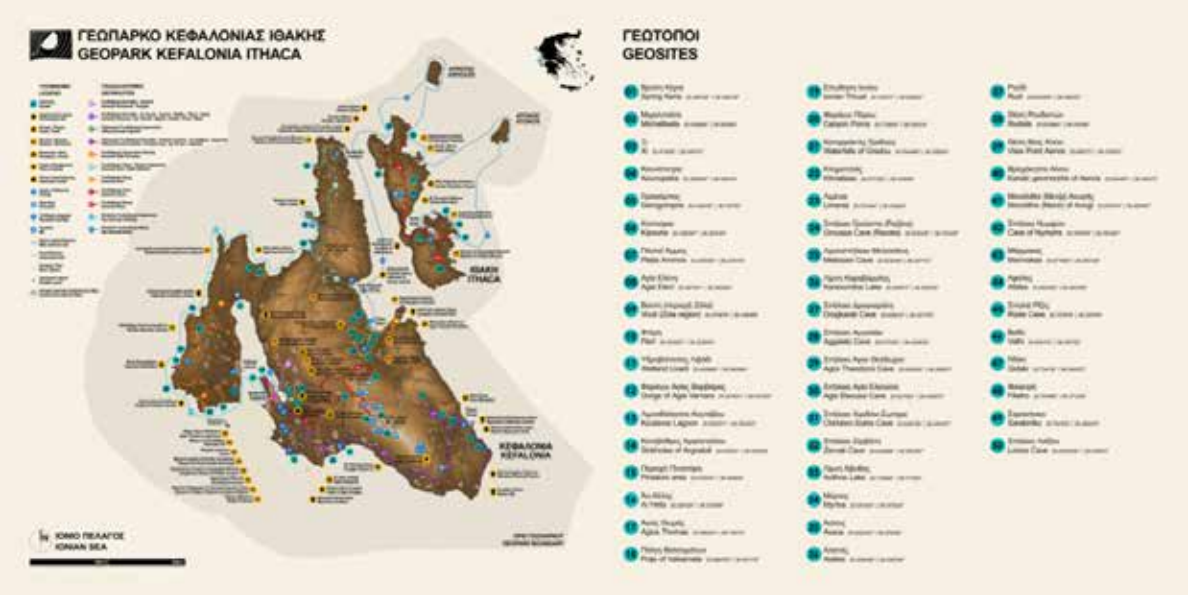

Figure 2. Map of the Geopark of Kefalonia Ithaka

Statistical analysis

Statistical interpretation of the results (tourist's answers) was performed with SPSS statistical analysis in order to investigate the interdependence of the questions. The methodological approach of the process of the present study has been directed to the area of the quantitative research approach to collect and analyse the research data. The study focuses on the quantification of collected data and on the interpretation of the results.

Results and Discussion

A total of 300 questionnaires were filled out. The age of those which were filled out the questionnaires was from 18 to 75 years old, while the 55% of the respondents were men. Based on the questionnaire survey conducted in

collaboration with a geo-friendly hotel in Kefalonia, on a representative sample of 300 people in low-stress conditions for respondents and in a beautiful and natural environment, important points that should be considered in any future research or in a pilot work were identified, while at the same time, concerning the issue of geoeducation in general public. More specifically, the following results indicate that even a large amount of the respondents had heard about the geotourism, they have been trained in a substantial and in-depth way on the subject.

While the majority of respondents has finished high school and they have subsequent activities or studies, as shown by the answers of the first question, it does not seem that they have been substantially educated on geoeducation issues and natural resources protection (questions 5 & 7). Particularly important seem to be the results of questions 2, 3 and 4. Even the general public has visited a geopark or a geotope in the past, the 91% may not be able to understand the concept of a geotope as a geological unit of increased and timeless value.

On the other hand, the answers of question 3, 4 and 6 reveal the potential interest that the general public seems to have in geoeducation as long as they are aware of it and have been guided on this knowledge, which makes geosciences education from the young people possible to be a key focus. Finally, the results of questions 5 and 7 clearly indicate that there is a clear gap in the education (answers of question 7) regarding the use and the importance of mineral raw materials due to the absence of a strategic and common public awareness of geoeducation in all countries. Electrical and electronic devices such as mobile phones, computers, TV are made by a large amount of mineral raw materials (i.e. minerals, metals).

Table 1. Statistical results of the respondents.

1 Question	Primary school 15%	Secondary school 65%	Master degree 18%	PhD 2%
2 Question	YES 9%	NO 91%		
3 Question	YES 74%	NO 26%

Conclusions

The conclusions of this study seem to be double. The first one is related to the poor knowledge about the mineral raw materials, geo-investigations and Geoparks, while the second is related to the social acceptance of Geoeducation.

The main conclusions of the study are summarized below:

- Geosites play significant role in geoeducation even they have not always been used properly often due to lack of knowledge.
- Schools play a crucial role in the development of geoeducation and geotourism, as cognitive needs are formed.
- The majority of the respondents consider that geotourism constitutes an important tourist activity.
- It should be mentioned that there should be an organized project in all European countries in order to communicate the scientific knowledge to a wider European audience, with having as an ultimate goal the consolidation of sustainable development in Europe.

Research Highlights

Pseudokarst features at the small islet of Kaki Thalassa, reveal previously unknown ancient mining activities.

The Lavreotiki UNESCO Global Geopark comprises one of the nine Greek UNESCO Geoparks, promoting the significant geological heritage of Greece. It is the only geopark located close to Athens, the capital city of Greece and bears a long and rich mining history. Lavreotiki Geopark occupies the southeastern part of the Attica Prefecture and its spatial extent coincides with the region of the Lavreotiki Municipality. Although, mining heritage represents the core of the Lavreotiki Geopark, other geological features such as coastal, geomorphological landforms enclose high scientific and educational value, revealing unknown aspects of this deep-in-time heritage.

The Lavrion mining district covers an area of >100 km^2 and has been exploited nearly continuously for silver (Ag) and lead (Pb) from 4000 BC until the late Roman times (Conophagos, 1980; Rosenthal *et al*., 2012). It is also considered that Lavrion was a source of copper (Cu) for a large part of the latter period (Gale *et al*., 2009; Kayafa, 2020). Monumental sites and structures such as the Industrial District, as well as the Thorikos theater at the flanks of the Velatouri hill, reveal the inseparable connection of the ancient local people with their peculiar local geology. This type of geology provided the appropriate resources to the Athenian Democratic Polis to be transformed during the Classical period and fund the trireme fleet, which determined the naval battle at Salamis against the Persians.

Apart from this mining wealth, the Lavreotiki Geopark includes a 73-km long coastline, hosting a rich geodiversity and biodiversity. With the aim of assessing the impact of the future sea level rise on the coastal landforms, which can also be potential future geosites, the geopark's personnel undertook an extended project between 2022-2024 for surveying and mapping the geological/geomorphological sites on the coastline. During these activities at the Kaki Thalassa Bay (Keratea, Lavrion), a small rocky islet was surveyed (Fig. 1). This islet consisting of Pounta marble, is located 128 m from the closest coast and hosts two strange pool-like structures at its eastern side (Fig. 2).

These morphological structures were considered to be the result of natural processes and were often referred as natural pools. On the contrary, detailed geomorphological mapping with the application of drone-assisted technology and S-f-M (Structure-from-Motion) technique in combination to geological observations, resulted in anthropogenic pseudokarst features in the sense of Veress (2022).

The assessment of the origin of these pools was implemented with the use of sophisticated, low-cost, non-destructive photogrammetrical technique, employing two-dimensional (2D) aerial mapping and geological-geomorphological field-based observations. The same technology has been applied in other locations of the geopark (Kampolis *et al*., 2024) as well as in other sites of interest (Kampolis *et al*., 2021) with valuable results.

Figure 1. The small islet close to the northern coast of the Kaki Thalassa Bay.

Figure 2. Aerial photo of the two pool-like structures at the islet. The red dashed line represents the fault crossing the western part of the islet.

The followed methodology was arranged in two separate phases. The first phase included the aerial 2D mapping and the photogrammetry of the small islet and the second one comprised the in-situ geological and geomorphological observations, as well as the extraction of samples for subsequent analysis.

During the first phase of the project, a *DJI Mavic Air 2* drone was employed for the 2D mapping of the islet, after setting up its flight mission within the *Copterus* app, running on an "*iphone 13 mini*" mobile phone. The drone's flight was programmed at an altitude of 30 m with a 75% frontal and lateral overlap, yielding a total (real) flight duration of 13 min. The collected aerial photos were then inserted in *Agisoft Photoscan Pro* software and following the photogrammetrical work-flow without ground control points, the three-dimensional (3D) reconstruction of the small islet was generated (Fig. 3). The Agisoft work-flow includes certain stages of multi-image processing: A) photos alignment, B) point cloud building, C) mesh reconstruction and D) Digital Elevation Model (DEM) generation (Semaan and Salama, 2019). For the in-depth exploitation of the islet's 3D reconstruction, the exported mesh file from Agisoft was input in *CloudCompare* software and converted into a point cloud for further geometric measurements. The latter enables various measurements such as inclinations, azimuths, lengths, areas and geometrical features of plane surfaces (dip and dip direction) on certain features.

The second phase consisted of the mineralogical observations on mineral assemblies found on the perimetry of these pool-like structures. Also, geomorphological observations on the morphology of the pools took place in-situ. The depths of their bottom were measured with a SUUNTO D3 digital depth gauge (accuracy ±0.1 m).

The generated 3D model of the small islet in combination to the field-based geomorphological measurements, provided the ability to assess the formation origin of the pools, present at the eastern side of it. According to the geomorphology of the coastal part of the islet and the bathymetry of the pools' bottom, it is unlikely for the pools to be the result of natural erosional processes. This can be supported by the bathymetry of the connection passage between the open sea and the easter pool (Fig. 4). The depth at this point reaches only 0.3 m and thus prevents the wave activity and its subsequent erosive force to enter the eastern and western pool and form them, as the erosive force is consumed on the shallow coastal part. Additionally, the eastern pool reaches a depth of 2.5 m, which cannot be justified by natural processes (i.e. waves, karstification).

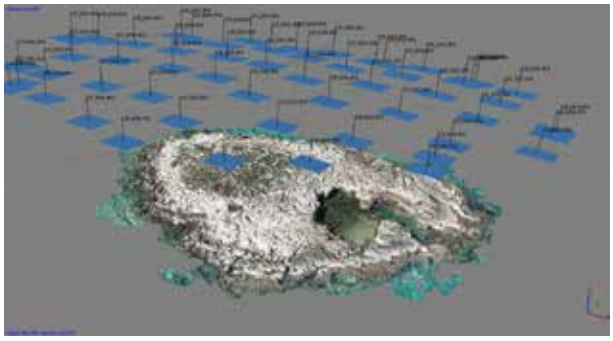

Figure 3. The 3D model of the small islet and the acquired aerial photos during the flight mission of the 2D mapping.

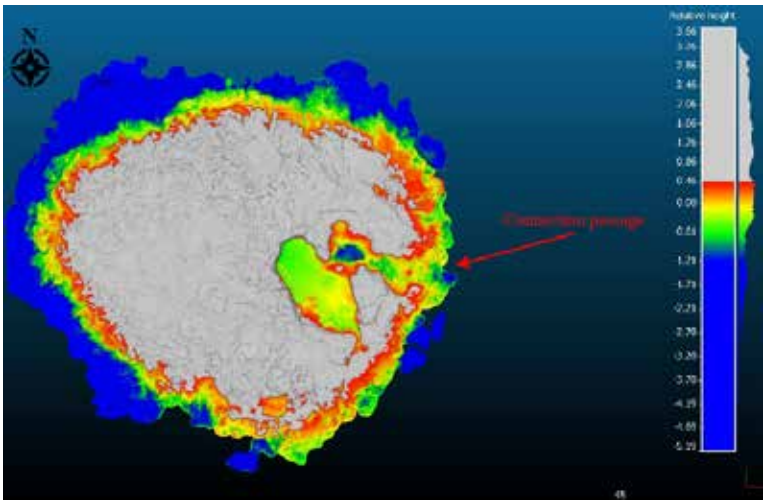

Figure 4. The bathymetry of the coastal part of the islet, generated in the CloudCompare software. The colored scale on the right provides the depth.

Moreover, the presence of a tectonic structure trending NW-SE (15°/204° – Dip/DipDir) and crossing the western part of the islet (Fig. 2) may be an extension structure related to the Miocene low-angle detachment fault developed during the top-to-SSW crustal extension, resulting in the Western Cycladic Detachment System (Loisl *et al.,* 2014), and locally referred as the South Attic Detachment (SAD) (Ross *et al*., 2021). This fault seems to play a role on the presence of sulfide mineralization (now oxidized to iron oxides), recorded on the periphery of the pools and along its surface (Fig. 5). The oxidized mineralization occurs above the SAD, where it replaces, and also cements brecciated fragments of the Punta marble. Ross *et al.* (2021) mentioned that normal faults rooted within the SAD are linked to its movement and have hydrothermally affected the Pounta marble. Consequently, it is possible that this NW-SE fault has designated the oxidized sulfide mineralization on the Pounta marble of the islet, which also attracted the interest of the ancient people. The latter must have started exploiting this mineralization, leaving open depressions that were later inundated by the sea level rise since the antiquity. Ancient miners extracted the mineralized layer, and this is probably the reason for the flat, shallow bottom of the western pool. The pool was excavated for the extraction of the mineralization, whereas natural processes like karstification would have resulted in a more uneven bottom. Therefore, these depressions originated by the anthropogenic activity on the carbonate rock of the islet, can be falsely interpreted as karst landforms and thus, represent the so-called anthropogenic pseudokarst. The nature of the latter revealed these previously unidentified ancient mining works.

Figure 5. The oxidized sulfide mineralization on the eastern side of the eastern pool.

EXTENDED ABSTRACT 128

Preliminary results of black sands in Corfu Island (Ionian Sea, Greece)

Kanellopoulos C.[1*], Aggelatou, V.[1], Papatrechas C.[1]

[1] Hellenic Survey of Geology and Mineral Exploration (HSGME), 1 Spirou Loui str., Olympic Villa, 13677, Acharnae, Attiki, Greece; ckanellopoulos@gmail.com , vaggelatou@eagme.gr , chpapatrechas@eagme.gr

The grains of beach sand results from the weathering and transportation of geological formations. From a mineralogical perspective, beach sand typically consists of the durable remnants of weathering, providing insights into the original rock formation, while the transport process may involve a combination of factors such as river, wind, and sea transportation.
Typically, near the coastline, an accumulation of heavy minerals is found in certain limited places, such as the swash zone of wave run-up. These accumulations are typically distinguished by their dark color (black sands). The accumulation sites could change rapidly over time due to varying factors that influence transportation routes, such as changes in wind or sea current patterns.
In some cases, black sands are enriched with economically significant minerals, forming placer deposits in coastal regions through gravitational segregation. Their minerals exhibit weathering resistance and, in numerous cases, are enriched with elements characterized as critical in adequate concentration and quantity that they can be extracted.
The mineral phases commonly found in black sands include quartz and other tectosilicates, phyllosilicates such as micas, chlorite, and serpentine, orthosilicates such as zircon, olivine group, and garnet group minerals, as well as spinels, titanite, rutile, and minerals from the epidote group, such as allanite.
In Greece, in recent years, numerous studies have been conducted on black sands, especially in the Northern Aegean Sea, i.e., Eastern Macedonia coastline, such as the Kavala region (Papadakis, 1975; Perissoratis et al., 1988; Pergamalis et al., 2001a, 2001b; Aggelatou et al., 2018; Papadopoulos et al., 2015, 2016, 2019; Tzifas et al., 2019; Stouraiti et al., 2020; Peristeridou et al., 2022) and in few cases in volcanic islands in Aegean Sea, such as Nisyros (Tzifas et al., 2017). Significant geochemical anomalies specifically in La and Zr, were detected along the Eastern Macedonia coastline, prompting further exploration and study to ascertain the source geological formation.
No occurrences of black sand have been reported in the Ionian Sea until now. For the first time, regions of black sand accumulation have been discovered on Corfu Island (Fig. 1). The deposits were located in the swash zone of wave run-up. Mineralogical (optical microscopy, XRD and SEM-EDS) and geochemical analyses (XRF, ICP-MS) were performed at the laboratories of the Hellenic Survey of Geology and Mineral Exploration (HSGME). Preliminary mineralogical and geochemical analyses revealed that the black sand mostly consists of chromium-rich mineral phases, iron-titanium oxides, and shows elevated concentrations of chromium, iron, and titanium, among other elements. The comprehensive investigation and characterization of areas displaying these characteristics, together with the identification of the parent geological formation, is of significant importance.

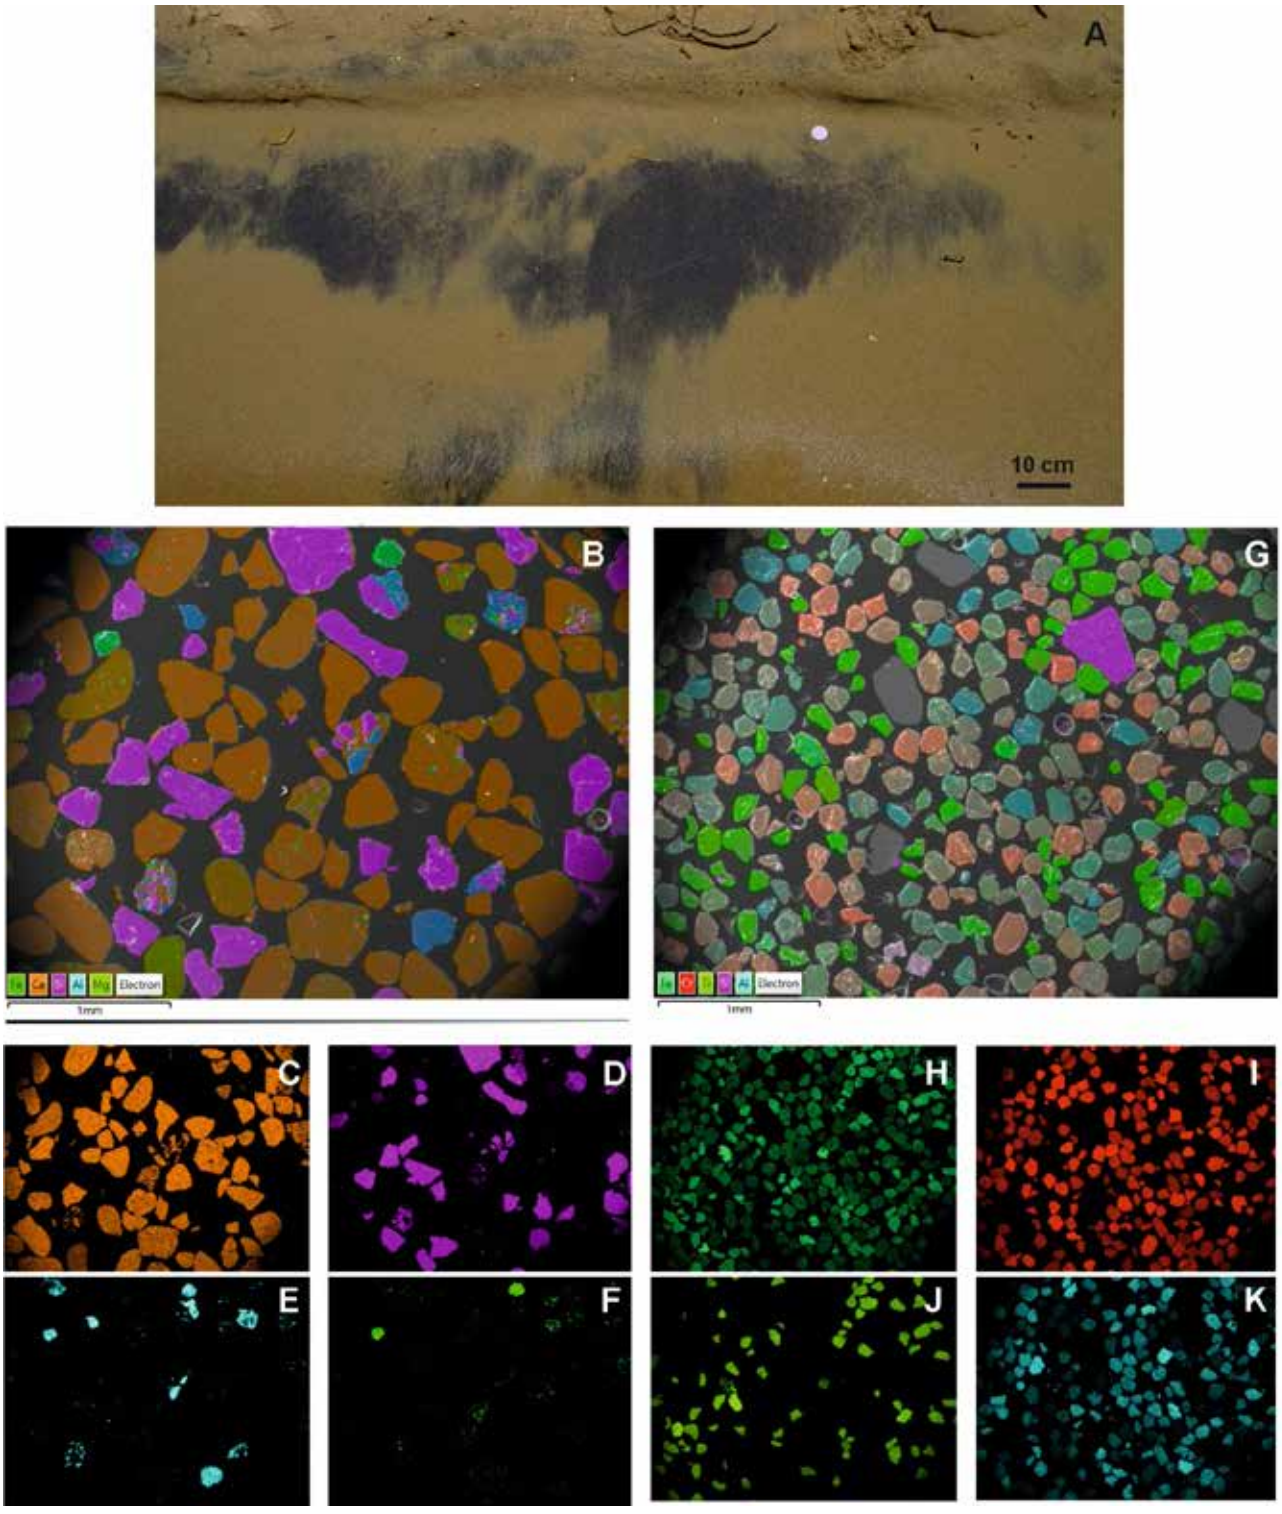

Figure 1. (A) The swash zone of wave run-up with black sand accumulation from Corfu Island. Agios Efstratios Island is a small, isolated island located in the northeastern Aegean Sea. The island is situated approximately 30 km southwest of Limnos Island and approximately 80 km northwest of Lesbos Island. It covers an area of approximately 43,000 km² and is distinguished by its rocky geomorphology. Despite its closeness to the volcanic islands of Lesvos and Limnos, as well as its location near the North Aegean Trough, geological data regarding it is limited (i.e., Fytikas et al., 1980, IGME, 1983, Pavlidis and Tranos, 1991).

In light of these conditions and the limited geological understanding of the region, the Hellenic Survey of Geology and Mineral Exploration (HSGME) organized a field expedition. The objectives of the expedition were to achieve a more thorough comprehension of the geology of Agios Efstratios through the creation of a new geological map (Fig. 1), identifying and mapping new geological formations, and an assessment of the island's volcanic formations.

Seven distinct geological formations were recognized and sampled on Agios Efstratios island. No Alpine basement formation has been identified on the island; However, many volcano-tectonic data and structures have been documented. The two primary formations are volcanoclastic-pyroclastic formations of significant thickness (several tens of meters) of Oligocene to Lower Miocene age, covering most of the island. The volcanoclastic formations consist mostly of epiclastics (debri flows, lahars, hypercocentrated flood flows) and in a less extension of tuffs and tuffites, primarily of intermediate to acid composition. These formations typically have well-defined stratified layers (Fig. 1). Irregular, scattered, and ungraded fragments of volcanic rocks, mostly boulders of lavas, are incorporated into the tuffs, alongside ejecta and bombs predominantly of high-K calc-alkaline tracyandesitic to andesitic-dacitic composition (Fig. 2), based on new geochemical analysis. The southern volcaniclastic-pyroclastic formation developed from nonvisible nowadays volcanic center(s) south of Agios Efstratios, whereas the northern volcanoclastic formation also formed from nonvisible nowadays volcanic center(s) north-east of Agios Efstratios. According to Fytikas et al. (1980), these deposits belong to the late Oligocene-early Miocene (17 Ma, 22 Ma), similar to the age of Lemnos Island volcanic products. Volcanic vents and block and ash flows were detected on the island's southeastern coast. Intense fault-related hydrothermal alteration has been reported on the island, leading to the development of bentonites and zeolites (Pe-Piper and Piper, 2002).

The other five geological formations of the island occur mainly in the northern and northeastern parts; there are small occurrences of the recent Holocene alluvial deposits, coastal deposits, talus cones and scree, Upper Miocene marine limestones, and Oligocene clastic formations (Fig. 1).

The recent Holocene alluvial deposit reaches a thickness of up to 20 m and is predominantly composed of sandy, clay, and pebble materials; in the NE part of the island, there appears to be a fluvial deposit of dunes. The Oligocene sediments consist of clays, mudstones, sandstones, and conglomerates (Fig. 3). The IGME (1983) mentions that lignite intercalations occur in the deeper sections of the Oligocene sediments. The Miocene limestone consists of bedded to massive calcite-marly organogenic limestones from a shallow water environment (Fig. 4), with dip 10-15° to the E-SE, including pieces of lamellibranchs, gastropods, algae, ostracods, and foraminifera (Milliolidae, Rotaliidae). The formation unconformably overlays the pyroclastic formation (IGME, 1983).

The geological formations of the island demonstrate substantial evidence of neotectonic movements from the post-middle Miocene to the present (Pavlidis and Tranos, 1991). Mercier et al. (1989) suggest that the neotectonic regime of the island is extensional and can be categorized into two separate periods. The minimal primary stress (σ3) during the Pliocene-early Pleistocene epoch was oriented NE-SW, whereas the σ3 axis from the middle Pleistocene to the present phase trends N-S.

The current geodynamic regime activates NE-SW direction strike-slip dextral faults, which displace older neotectonic structures and geological formations. The last activation occurred in 20th February 1968 after a strong 6.8 earthquake when the seismic strike-slip fault cut the island in half with a NE-SW direction (Fig. 1).

In the greater Pagasitikos Gulf, Oreoi Strait, northern Euboea Gulfand NW Aegean Sea regions, a series of volcanic centers, namely Lichades, Kamena Vourla, Achillio, Mikrothives, and Porfyrio, occur at the western extremity of the southwestern segment of the North Anatolian Fault, (e.g. Ktenas, 1927; Georgalas, 1938; 1940; Georgiades, 1958; Marinos, 1958; Pe & Panagos, 1976, Innocenti *et al.*, 1979, Clapsopoulos, 1991, Pe-Piper and Piper, 2002, Fig. 1). Despite their early identification and studies (e.g., Ktenas, 1927, Georgalas, 1938, 1940), their proximity to important tectonic structures, and their correlation with other geological features, i.e. presence of hot springs/geothermal fields (Kanellopoulos *et al.*, 2017a, 2017b, 2018), there are no further systematic geological studies conducted for these occurrences.

The Lichades island complex consists of a series of trachyandesite volcanic islands (Georgalas, 1938; Georgiades, 1958), with a characteristic dome on the island of Strongili. The geochronological dating for the lava flows of the Lichades islands indicate an age of 0.5 Ma (K-Ar, Fytikas *et al.*, 1976).

Adjacent to Lichades is the trachyandesitic lava outcrop of Kamena Vourla (formerly known as Agios Ioannis), located on the mainland (Georgalas, 1938; Georgiades, 1958, Kanellopoulos *et al.*, 2019). The geochronological data for Kamena Vourla indicate an age of 1.7 Ma (K-Ar, Bellon *et al.*, 1979).

At Achilleon, occur a trachyandesite dome, located near Tymbanos Hill (Marinos, 1958). The geochronological data at Kamena Vourla indicate an age of 2.68-3.4 Ma (K-Ar, Innocenti *et al.*, 1979; Pe-Piper and Piper, 1979).

At Porphyrion near Volos, a trachyandesite lava flow is present (formerly known as Kadir Agas in earlier literature) (Georgiades, 1958). Geochronological data indicate an age of 1.2-1.6 Ma (K-Ar, Innocenti *et al.*, 1979; Pe-Piper and Piper, 1979).

At Microthibes, a plateau of trachyandesite lavas, with a total volume of around 0.2 km³, is present (Ktenas, 1927). Geochronological data indicates an age of 1.5 Ma (K-Ar, Innocenti *et al.*, 1979).

At Psathoura island in the NW Aegean Sea, basaltic trachyandesite lavas compose the island (Koutsovitis *et al.*, 2015; Ntaflos *et al.*, 2017). Geochronological data indicate an age of 0.7 Ma (K-Ar, Fytikas *et al.*, 1984).

In the past, multiple theories have been proposed regarding these volcanic centers; among which is that are related to the western extension of the South Aegean active volcanic arc (Pe and Panagos, 1976; Pe-Piper and Piper, 1989), and they are associated with a deep source likely linked to the continuation of the North Anatolia fault, and unrelated to the plate subduction context (Fytikas *et al.*, 1985). Innocenti *et al.* (2010) utilized Sr–Nd–Pb isotopic data to associate this volcanic center with the extensive volcanic belt that formed north of the Pelagonian–Attic–Cycladic–Menderes massifs, which spans a considerable region from NW Greece–Macedonia to the Aegean–western Anatolia, covering a duration of 35 Ma.

Kanellopoulos *et al.* (2017a, 2017b, 2018) proposed that the volcanic center of Lichades and its associated magmatic chamber serve as the thermal source and contribute a fraction of deep magmatic fluid to the geothermal fluid of the Euboea-Sperchios system, in conjunction with seawater and minimal meteoric water input. Northern Euboea (or Evia) and the adjacent region of the mainland in eastern Central Greece (Sperchios area) are acknowledged as possessing one of the highest geothermal gradients in Greece, following the active volcanic arc of the southern Aegean (Fytikas and Kolios, 1979).

New data derived from geochemical and mineralogical analyses, tectonic measurements, and field observations confirmed the strong geochemical correlation between these volcanic centres and simultaneously elucidated their connection to the region's dynamic tectonic setting.

Based on geological, seismological, and geodetic data (e.g. Galanakis, 1997; Galanakis *et al.*, 1998; Chousianitis *et al.*, 2024 and references therein), the study area undergoes a roughly N-S oriented extension. As a result, E-W- to ESE-WNW-striking normal faults dominate in the area. However, the shear that prevails in the North Aegean Sea, as the western continuation of the North Anatolian Fault, seems to affect the eastern part of the Pagasitikos Gulf and North Euboea, forming a locally transtensional regime. Neotectonic investigations in central Greece suggest that the current extensional stress field dates back to Middle

Pleistocene, following a NE-SW trending extensional phase which was active from Pliocene to Early Pleistocene (e.g., Caputo & Pavlides, 1993). The faulting due to the current stress field has significantly affected the topographic relief by forming horst-graben systems of various scales.

The volcanic centers are located along neotectonic structures (Fig. 1). The Porphyrio and Microthebes centers are related to the Nea Anchialos fault zone, an active structure responsible for the July 9, 1980, double earthquake (two strong earthquakes of M_W 6.5 and M_W 6.1, 24 mins apart). The Achillio center is located next to the Oreoi Strait, in a small fault system that is affected by the narrow graben that forms this NE-SW trending channel. The Kamena Vourla center outcrops along an area of dense faulting where the western prolongation of the Atalanti and the eastern tip of the Kamena Vourla faults occur. The Lichades center is situated on the western prolongation of the Gialtra – Agios Georgios fault, which shapes the southern coastline of the westmost part of Euboea. It is obvious that all volcanic occurrences coincide and are associated to the active tectonic of this region.

EXTENDED ABSTRACT 131

Investigating crustal deformation of Zakynthos Island using Satellite Interferometry (InSAR): pre- and post- seismic analysis of the October 25, 2018 earthquake.

Kantareli K.[1], Sakkas V.[1].
(1) Geophysics Laboratory, Department of Geology and Geoenvironment, National and Kapodistrian University of Athens, Greece, ntinakanta@gmail.com

Introduction

This study focuses on the analysis of crustal deformation the period before and after the strong M_w6.8, 2018 Zakynthos earthquake, utilizing Interferometric Synthetic Aperture Radar (InSAR) data detecting ground surface changes over a period of six years. The earthquake took place southwest of Zakynthos Island on October 25, 2018, with an estimated magnitude of M_w6.8 (Papadimitriou et al., 2021). The earthquake was one of the most significant events in recent years in the broad region, producing noticeable ground displacement (~40 mm in the southern part of Zakynthos), reflecting the dynamic tectonic processes on the south Ionian Islands. Analysing pre- and post- seismic InSAR datasets, patterns of ground motion were identified and quantified aiming to assess the deformation processes before and after the earthquake based on the estimated velocity changes and its spatial distribution across Zakynthos.

Geology and Seismicity

Zakynthos island, located in the southern Ionian Sea, is part of the External Hellenides, a geotectonic domain shaped by the convergence of the African and European plates (Papanikolaou, 2021). The island's tectonic framework is influenced by its position along the Hellenic Subduction Zone, the active boundary of the subduction of the eastern Mediterranean oceanic lithosphere under the Aegean microplate. The island consists of series of stacked tectonostratigraphic units that were accreted during the alpine orogenic system. A significant part of the island in its western part is mainly structured by the Paxoi Unit and represents the primary tectonostratigraphic feature. In the eastern part, the Paxoi Unit is overthrusted by the Ionian unit, a structural feature that emphasizes the tectonic complexity of the region (Figure 1).

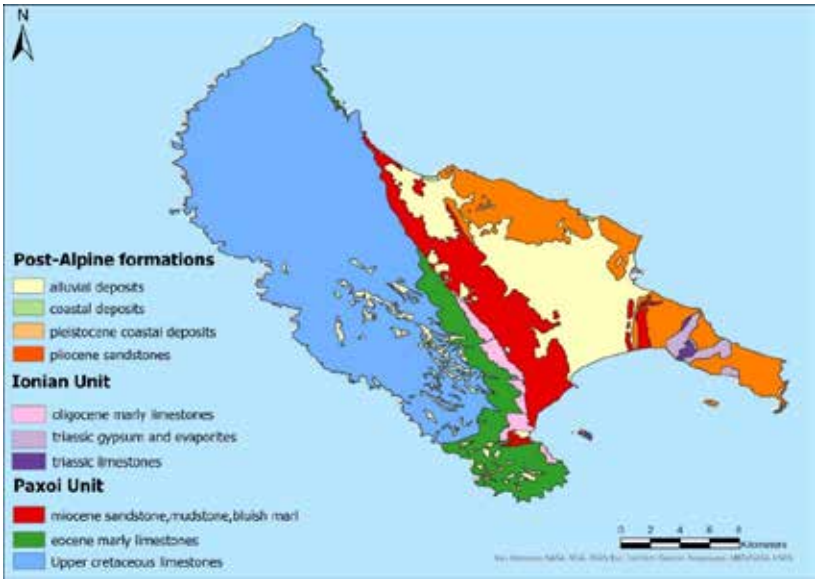

Figure 1:Geological map of Zakynthos Island (IGME, Geological Map of Greece, 1983)

The Paxoi Unit consists of a well-developed carbonate sequence that spans from the Upper Cretaceous to the Oligocene (Papanikolaou, 2021). This sequence is characterized by thick fossiliferous limestones and marly limestones, and above these carbonate rocks lie Miocene deposits, made up of marls, sandstones, and mudstones. This stratigraphic succession captures the evolving depositional setting which was influenced by the tectonic changes over millions of years. The Ionian unit comprises a Triassic sequence of limestones, evaporites and breccias, which

represent different geological episodes, consisting of restricted marine deposition and subsequent tectonic disruption (Papanikolaou 2021). Overlying both units are post-Alpine Quaternary deposits, which consist of alluvial and coastal sediments, deposited during the Pleistocene and Holocene. The presence of the two distinctive geological units, Paxoi and Ionian, that dominate the eastern and western part of the island, respectively, may infer different kinematic behaviour. However, the absence of a clear tectonic feature (i.e. fault) in between these two units is questioning this assumption. Using the InSAR technique the latter will be studied aiming to examine this hypothesis.

The earthquakes that occur in the Ionian Sea are mainly generated along the Cephalonia-Lefkada transform fault zone (CLTFZ), which plays a significant role in the kinematic field of the region (Sakkas et al., 2022). This zone divides the Ionian margin into two areas, the North Ionian islands, which move north-northwestward at rates slower than 5mm/year relative to Eurasia, and the South Ionian islands that move southwestward with velocities of 6-30mm/year (Sakkas et al., 2022). The intense seismicity on the southern Ionian Sea is attributed to the proximity of this area to the CLTFZ and the Hellenic Trench (Figure 2). Zakynthos in particular, experiences intense seismic activity frequently, as it lies at the northwesternmost edge of the Hellenic arc, near the boundary where the eastern Mediterranean lithosphere subducts beneath the Aegean microplate. This complicated geotectonic setting highlights its significance in understanding regional deformation processes.

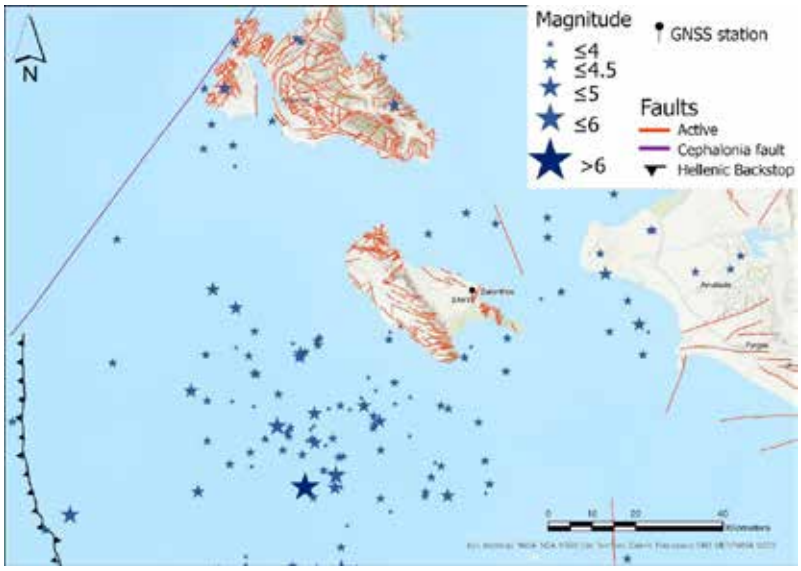

Figure 2: Seismicity of the broad area of Zakynthos Island (2015-2021) with M≥4.0 based on the catalogue of Seismological laboratory of NKUA (Fault lines from Ganas, et al., 2024)

Radar Interferometry

Interferometric Synthetic Aperture Radar (InSAR) is an advanced geodetic technique used for precise measurements of surface deformations and topographic variations on the Earth's surface. Utilizing radar signals transmitted and received by satellites, InSAR exploits the phase differences between radar acquisitions taken at different times or from slightly varied perspectives to derive changes in ground displacement. SAR satellites collect data during ascending (asc; from south to north) and descending (desc; from north to south), with the radar sensor looking to the right of the orbit trajectory. The two viewing geometries result in different line-of-sight (LOS) observations of the ground surface and refer to the displacements along the direction in which the satellite's radar beam travels, which is inclined relative to the vertical and horizontal axes. Since ground deformation occurs in multiple directions, LOS data from both ascending and descending passes are combined, to resolve the ground motion into its vertical (Vup) and horizontal eastward (Veast) components.

The decomposition of the LOS displacements into vertical and horizontal components requires knowledge of both the incidence angle (θ) and the track/azimuth angle (α) of the satellite's orbit geometry, as they define the orientation of the radar signal and the satellite's path relative to the Earth's surface (Figure 3). The incidence angle is the angle between the radar beam and the vertical axis at the point in reference, on the Earth's surface. SAR sensors typically have an incidence angle of 20-45 degrees depending on the satellite's orbit. The track angle is the angle between the satellite's orbital path and the true north. Combining the LOS displacements of ascending and descending orbital geometries (Ulos asc and Ulos desc) the vertical and horizontal components of the displacement vector are extracted

based on the following expression (Fuhrmann, 2019):

$$\begin{pmatrix} U_E \\ U_U \end{pmatrix} = \begin{pmatrix} -sin\theta_{asc}\, cos\alpha_{asc} & cos\theta_{asc} \\ -sin\theta_{desc}\, cos\alpha_{desc} & cos\theta_{desc} \end{pmatrix}^{-1} \begin{pmatrix} U_{asc} \\ U_{desc} \end{pmatrix} \quad (1)$$

Where U_U is vertical component, U_E the east component, Uasc and Udesc are the velocities in LOS direction, and θ and α are the incidence and track angles as descripted above.

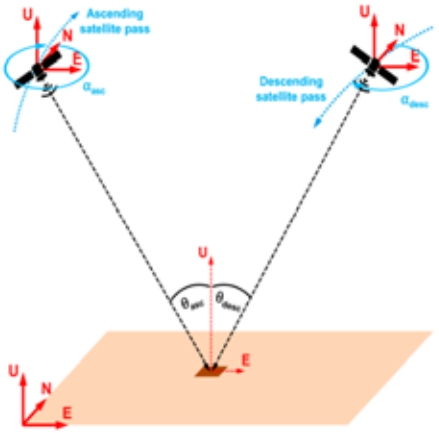

Figure 3:Schematic view of the interferometric aperture radar (InSAR) geometry for line of sight (LOS) measurements on ascending and descending satellite passes (after Fuhrmann T. 2019)

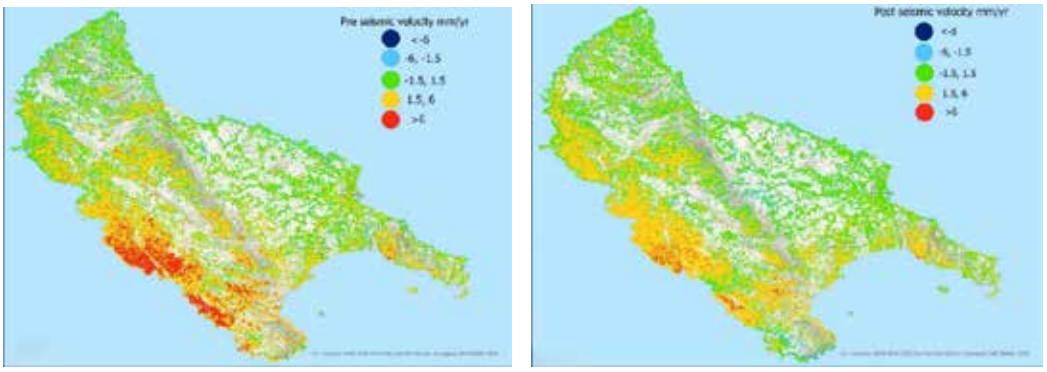
Data processing and analysis

In this study, the data utilized were derived from the European Ground Motion Service (EGMS, https://egms.land.copernicus.eu/). This service provides processed results in LOS direction, called "*Basic Product*". In this study the used results are covering the period 2015-2021 in the Island of Zakynthos. The *Basic Product* provides for each measurement point time series of displacement in the satellite LOS geometry, the estimated LOS velocity and the acceleration value for the whole-time span of the product (in this case 2015-2021). Additionally, the service offers annotated geo-localization and quality measures per measurement point. The dataset is generated from the interferometric analysis of Sentinel-1 radar images and is visualized as a vector map of measurement points color coded, both as *Ascending* and *Descending* data. The ascending measurement points were approximately 600000 and the descending approximately 380000, where each has a mean velocity and acceleration value, estimated on the time-series residuals (measured in mm/yr), and incidence and track angle values (degrees).

To estimate the velocity field before and after the October 25, 2018, a MATLAB code was used to calculate the mean velocity of each data point before and after the main shock occurrence, utilizing the time series of each one. The velocity for each period was realized applying linear least squares fitting process, using the MATLAB curve fitting tool. This toolbox utilizes the least squares method to fit a polynomial to a set of data, through minimizing the sum of the squared residuals between the observed and the predicted values of the line. The final dataset that was used, included approximately 500000 measurement points on ascending and 300000 points in descending orbit.

Data calibration



The raw time series of each measurement point provided from the EGMS dataset were divided to pre- and post-seismic periods, to enable independent analysis of each phase. These categorized data were then absolute calibrated using the velocity vector of a permanent GNSS station on Zakynthos Island (station ZAKY) with well-established ground displacement components for both these periods. Table 1 presents the velocity components of the ZAKY station, for the pre- and post- seismic period. Indicative of the calibration procedure are Figures 4 that present the calibrated velocity maps for the Ascending data set. The GNSS velocity vector was projected on the LOS direction of the two orbital geometries based on the average (due to the relatively small spatial extent of the Island) incidence and track angles for each geometry, using the expression (Hansen 2001).

$$LOS = U_U cos\theta - sin\theta \left[U_N \cos\left(a - \frac{3\pi}{2}\right) + U_E \sin\left(a - \frac{3\pi}{2}\right)\right] \quad (2)$$

Where U_N is the real north component, rest of the annotations are presented above.

Table 1: Velocity components of ZAKY GNSS site and its LOS projection

	Pre-seismic period (mm/yr)	Post-seismic period (mm/yr)
Vup	-0.33	0.03
Veast	12.81	11.51
Vnorth	-2.50	-1.89
Vlos Ascending	-3.45	-2.62
Vlos Descending	-0.13	-0.09

Figures 4: Ascending absolute calibrated pre- seismic (left) and post-seismic (right) velocity maps as calculated in the LOS direction.

The overall image of the crustal velocity field before and after the M_w6.8 event shows a similar pattern but of slightly different amplitudes mainly in the SW part of Zakynthos. The pre-seismic motion on the southwest part of the Island seems more intense compared to the post–seismic one, which shows smaller velocity range. As, as it is revealed by the approximately 70000 more points that have calibrated velocity value above 6mm/yr in the pre-seismic period compared to the post-seismic one.

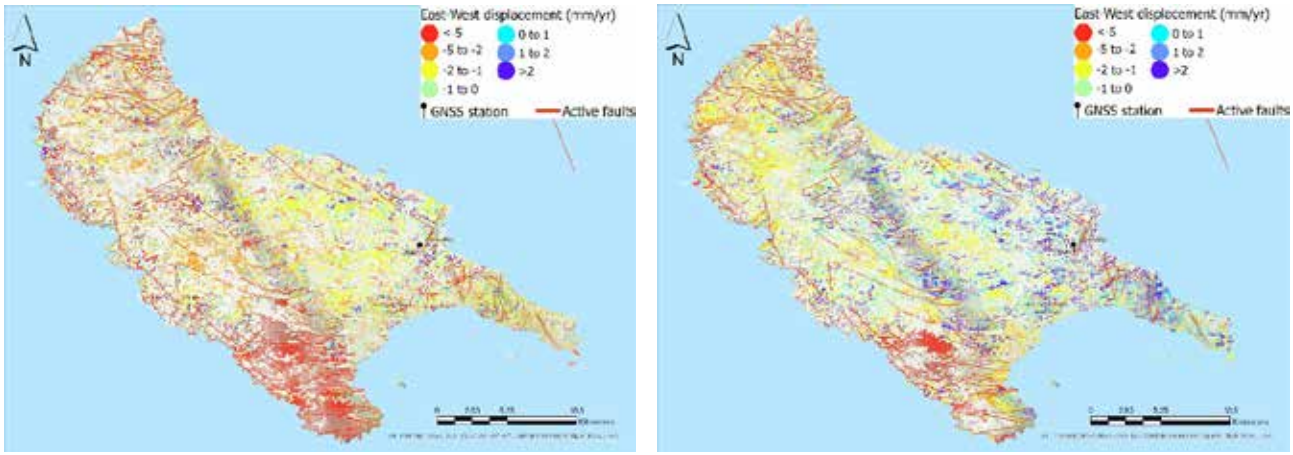
Ortho map generation

The calibrated LOS velocity vector was then decomposed into its east-west and vertical component using the expression (1). Both incidence and track angles were measured in degrees, but in the velocity calculations were converted into radians. The used angles for both acquisition geometries are summarized in Table 2. Since the two acquisition geometries cannot have common data points, additional processing steps were adopted aiming to combine the ascending and descending data sets. As to generate the ortho maps, first a *kriging* interpolation technique was applied, to estimate values at unsampled locations based on the spatial correlation of measurement points, ensuring that the dataset is spatially continuous. This process resulted in a dataset of approximately 68000 points for the ascending and descending dataset individually. Then a *contour* tool was used, to create contour lines that visualize the variations within the dataset, and a *grid to point* conversion tool, to convert the raster data of points (grid cells) into vector point data and create a grid over the area of Zakynthos. Finally using the *extract by mask* tool, with the shoreline of the Island as a mask, the grid was refined as to include only the island and not the broad area that was automatically calculated during previous steps (Esri. *Anatomy of a Tool Reference Page*. ArcGIS Pro Documentation). With the *extract by mask* tool the dataset was reduced to 60000 points per orbital geometry, equally divided for the pre- and post- periods.

Table 2: Summary of the angles that were used in the estimation of the vertical and east-westward velocities.

Orbital geometry	Incidence angle (degrees)	Track angle (degrees)
Ascending	44.88	-9.22
Descending	38.72	190.18

The final east-west and vertical velocity field for the pre- and post- seismic period are presented in Figures 5 and 6, respectively. For the east-west velocity field, positive values indicate eastward motion, while negative values represent westward motion. Both components show similar pattern of ground motion before and after the earthquake,



but of different amplitudes and spatial coverage. The central part of the Island is the area that shows the more intense discrepancies, while in the SW part of Zakynthos the overall surface motion retains its basic characteristics in between the two periods.

Discussion

The east-west displacement maps (Figure 5) reveal distinct patterns of deformation in between the two-time spans. In the pre-seismic period, the western and mostly the southern regions exhibit westward velocities below -5mm/yr, while the central and northern ones show relatively stable conditions, with velocities ranging between -2 to 1mm/yr. After the 2018 earthquake (post-seismic period), the Island shows a slight shift to the east, with more data points assigning velocities above 2mm/yr, this kinematic behaviour is more evident in the eastern and southeastern part. The more significant changes in velocity are shown near fault zones that may indicating possible co-seismic fault-related movements and ground deformation, as well as, across the main geological boundary (in the central part of the island) in between the Paxoi and Ionian units (Figure 1), since there are significant more data points exhibiting velocities over 2mm/yr.

The vertical displacement maps (Figure 6) have noticeable changes across the two periods. Before the earthquake, the southern-most region shows subsidence with velocities even lower than -10mm/yr, while the central-southern part remains relatively stable, without any clear pattern of subsidence or uplift (the velocities range between -2 to 2mm/yr). However, the northern part of the Island reveals an uplifted character, with areas exhibiting vertical velocities up to 10mm/yr. In the post-seismic period, the southern part of Zakynthos does not alter its motional pattern, except that the velocities of several data points are dropping quite a lot below -10mm/yr (up to -18mm/yr). The most considerable changes are observed in the rest of the Island (northern, central and SE part) where the pre-seismic uplift pattern alters to minor subsiding motion (up to -5mm/yr). In comparison to the east-west displacement maps, the vertical ones, also seem to have fault related deformation, with differential motion across them, but not so noticeable in the geological boundary between the two units.

The overall image of the two displacement components (E-W and Up), indicates major changes primarily on the northern and central-eastern part of Zakynthos. The pre seismic period is characterised by mostly stable conditions, with small westward motion and slight uplift. The post-seismic period shows change on the sign in both components. After the M_w6.8 main shock, the geological boundary seems to play a less significant role in terms of vertical displacement, since there is no clear differentiation between the two geological units. In contrast the east-west component shows a more noticeable differentiation, with the motion gaining an eastward character. The vertical component highlights a more distinctive change in between the northern and southern part of the Island, since the northern part is clearly changing its kinematic behaviour, from uplift before the earthquake to subsidence after it. Conclusively, the comparison between the pre- and post-seismic period highlights a kinematic differentiation between the northern and southern part of the Island, which does not coincide with any geological boundary or tectonic feature. This change takes place in a zone that crosscuts the Island (with east-west direction) along the centre of the island (Figure 6, lower part).

Figures 5: Pre- seismic (left) and post-seismic (right) east-west displacement in the island.

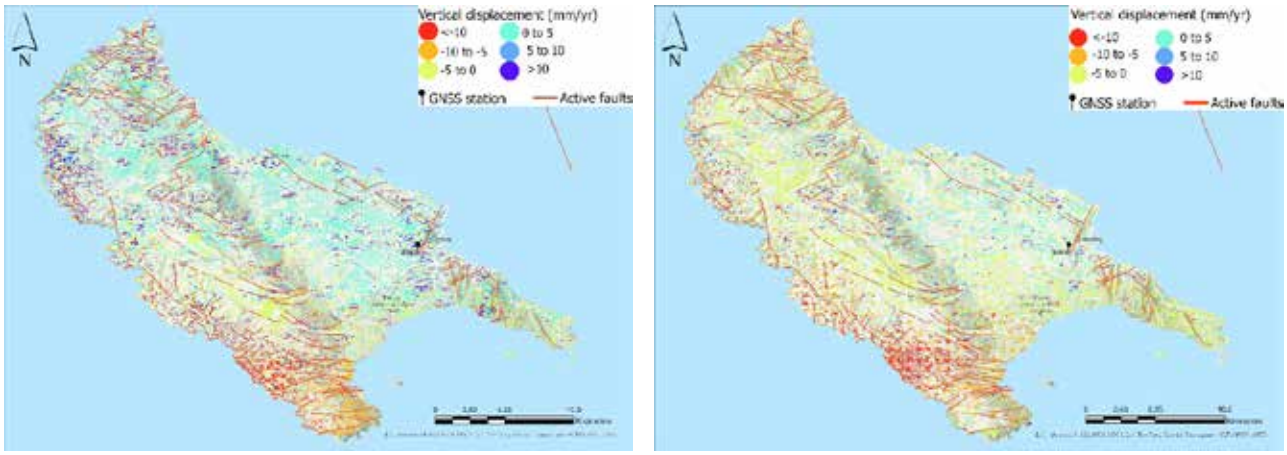


Figure 6: Pre- seismic(left) and post- seismic (right) vertical displacement in the island. The dash line indicates the approximate position of the zone that differentiates the northern and the southern kinematic behavior of Zakynthos.

Acknowledgements

The authors would like to thank Prof. A. Tzanis (Department of Geology and Geoenvironment, NKUA) for his help on the MATLAB codes used in this work. The Seismological data were obtained by the Seismological Laboratory of NKUA.

Research Highlights

- First motion polarities determined using an ML model yielded results comparable with manual measurements.
- Discrepancies were mainly observed at stations in larger epicentral distances or equipped with accelerometers.

Introduction

The large quantities of available seismic waveform data have rendered their manual analysis a challenging task. The unification of seismic networks in Greece (e.g., Evangelidis et al., 2021) has improved the completeness of the routine analysis seismic catalogs. However, as the number of earthquakes is multiplied almost tenfold for every lowering of a magnitude unit, manual analysis can only go so far before the workload becomes prohibiting. Conventional automatic seismic P- and S-wave arrival-time picking methods also have downsides, depending upon the objective function used in each case. Despite providing quick solutions, the measurements of these automatic methods are usually less accurate than those performed by human analysts, and they need to be manually revised for their quality to be improved. However, in recent years, the rise of Machine-Learning (ML) models has revolutionized the automatic processing of seismological data. ML models, such as PhaseNet (Zhu & Beroza, 2019) and EQTransformer (Mousavi et al., 2020), are now used for the automatic analysis of huge datasets, greatly augmenting the number of detected events and lowering the completeness magnitude of seismic catalogs. Even more surprisingly, in terms of accuracy, these ML methods provide results that are on par with manually analyzed data (e.g., Mousavi et al., 2020) and can even recognize P- and S-wave arrivals in noisy signals without filter application (e.g., Zhu & Beroza, 2019).

An even more challenging task is the automatic identification of P-wave First Motion Polarities (FMPs). For earthquakes of moderate or higher magnitude (e.g., M³3.6), the focal mechanisms can usually be determined through moment tensor inversion, by fitting synthetic to the observed waveforms. FMPs, on the other hand, are useful for determining focal mechanisms for weak events (M£3.5), particularly when the network density is adequate near the epicentral area. The distribution of FMPs depends on the radiation pattern of seismic energy at the source. In the double-couple model, FMPs are distributed in four quadrants, characterized by the alternating sign of the first motion recorded at the vertical component of the seismic stations. These first pulses can be impulsive or emergent, depending on the angle of emergence of the seismic ray at the focus, relative to the radiation pattern of the faulting, which defines the focal mechanism; i.e., the strike, dip, and rake of the rupture. Rays originating near the P or T principal axes of the moment tensor are expected to produce impulsive negative or positive first motions, respectively. On the other hand, rays originating near the nodal planes or the null axis are likely to produce emergent first motions, which cannot be easily distinguished (small, nearly zero amplitude). Furthermore, the Signal-to-Noise Ratio (SNR) of weak-magnitude events can be too low for even a P-wave arrival to be picked. The application of filters to lower the noise level and improve SNR can distort the first pulse and lead to an erroneous FMP measurement. Even when a P-wave arrival-time can be roughly assessed, the analyst must decide whether to characterize the polarity of the first motion or skip it to avoid an error. Other measurements that can help constraining the focal mechanisms of weak events include the S-to-P amplitude ratio and the S-wave polarization direction (e.g., Kapetanidis et al., 2015).

As the characterization of the FMP is a pattern recognition task, it has also been the subject of studies employing methods based on artificial intelligence. Such ML models can recognize these patterns and classify the first pulse as being positive or negative, assess whether it is impulsive or emergent, or decide to dismiss a measurement if the polarity cannot be safely determined. Examples of such ML models include those presented by Ross et al. (2018) and Zhao et al. (2023). Both models were trained on a large dataset of seismic waveforms from Southern California, and the authors reported a precision of ~95% or more compared to the respective FMP measurements by human analysts.

Background

The Corinth Rift Laboratory is a dense local seismological network that has been established in the Western Gulf of

Corinth (WGoC; Figure 1) since the early 2000s (Chiaraluce et al., 2022). It is one of the Near-Fault Observatories (NFOs) of the European Plate Observing System (EPOS), complemented by stations of the regional Hellenic Unified Seismic Network (HUSN). WGoC is one of the most seismically active areas in Greece, due to a high extension rate, reaching ~16 mm/yr in a ~N-S direction (Avallone et al., 2004), mainly characterized by E-W-striking normal faulting. Between December 2020 and February 2021, an intense seismic swarm occurred in WGoC (Kaviris et al., 2021; Papadimitriou et al., 2022; Serpetsidaki et al., 2023). The swarm mainly evolved in three phases, each triggered by a significant earthquake: an M_w=4.6 event on 23 December 2020 near Marathias; an M_w=5.0 event on 12 January 2021 near Trizonia Island; and an M_w=5.3 event on 17 February 2021 (Zahradník et al., 2022), north of Psathopyrgos. An examination of the aftermath period up to December 2022, showed that the swarm activity diminished after March 2021, and a background seismicity level was established, with only a few spatiotemporal clusters and two significant earthquakes of M_w=4.2 and M_w=4.3, on 30 November 2021 and 29 July 2022, respectively (Kaltsas et al., 2024). In the framework of the studies of Serpetsidaki et al. (2023) and Kaltsas et al. (2024), a total of 117 focal mechanisms were calculated between December 2020 and December 2022, with 20 from the former study being assessed through moment tensor inversion, while the rest were determined using P-wave first motion polarities. Most focal mechanisms indicate normal faulting, with a smaller proportion of strike-slip or oblique-normal events also being detected.

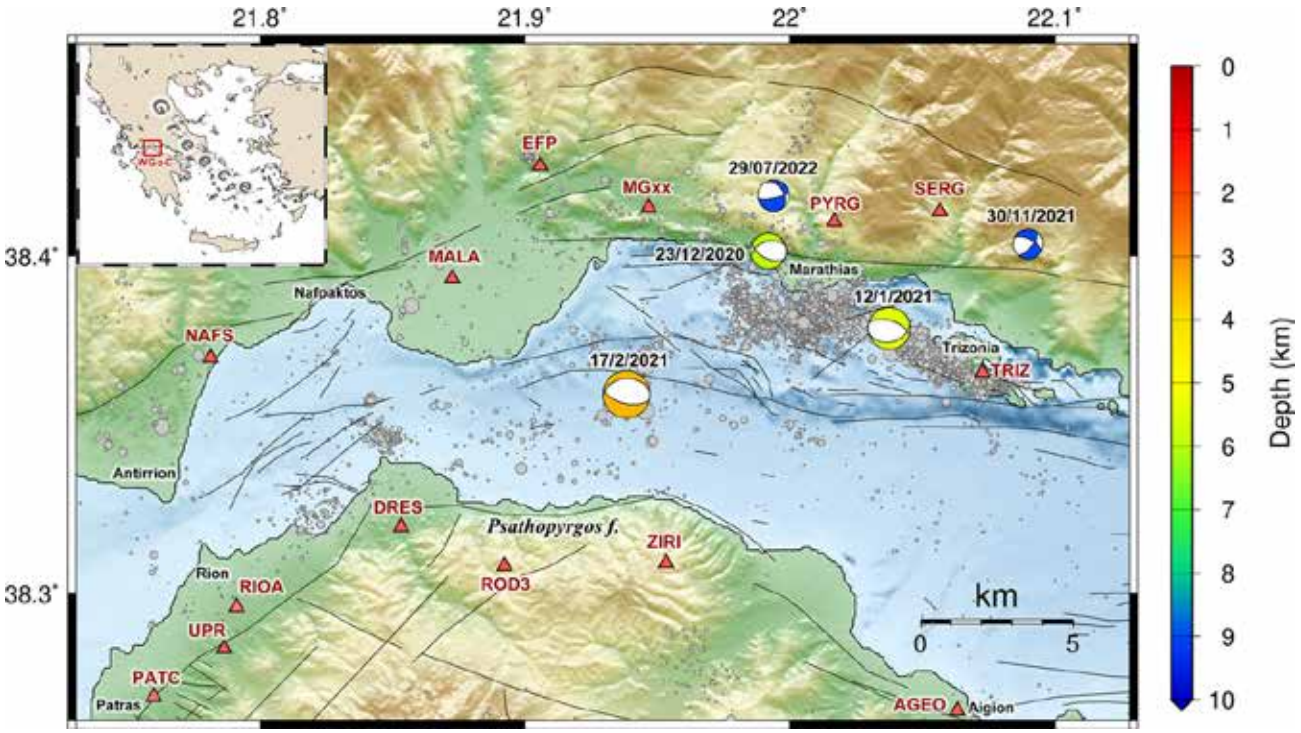

Figure 1. The Western Gulf of Corinth (WGoC) in Central Greece. Seismological and accelerometric stations of the Corinth Rift Laboratory Near-Fault Observatory (CRL-NFO) are depicted as triangles. The focal mechanisms of selected significant (M_w ³ 4.2) earthquakes of the period December 2020 – December 2022 are presented with beachball symbols. The relocated seismicity of the period December 2020 – February 2021 (gray circles) is after Serpetsidaki et al. (2023). The fault lines are from the NOAfaults database (Ganas et al., 2013).

Objectives

In this work, we apply a machine-learning model to identify the FMPs and determine the focal mechanisms of earthquakes that occurred between December 2020 and December 2022 in the western Gulf of Corinth. This will provide a perspective on the efficiency and accuracy of the applied model on the abovementioned dataset, as there are also available manually defined FMPs for a subset of the events that will be processed. The latter will be used to examine the validity of the FMPs, but also to quantify the difference in the resulting focal mechanisms derived from the herein-applied method compared to previous results of manually measured FMPs.

Data and Methods

We use a catalog of ~460 manually analyzed and relocated events from the seismic crisis in WGoC between December 2020 and February 2021 (Serpetsidaki et al., 2023), as well as 82 events from the aftermath period between March

2021 and December 2022 (Kaltsas et al., 2024); the selected events have M³2.0. In both cases, there is a subset of events with available manually measured FMPs and calculated focal mechanisms with a grid-search method, that will be used for comparison. We acquire seismic waveform data from the EIDA nodes of Reseau Sismologique et Geodesique Francais (RESIF; https://seismology.resif.fr/eida/), for stations of the CRL network, and the National Observatory of Athens – Geodynamics Institute (NOA-GI; http://eida.gein.noa.gr/webdc3/), for stations of HUSN.
We employ the DiTing-Motion (DTM) machine-learning model (Zhao et al., 2023) to automatically identify the FMPs at local stations in the area of WGoC. For each station, the waveform recording of the vertical component is detrended, resampled to 100 sps, if necessary (e.g., for accelerometric stations, which are usually at 200 sps), and cropped to a 128-sample window of ±0.64 s around the P-arrival. We follow the workflow established by Zhao et al. (2023), also measuring the S-to-P amplitude ratio (SPR) and employing the HASH code (Hardebeck & Shearer, 2002, 2003) to determine the focal mechanisms using both FMPs and SPR. To assess the influence of the P-wave's arrival-time accuracy on FMP identifications, we also test the procedure after re-picking the P-wave in the vicinity of the previously available arrival-time with Phasenet, pre-trained with data from the INSTANCE dataset (Michelini et al., 2021). We examine DTM results in terms of FMP identification accuracy, compared to manually analyzed events, both automatically and by visually reviewing the automatic FMP characterizations (Figure 2, left). The discrepancies are also examined on a per-station level to identify any systematic issues related to particular stations. For the difference between the newly determined focal mechanisms and the previously available ones from the common subset, we calculate the Kagan angle between the two solutions and also examine the whole image of their beachball projections on the map for visible similarities or differences.

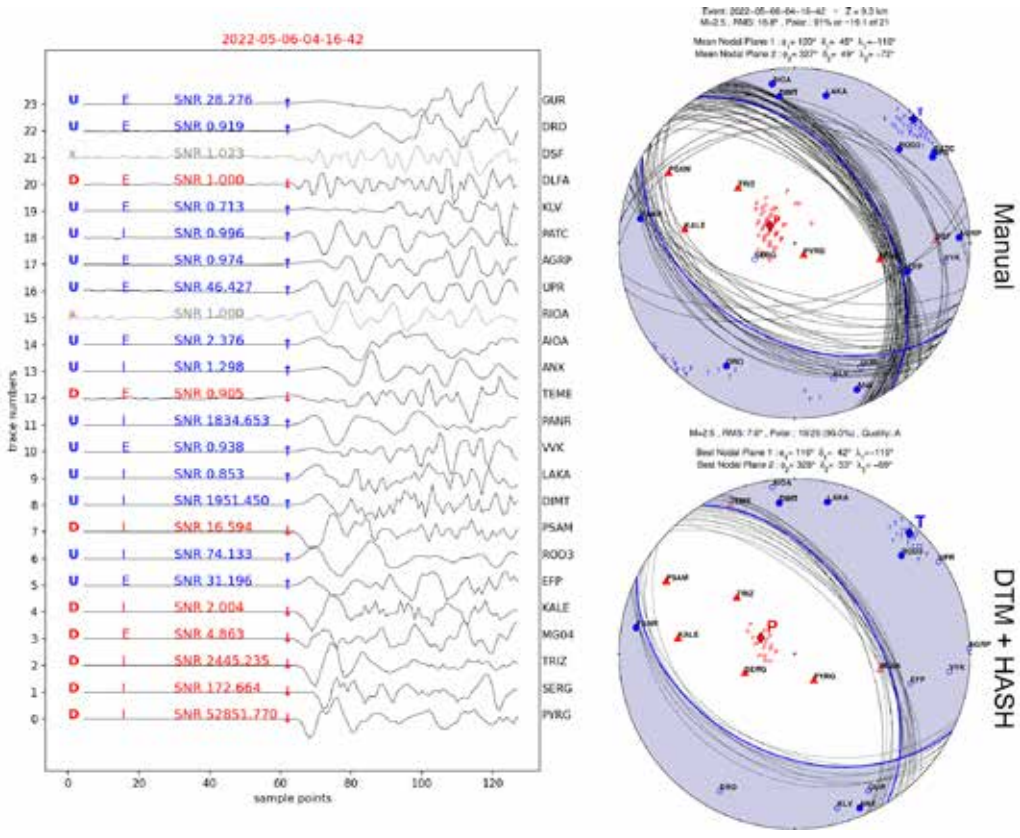

Figure 2. (Left) Example of automatic FMP identifications derived by the DiTing-Motion machine-learning model. The blue letters marked with "U" denote compression whereas the red letters marked with "D" denote dilatation. Gray lines (marked with "x") denote no measurement. "I" and "E" denote impulsive and emergent first motion, respectively. SNR is the Signal-to-Noise Ratio. (Right, Top) focal mechanism derived from manually measured FMPs and a grid-search over fault plane solutions that are consistent with the FMPs. (Right, Bottom) focal mechanism for the same event derived by HASH using the FMPs of the left panel. The RMS value refers to the angular difference between the best solution (bold blue nodal planes) and the valid individual fault planes (thin nodal planes). Blue circles denote compression and red triangles denote dilatation. Small red P and blue T symbols show the distribution of the P- and T-axes projections for valid individual solutions.

Results

The automated workflow yielded 370 focal mechanisms for the 2020-2021 WGoC seismic crisis and 65 for the aftermath period, classified by HASH with a quality grade "A". Figure 3 (left) shows a confusion matrix comparison between characterized polarities by the applied workflow and FMPs identified for the second period by Kaltsas et al. (2024), for 65 common events. The comparison shows that 82-89% of the FMPs were assessed in a similar manner both automatically and manually. Notably, however, 10-13% of FMPs were discarded by DTM. A closer examination revealed that the cases of "missed" FMPs by DTM mostly belong to either stations with accelerometric instruments, or stations at larger epicentral distances (>30 km). With the more distant stations removed from the comparison, the percentages of consistent FMP measurements rise to 87-91% and "missed" FMPs drop to 7-8% (Figure 3, right). Still, ~1% of compressional and 6% dilatational manual FMPs were characterized as being of the opposite polarity by DTM. A more detailed example is presented in Figure 4 for common events of the crisis period, where FMPs are additionally characterized as impulsive or emergent. This is a more subjective matter from the point of view of a human analyst, as an "emergent" characterization may refer to either a "gentle slope" first motion or a low-amplitude first motion, which can also be due to low SNR. DTM results show a larger percentage of agreement for impulsive FMPs than for emergent ones. A larger percentage of manually characterized "emergent" FMPs also tend to be rejected by DTM, which indicates that the classification of the ML model is generally on the more conservative side. An emergent FMP can probably be misjudged as an impulsive FMP of the same polarity, less probably as an emergent FMP of the opposite polarity, and even more rarely as an impulsive FMP of the opposite polarity.

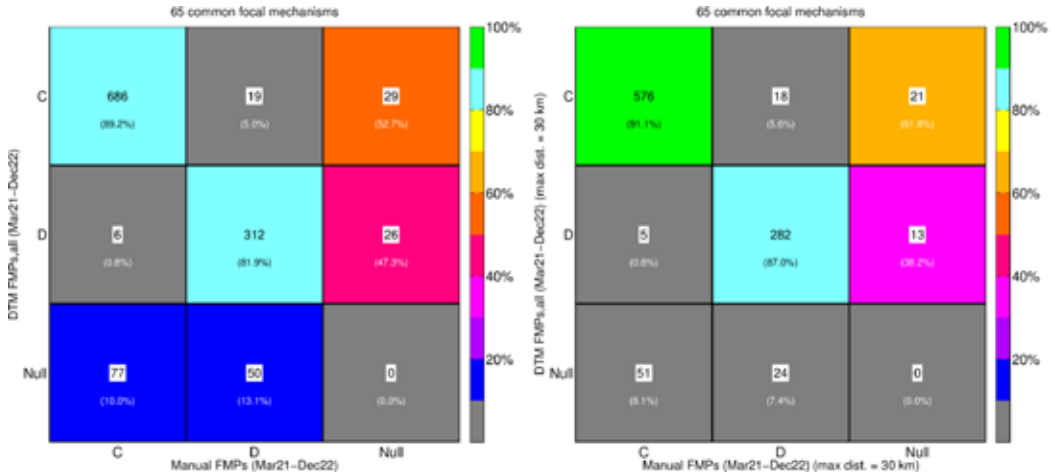

Figure 3. Confusion matrix between FMPs identified with DTM (rows) and manually (columns) for the aftermath period (March 2021 – December 2022). (Left) for all available stations, (Right) only for stations at epicentral distances < 30 km. Letters "C" and "D" denote Compression and Dilatation, respectively. The "Null" row indicates "missed" FMPs, while the "Null" column corresponds to additional automatic FMPs missing from the manual dataset.

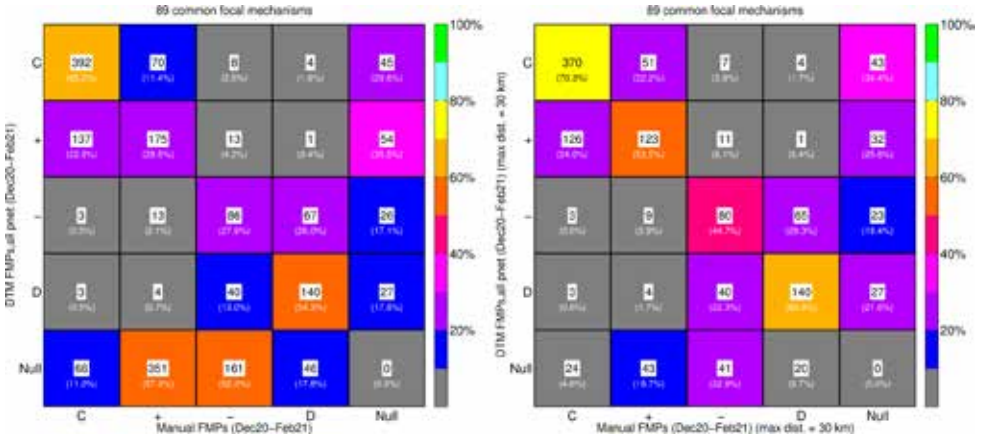

Figure 4. Same as Figure 3, but for the crisis period (December 2020 – February 2021). Symbols "+" and "-" denote emergent, whereas letters "C" and "D" denote impulsive compressional and dilatational FMPs, respectively.

A visual inspection of a subset of identified FMPs alongside the respective P-wave first pulses on the vertical component (e.g., Figure 2, left) confirmed the findings of the confusion matrices, with a generally impressive accuracy of FMP measurement in the majority of instances. There were, however, cases where the polarity of the first motion was seemingly evident to the human eye, but for some reason DTM either dismissed the measurement or misjudged the polarity. As previously noted, null measurements were mostly observed at more distant stations, where the first motion usually has a larger-period pulse than at stations near the epicenter. Erroneous DTM measurements mainly occurred in instances where the P-wave arrival-time pick was not accurate enough, which may be attributed to the applied filter during picking. We tested re-picking on the vertical component with Phasenet, retaining the P-wave pick that was found within ±1 sec of the previously available pick. When the DTM model was re-applied, some results were changed, with new FMPs added, but also with some polarities being reversed and, in some cases, previous FMP measurements being rejected. For the dataset of the 2020-2021 crisis period, the confusion matrix showed an accuracy of 89% and 80% for positive and negative polarities, respectively, taking into account stations at epicentral distances < 30 km and excluding accelerometric stations, after re-picking the P-waves with PhaseNet.

Concerning the focal mechanisms, the similarities between the solutions of the automated workflow with DTM+HASH and those with manually measured FMPs and a grid-search over all fault plane solutions that satisfy a minimum percentage of measured FMPs are quite strong (Figures 5 and 6). HASH was configured to allow for one (1) assumed erroneous FMP for each event. Most of the common solutions with quality grade A, for both the crisis and aftermath periods, exhibit a Kagan angle of less than 30°. Larger deviations can be visibly noticed as a rotation in the focal sphere, mainly affecting the strike-slip component of the focal mechanism. Although the DTM+HASH solutions usually include fewer FMPs than the manual ones, the additional measurement of the S-to-P amplitude ratio likely helps with providing a constrained solution. However, the lack of data from some local stations, particularly for small-magnitude events, can significantly reduce the available FMPs, making the derivation of a quality grade A focal mechanism more difficult. This is especially true during the crisis period (Figure 5), as several local stations experienced technical issues that were later resolved during the aftermath period. Significant differences may also occur as the manual solutions were constrained by the addition of FMP measurements at more distant HUSN stations, where the DTM approach seems to fail to measure the FMP, as also happens sometimes at accelerometric stations due to low SNR. Figure 6 shows a comparison between 57 common solutions of manual and DTM+HASH grade A solutions for the aftermath period, indicating very similar focal mechanisms in both cases, with few notable discrepancies.

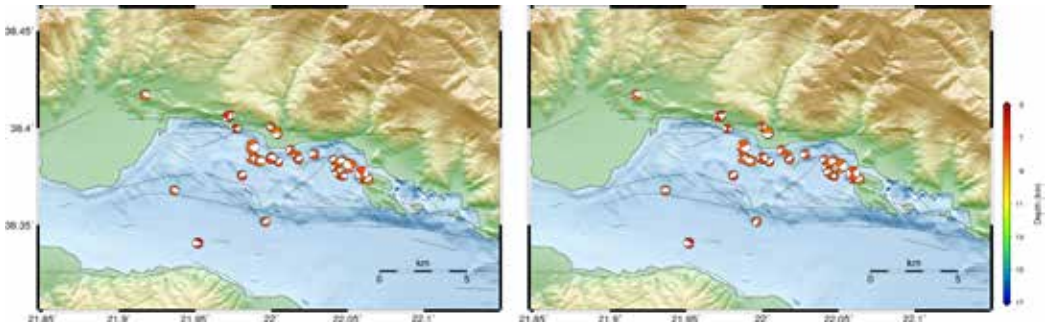

Figure 5. Focal mechanisms of 31 earthquakes during the crisis period, (Left) derived from manually determined FMPs and grid-search over adequate fault plane solutions, (Right) derived with DTM+HASH. The common events presented are those for which the DTM+HASH solutions yielded a quality grade A.

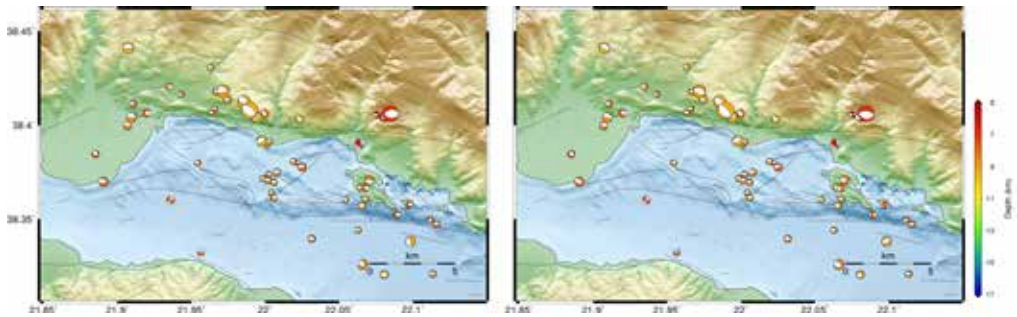

Figure 6. Same as Figure 5, but for the focal mechanisms of 57 common earthquakes during the aftermath period.

Conclusions

In this work, we showcased an application of the DiTing-Motion machine-learning model to fully automate the procedure of first motion polarity measurements in order to determine focal mechanisms of small earthquakes in the Western Gulf of Corinth, Central Greece. As with other methods that employ artificial intelligence, this is a useful tool that can automatically extract a large amount of information that was previously unavailable. We assess the accuracy of the model to identify the polarity of the first motion and examine the cases where it rejects or produces an erroneous measurement. The method requires the availability of accurate P-wave arrival picks at local velocimetric stations for best results. With enough FMP data, even allowing for 1 or 2 erroneous measurements, an accurate focal mechanism can be determined. Despite the abovementioned issues, the results are still remarkable, given that they were produced with a model that was trained with a completely different dataset at a different site. As ML models can be improved by re-training, using site-specific data, this method is promising, regarding the generation of large datasets of focal mechanisms of small earthquakes. The latter could be useful for studies of fault geometries, spatial stress patterns, and even temporal stress changes prior to impending large earthquakes.

EXTENDED ABSTRACT 133

Preliminary results of physicomechanical properties of lightweight mortars using palygorskite as sand replacement

Karachaliou A.T., Vogiatzis D., Kantiranis N.

Dept. of Mineralogy-Petrology-Economic Geology, School of Geology, Aristotle University, Thessaloniki, Greece, akaracha@geo.auth.gr

Introduction

Cements are any kind of solid or liquid fine-grained material that can be used as a binder for aggregates. After mixing with a liquid, which is mainly water, the cements harden and eventually solidify gradually. During this period of time, i.e. the change from harden to solidification, cement acquires its final form but also it develops specific properties (bonding and mechanical strength). Cements are divided either on the basis of their origin, into natural and artificial cements (Mohammed, 1996), or on the basis of the way of solidification and hardening, into air hardening and hydraulic mortars (Legakis, 1954 & Zacharopoulou, 2004).

Mortars are mixtures consisting of one or more cements, aggregates, any other special materials and mainly water and/or other mixing liquids. The strength of the mortars is mainly dependent on the type of aggregates they contain. Before drying they have good plasticity, but also workability, while after setting and hardening they develop high compressive strength, but also physical and chemical properties that depend on the materials they contain. Lightweight mortars are a subcategory of mortars. These are those with an apparent density of a dry powdered mortar of less than or equal to 1500 kg/m^3 (1.5 g/cm^3) according to ELOT EN 1015-10 (2000). They are characterized by low specific weight and high porosity. Depending on the aggregates used to prepare them, they can be fire-resistance or have sound and heat insulation properties. In general, the category of lightweight mortars is one of the many categories of mortar classification based on specific characteristics such as specific weight, application, type of cement, type of aggregate, etc. (Papagianni, 2000 & Vogiatzis, 2009).

According to the Greek Concrete Technology Regulation (2016), aggregates are defined as all those materials of geological or industrial origin, which are used either together with some kind of cement (in order to create mortars, concretes, etc.), or on their own in all kinds of technical works. This includes natural or artificial materials used either in their original form or after crushing, grinding or grading for the production of concrete and other applications. Included raw materials for the production of lime, cement or metallurgical fluxes.

The natural materials used in mortars include, among others, pumice, zeolites, vermiculite, perlite, diatomite, etc., while the artificial materials include fly ash, blast furnace slag, etc. The use of clays, particularly those rich in palygorskite, has not been studied in this particular application as a substitute for conventional sand for the production of lightweight mortars.

Palygorskite is a hydrated magnesium aluminosilicate mineral with the general chemical formula $(Mg,Al)_2Si_4O_{10}(OH)\cdot 4(H_2O)$. It occurs in the form of elongated (vacuum tube type) crystals and a structure that can be characterized as chain type. When dispersed its crystals remain inert and without any expansion. It retains liquids and gives thickening, thixotropic and other properties. It has a highly porous structure which makes it a very absorbent material but also shows resistance to high temperatures and to environments of high salinity and alkalinity.

The aim of this study is to evaluate the ability of a clay rich in palygkorskite from the Ventzia basin of the region of Grevena, Macedonia, Greece, in the preparation of lightweight mortars when used as a partial substitute of sand. A mixture was prepared, and standard samples were used to evaluate specific physicomechanical properties such as specific weight, porosity, uniaxial compressive strength and mineralogical composition of the standard samples of the prepared mixture.

Materials and methods

The materials used in the present work, for the creation of the mixtures, are palygorskite from the company Geohellas SA, commercial quality sand, which comes from the riverbed of the Axios river and Portland cement type CEM II/B-M 42.5 from the company ISOMAT. For the present study, ten 5 cm cubic specimens were prepared according to ASTM C109/109M, in which 50% of the sand was replaced by palygorskite and the specific weight, porosity, uniaxial compressive strength and mineralogical composition were evaluated for hardening period of 3, 7, 28 and 90 days. For the evaluation of the results, standard specimens were used which were prepared in previous work (Vogiatzis, 2009).

The specific weight was obtained as the result of dividing the volume of each cubic specimen by its weight after weighing on a high precision balance and is expressed in units of g/cm^3. This constitutes the most important property for classifying a mortar as lightweight. The porosity was calculated from the formula of Wyllie *et al.* (1956):

$$\frac{1}{Vp} = \frac{\varphi}{Vpf} + \frac{1-\varphi}{Vpm}$$

where the velocity V_p of primary (P) waves, in a material with porosity φ is given by the above relation in which V_{pf} is the velocity of wave travelling through the material with which the pores of the rock are filled, whether this is air (330 m/sec) or water (1,450 m/sec), and V_{pm} is the velocity of the wave travelling through the studied material without pores. The V_{pm} value used for this work is 5,840 m/sec (Berge *et al.,* 1995). A Pundit Lab type ultrasonic device was used to measure the velocity of the primary (P) waves in the studied specimens.
For the evaluation of the uniaxial compressive strength, a hydraulic press was used directly on the prepared specimens. The strength is calculated as the ratio of the value of the applied crushing force to its applied area, with the result given in MPa.
In order to determine the mineralogical composition of the samples both quantitatively and qualitatively, the X-ray diffraction method was used on a powder sample. A Bruker diffractometer (D8 ADVANCE), Cu tube and Ni filter were used to isolate Cu_{Ka} radiation, at operating conditions of 40 kV & 40 mA, for a scanning range of 3-63° 2θ, step 0.02° and a step time of 0.25 sec. The results were qualitatively evaluated using the DIFFRAC.EVA (v7.1) software with PDF4+ (2004) database, while the quantification of the minerals identified was performed using Bruker's DIFFRAC.TOPAS v6 (2018).
All measurements were conducted in the laboratories of the School of Geology of Aristotle University of Thessaloniki.

Results and discussion

Concerning the raw materials, the sand mainly consists of feldspars, quartz and mica, while minor amounts of amphibole chlorite, serpentine and talc were also measured. As for the clay, the mineralogical analysis showed that it consists mainly of palygorskite (90 wt.%) and in minor amounts of serpentine and chlorite. The mineralogical analysis of the cement showed that it consists of hatrurite (33 wt.%), larnite (24 wt.%), anhydrite (12 wt.%), calcite (12 wt.%), dolomite (10 wt.%), gypsum (5 wt.%), brownmillerite (3 wt.%) and quartz (1 wt.%). In figure 1 the X-ray patterns of the raw materials were shown.

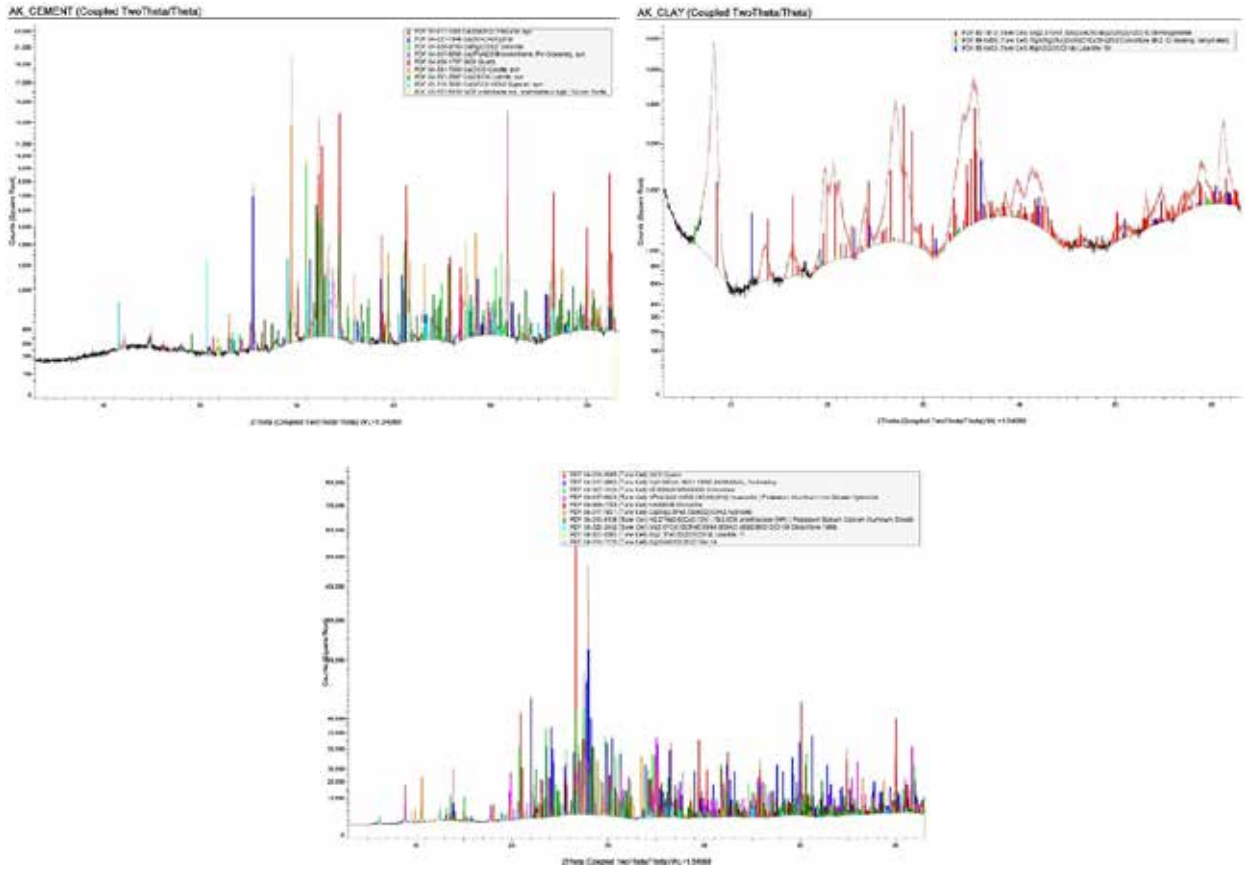

Figure 1. X-ray patterns of the raw materials (cement, clay, sand).

The physical properties of the studied mortar are presented in Table 1. Regarding the specific weight, the studied mortar does not show any change in the first 3 (1.298 g/cm^3) and 7 (1.300 g/cm^3) days, while a significant change in the specific weight occurs on the 28th (1.114 g/cm^3) day, which becomes more obvious on the 90th (0.731 g/cm^3) day. This continuous decrease in specific weight is caused by the porous structure of the palygorskite and the loss of water from

the pores of the specimen throughout its compaction mainly due to hardening reactions and secondly to its contact with the atmosphere. This results in a relatively large and continuous final reduction in the specific weight of the mortar (90 days 0.731 g/cm^3) of 43.7% compared to the initial values (3 days 1.298 g/cm^3).
The velocity of the primary (P) waves (Tab. 1) has a decreasing trend from day 7 to day 90 which is mainly due to the increase in porosity during the same period. At 3 days of hardening the average P-wave velocity was measured 1414 m/sec, which at 90 days was measured at 1068 m/sec, i.e. the P-wave velocity at 90 days decrease to approximately 25% of the 3-day value. Standard cement:sand mortar (conventional mortar) shows at 90 days a P-wave velocity of 3.126 m/sec, while zeolitic mortar (50 wt.% replacement of sand by natural zeolite) specimens showed after 90-day of hardening a P-wave velocity of 2.736 m/sec (Vogiatzis *et al.,* 2008 & Vogiatzis, 2009).
Porosity, which is negatively correlated with P-wave velocity (Wyllie *et al.* 1956), showed an increasing trend throughout the hardening period. In the first week (3 and 7 days) of hardening a relatively similar values of 28.9 and 30.7% v/v, were calculated, while after 28 and 90 days of hardening porosity gradually increases to 35.9 and 38.7% v/v, respectively. This variation in porosity can be attributed to the porous structure of palygorskite, the gradual removal of pore water after day 7 until the end of hardening, but also to the hardening reactions that take place until the 90th day.

Table 1. Measurements of the physical properties of the mortar under testing.

Sample	Consolidation days	Specific weight, S.W. (g/cm^3)	Average value of S.W.	Vpx (m/sec)	Vpz (m/sec)	Vpy (m/sec)	Average Vp (m/sec)	Porosity (% v/v)
K3.1	3	1.390	1.298	1450	1405	1400	1414	30.7
K3.2		1.207		1398	1444	1387		
K7.1	7	1.364	1.300	1526	1522	1509	1525	28.9
K7.2		1.236		1408	1594	1589		
K28.1	28	1.114	1.114	1184	1143	1108	1172	35.9
K28.2		1.086		1126	1169	1154		
K28.3		1.125		1234	1235	1194		
K90.1	90	0.731	0.731	1026	1042	1065	1068	38.7
K90.2		0.686		1141	1188	1225		
K90.3		0.778		1044	958	923		

Uniaxial compression tests showed low strength values, varying from 1.6 MPa at 3 days to 1.0 MPa at 90 days of hardening. The uniaxial compressive strength values show an inversely proportional variation with P-wave velocity and porosity (Fig. 2), a behavior that is attributed to the increase of empty spaces in the specimens from the studied mortar which cause their break by applying a smaller force on the same specimen surface (Kantiranis *et al.,* 2000 & Kantiranis, 2001, Vogiatzis *et al.,* 2008).

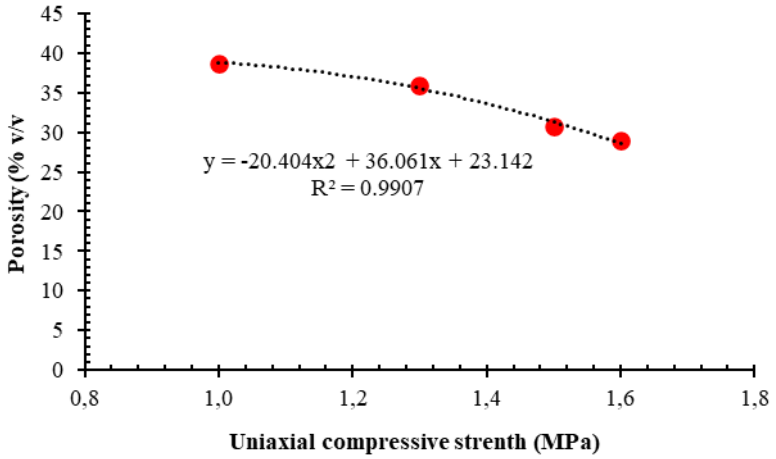

Figure 2. Variation of uniaxial compressive strength (MPa) with porosity (% v/v).

Mineralogical analysis of the studied mortar sample (Fig. 3) showed that the quantities of the mineral constituents (quartz, feldspar, mica, amphibolite, olivine, dolomite, calcite, chlorite, serpentine and palygorskite) of the original materials remain stable compared to the 90 days of compaction, with some variations in the relative variation of these phases on the intermediate days of compaction (3, 7 and 28 days). As for the cement phases, brownmillerite, tobermorite and larnite

show stable values with relatively low percentages, while hatrurite shows an increase of 14% between day 3 and day 28. Finally, portlandite remains stable for the first 28 days, then gradually decreases, reaching a very low rate (0.5% w/w) on day 90. The findings of the present study are similar to previous studies, e.g. Vogiatzis *et al.* (2012).

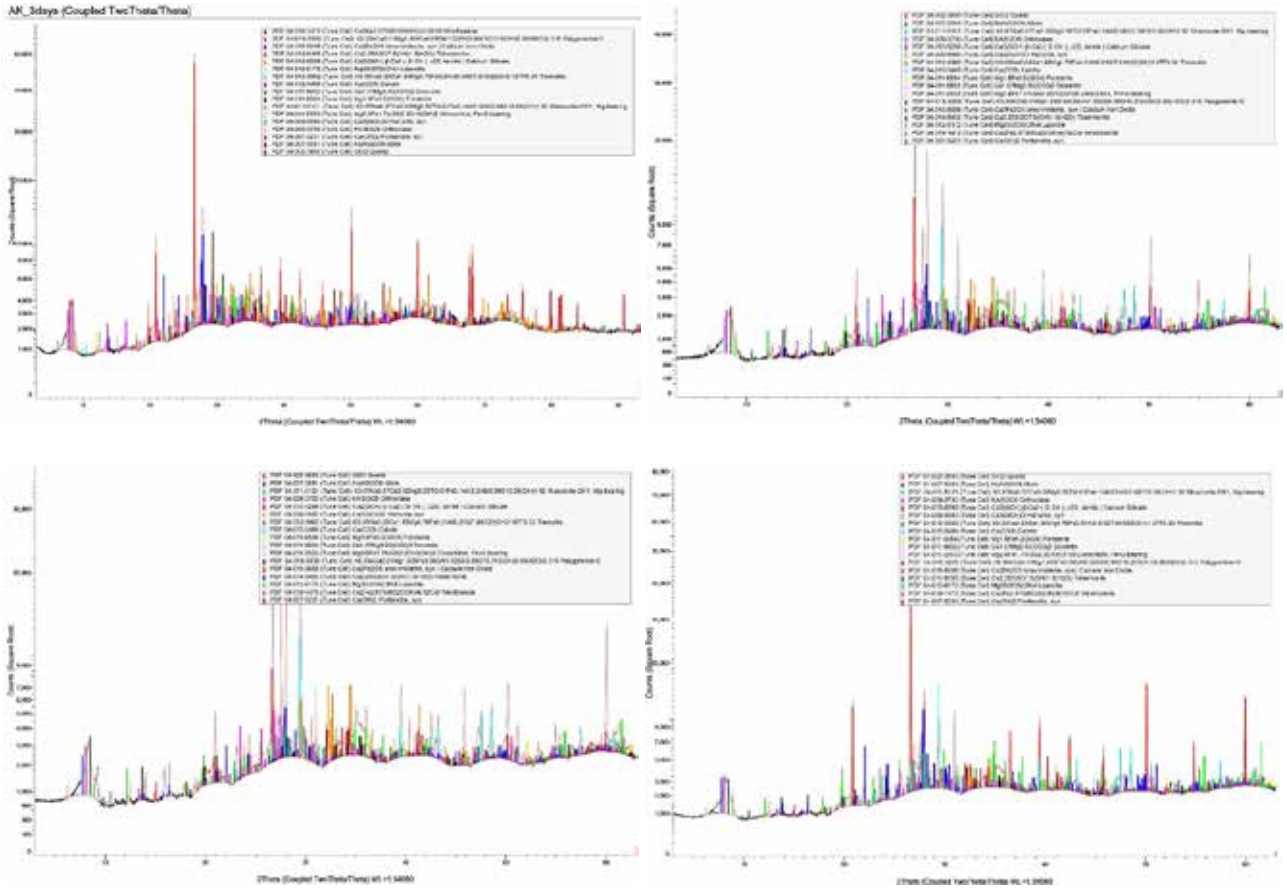

Figure 3. X-ray patterns of the studied mortar at 3, 7, 28 and 90 days of hardening.

It is worth mentioning that the use of clay minerals in mortars, more specifically that of palygorskite, can provide useful properties to the final products, which are the higher porosity and lower specific weight compared to conventional mortars or mortars using natural zeolites. Specifically, Table 2 presents the physical and mechanical properties of three different mortars: the conventional mortar (sand-cement-water) according to ASTM C109-109M (2002), the mortar with 50% wt. replacement of sand by natural zeolite and the mortar with 50% wt. replacement of sand by palygorskite clay. From the evaluation of the data in Tab. 2 it is clear that the use of palygorskite clay produces a much lighter mortar compared to both other mixes. It is observed a decrease in specific weight and an increase in porosity due to the unique microstructure (vacuum tube type) of palygorskite, which decisively affects the development of the final characteristics of the studied mortar. This variation is also observed in the mortar with natural zeolite content, which although not very pronounced, is attributed to the macro, micro & nano pores of zeolitic rock and the contained zeolite (clinoptilolite), respectively. In addition, the cementation and hardening reactions of the mortars play an important role in the change in specific weight and porosity, with zeolitic water having a significant influence on the progression and completion of these reactions (Vogiatzis, 2009).

Table 2. Comparative results of the physical and mechanical properties of mortars with different aggregates.

Samples	Specific weight (g/cm^3)	Porosity (% v/v)	Uniaxial strength (MPa)
Cement:Sand (conventional mortar)	1.869	19.0	14.6
Cement:1/2Sand:1/2 Natural zeolite	1.657	25.0	9.0
Cement:1/2 Sand:1/2 Palygorskite clay	0.731	38.7	1.0

Regarding the uniaxial compressive strength of these three mortars, the use of sand as the only aggregate (conventional mortar) produces the mortar with the highest strength values compared to mortars with natural zeolite rich in clinoptilolite and clay rich in palygorskite, since both these components, with their porous structure, give the mortars a higher porosity and therefore lead to lower uniaxial compressive strength. In comparison between mortars with clinoptilolite and those with palygorskite, the use of natural zeolite leads to higher uniaxial compressive strength values. According to ELOT EN 998-2 (2003), the mortar with palygorskite is classified as M1 (class with minimum compressive strength of 1 MPa), while that with natural zeolite is classified in M5 (class with minimum compressive strength of 5 MPa).

The specific weight was measured at lower values both in the mortar with palygorskite and in the one with natural zeolite, compared to the conventional mortar. Between them the mortars with sand replacement show a relatively large difference in specific weight, with palygorskite clay providing the mortar with values up to 50% lower than those of the mortar with natural zeolite. According to ELOT EN 1015-10 (2009), the specific weight value of palygorskite mortar meets the criteria for lightweight mortars.

Therefore, the addition of palygorskite clay can provide mortars with properties that classify them as lightweight, thus allowing their application in special uses, such as for thermal insulation, sound insulation, etc.

Conclusions

In the present study, the preparation and properties of lightweight mortars were studied through the partial replacement of sand, which is a basic aggregate component of conventional mortars, by palygorskite-rich clay, which is a natural clay material. The materials used include CEM II/B-M 42.5 type cement of the company ISOMAT, commercial sand from the Axios riverbed and palygorskite clay of GEOELLAS S.A. The mixing ratios of cement:aggregates:water were 1:2.75:0.485, with the aggregates consisting equally of sand and palygorskite clay. The aim of this study was to produce a mortar of lower specific weight than conventional mortars, which would be classified as a lightweight mortar, using palygorskite clay as a natural substitute for sand.

The specific weight showed a 43.7% reduction at 90 days, with values varying from 1.298 (3 days) to 0.731 g/cm³ (90 days), with the 90-day value being within the specifications for lightweight mortars. The porosity increased gradually during hardening, mainly due to the removal of pore water from the mixture, but also due to the mirco-structure of the palygorskite. Primary waves (P-waves) velocity showed a 25% decrease from 3 to 90 days of hardening, with mean values decreasing from 1.414 m/sec at 3 days to 1.068 m/sec at 90 days. This decrease is attributed to an increase in porosity, as the velocity of P-waves is inversely proportional to the porosity of a material. Consequently, the uniaxial compressive strength decreased, classifying the studied mortar in class M1 (minimum compressive strength of 1 MPa). Mineralogical analyses of the cement phases showed significant changes. Brownmillerite showed similar values in the first few (3 and 7) days of hardening, with a gradual increase thereafter due to its slow reaction with water. Hatrurite showed a strong increase in the first 28 days of hardening, with a decrease thereafter, as it reacts rapidly with water, contributing to the early increase in the strength of the mortal. Larnite decreased at 90 days of hardening, while tobermorite and portlandite showed constant values or a slight increase at the beginning, followed by a decrease at the end of hardening due to their involvement in hydration reactions. The use of palygorskite clay as a natural aggregate resulted in the production of mortar with low specific weight (0.73 g/cm³) and high porosity (38.7% v/v) at 90 days of hardening, fulfilling the criteria for lightweight mortars. The studied mortar, with 50% substitution of palygorskite clay for sand, was prepared without chemical or other treatment and based on its characteristics it is a lightweight mortar of low specific weight and high porosity.

Finally, further research on mixtures with different percentages of sand replacement by palygorskite-rich clay could lead to a complete evaluation of the specific properties and the identification of the optimal mixture for specific applications, especially in the field of thermal and acoustic insulation, making these mortars a promising material for construction applications.

Introduction

The seismic hazard analysis aims to minimize the damage by determining local site conditions and peak ground acceleration before an earthquake as much as possible. Engineering geophysical methods are one of the fast and economical ways to determine the strength of the soil that will carry engineering structures, the thickness of the layers, water content, behavior under dynamic load, etc. The surface wave analyses allow to S-wave velocity model of the soil layers from the shallow surface to the engineering/seismic bedrock at a site.

In the last 25 years, seismic hazard studies have become important for seismological and earthquake engineering applications in the world. Turkey is one of the countries that have suffered from destructive earthquakes, especially since the 1999 Kocaeli earthquake. The latest 6 February 2023 Kahramanmaraş earthquakes, defined as catastrophe earthquakes, show that we have not made enough progress in reducing earthquake risk since 1999.

Western Türkiye covers rapidly growing areas and encompasses the main financial and industrial centers, especially Istanbul, which is one of the most populated cities in the world, and the other cities in the Marmara Region, such as Tekirdag, Çanakkale, and Balıkesir are the part of the Marmara Supersite that are a high priority to the geohazard community (Figure 1). Additionally, Izmir, the third biggest city, is also located in western Türkiye and affected by earthquakes.

Historical records show that destructive earthquakes frequently visit the region. In the last century, the 9 August 1912 Mürefte (Mw 7.3) earthquake hit the western part while the 17 August 1999 Kocaeli (Mw 7.4) earthquake destroyed the eastern part of the Marmara Region. The Gokceada earthquake (24 May 2014, Mw 6.9) also affected the west of the region. The last destructive earthquake occurred on 30 October 2020, in the north of Samos Island. Even the Bornova Basin, where the city of İzmir is mainly settled, is 70 km away from the earthquake epicenter, significant damage occurred in the city center because of the tick sediment basin. The number of collapsed, heavily damaged and moderately damaged buildings in İzmir is 54, 676 and 789, respectively. A total of 7,683 buildings were labeled as slightly damaged. Totally 117 people died during the mainshock.

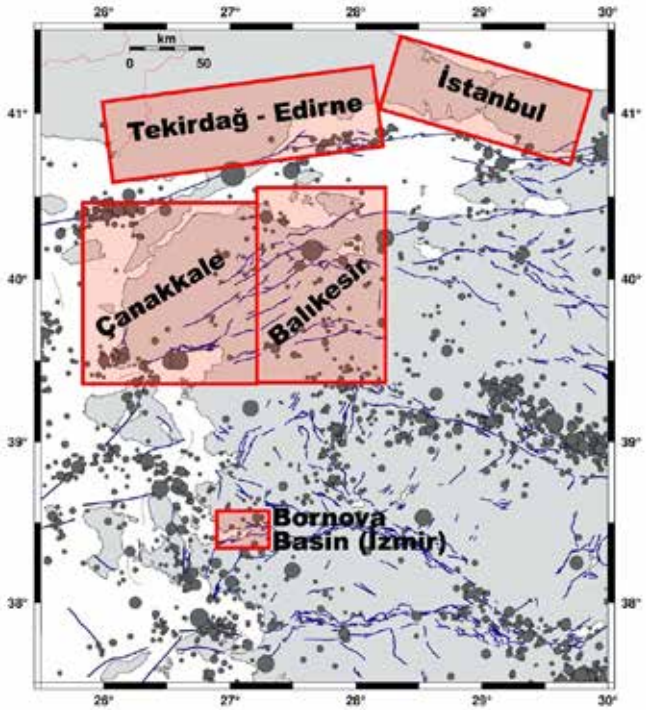

Figure 1. Microtremor study areas in the western Türkiye.

One of the important points for local seismic hazard studies is to define 1D S-wave velocity (Vs) structures from the surface to the seismic or engineering bedrock. This is necessary to know site responses to estimate the ground motion impact on the buildings. The local geology significantly modifies ground motion characteristics and controls the irregular distribution of damage during large earthquakes. Therefore, shallow low-velocity layers are responsible for the variation of earthquake ground motion amplification at a site. Heterogeneity of the soil structures, velocity impedance differences between layers, resonant effects, irregular topography of the layers beneath a basin, the effect of the surface topography, nonlinear soil behavior, fault geometry and lateral variation of Vs causes variation of earthquake ground motion amplifications. It is important to estimate the Vs structure in near-surface layers for estimating strong motion characteristics during an earthquake. Furthermore, investigating the amplification of shallow soil structures is essential as accurately as possible to close the real ones. It is the first step to reduce casualties and collapse buildings before an earthquake for damage assessment. The amplitude, frequency content, and duration of strong ground motions are generally controlled by the local soil structures and have the main role for building damage during an earthquake.

To reduce the earthquake local site effect, a 1D soil profile can be obtained by different geophysical methods, using earthquake data or ambient noise recording to retrieve the vertical soil structure as well as borehole logging. The 1D assumption of the soil structure is widely accepted and easy to implement. Array explorations of microtremors (i.e. SPAC) and MASW methods have been gaining much popularity in the world to obtain 1D Vs profiles. Because they are one of the economic methods and easily applicable for the estimation of Vs structure by a simple circular array with a few seismometers (Figure 2). The Rayleigh waves are considered when vertical sensors are used for microtremor records. Surface wave phase velocity dispersion curves from microtremor records can be utilized to investigate 1D S-wave velocity structures for shallow soil structures.

In this study, the results of array microtremor studies in western Türkiye are presented. The data are collected by the international and national projects from October 2013 to August 2024. The projects were focused on different methods and practices for disaster mitigation for western Türkiye. One of the main research fields of the projects is the determination of the deep and shallow velocity structure for “seismic characterization and damage prediction” that aims to improve the prediction accuracy of estimating the damages induced by strong ground motions.

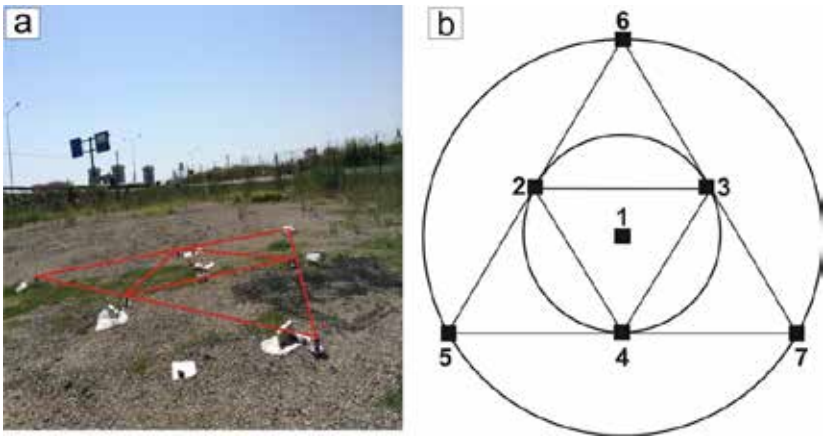

Figure 2. Photo from field measurement in Tekirdag city center (a) and diagram (b) of microtremor array configuration. Numbers show sensor location.

Results and Conclusions

1D Vs structures of shallow sedimentary layers down to the engineering bedrock were explored by applying short-period microtremor Spatial Autocorrelation (SPAC) array measurements (Aki, 1957; Okada, 2003) on the different geological units in Istanbul (Zeytinburnu), Tekirdağ, Edirne, Çanakkale, Balıkesir and İzmir in western Türkiye (Figure 1, 2).

The microtremor array data was gathered with temporarily installed seismic sensors, which were set by using the small and large array circles measurements (Figure 2). Phase velocities of Rayleigh waves were estimated from vertical components of microtremors using the SPAC method proposed by Okada (2003). The SPAC method computes cross-correlations between station pairs in the array with the SPAC coefficients for the calculation of phase velocity at different frequencies. Each vertical-component record was divided into 81.92 s time segments. Then, the transient and artificial noises generated by local conditions, such as pedestrians and cars near the sensors during the measurements, were removed. The Parzen window with a bandwidth of 0.2 Hz was chosen for smoothing in the data processing. We used the 6-14 segments (average 10) for averaging to get the phase velocity at each frequency (Karagoz et al., 2015).

The observed phase velocities were used for the estimation of 1D S-wave velocity structure profiles using the hybrid heuristic

method (Yamanaka 2007) as an inversion method to find an optimal S-wave velocity model. This method searches a 1D soil profile by minimizing the misfit function that is defined as a sum of squared differences between the observed and calculated phase velocities. The method used for theoretical dispersion curves of the fundamental mode of Rayleigh waves is based on Haskell (1953). We assumed a horizontally layered, isotropic and homogenous model. The layer model is characterized by four parameters; thickness (h), density (ρ), P-wave velocity (Vp) and S-wave velocity (Vs) for each layer. Thicknesses and shear-wave velocities are the unknown parameters in the inversion. The density was assumed to increase with increasing S-wave velocity. P-wave velocity is not inverted but derived from S-wave velocity by using the empirical relation by Kitsunezaki et al. (1990), defined as

$$Vp = 1.29+1.11*Vs$$

where the units of Vp and Vs are expressed in km/s (Karagoz et al., 2015).

The observed Rayleigh wave phase velocities from field studies were between ~200 and 1000 m/s, ~90 and 930 m/s, ~120 and 850 m/s, ~200 and 1000 m/s in a frequency range from 2 to 30 Hz, respectively, for Zeytinburnu, Tekirdag, Çanakkale and İzmir, respectively. Most of the sites in Tekirdag had predominant frequencies higher than 2 Hz., 0.5 Hz for Zeytinburnu, 0.8 Hz Çanakale, and 0.5 Hz for Izmir (Figure 3). The high amplifications at low frequencies are related to the thick sedimentary layers beneath the cities. Therefore, the reality of the seismic risk of the cities where close to the potential seismic sources (faults) and are on sedimentary basins must be considered for a sustainable future.

EXTENDED ABSTRACT 135

The 2025 seismicity burst in the Santorini – Amorgos seismovolcanic zone

Karakostas, V.[1], Lomax, A.[2], Anagnostou, V.[1], Papadimitriou, E.[1], Acocella, V.[3], Hicks, S.[4], Henry, P.[5]

Introduction

In January 2025, an intense earthquake activity started in the Santorini volcano area, southern Aegean, causing great concern among the local population and resulting in actions such as school closures and spontaneous evacuation. Seismic activity and geodetic motion increased inside the Santorini caldera in the last second half of 2024, intensifying in mid–January 2025 and extending offshore to the northeast around the Anydros islet between Santorini and Amorgos islands. This activity was remarkably dense, with turbulent variations over space and time (Figure 1). Up to 13 March 2025 over 4000 earthquakes exceeding *M*1.0 occurred and analyzed.

Santorini is an active stratovolcano in the volcanic arc of the Hellenic subduction zone, with several smaller craters in addition to a main caldera, which collapsed around 1625 BC (known as Minoan eruption). Volcanic centers (volcanoes, fumaroles or solfatara fields), epicenters of strong shallow earthquakes (with focal depths up to 20 km) and epicenters of intermediate depth strong earthquakes (with focal depths between 120 and 160 km) in the southern Aegean volcanic arc can be grouped into five well defined, linear clusters trending about N60°E, corresponding to five extensional zones (Papazachos and Panagiotopoulos, 1993).

Regional seismicity is mostly low-rate crustal activity. However, the largest instrumental earthquake in Greece during the 20th century is an *Mw*7.7 rupture in 1956 (Pacheco and Sykes, 1992), just south of Amorgos Island, caused extensive destruction in the southern Aegean. The earthquake ruptured an ENE–striking normal fault that lies parallel to the southern coastline of Amorgos (Papadimitriou et al., 2005). The area of the 2025 swarm coincides with the rupture area of the *M*6.9 main shock, that occurred 13 minutes after the first 1956 M_w7.7 main shock.

Relocated microseismicity recorded by a temporary network deployed in 2003 to investigate microseismicity of the Santorini volcanic center, revealed two clusters. The main cluster was located at the Columbo Reef, which is the top of a submarine volcano, whereas a smaller cluster was located near the Anydros islet, without seismicity inside Santorini caldera, both clusters were aligned in a NE–SW direction (Dimitriadis et al., 2009). During February 2011 an intense microseismicity was initiated within the caldera and lasted until March 2012. In addition to increased seismicity, the volcano showed significant ground uplift, reaching 14 cm within this period (Foumelis et al., 2013). Manual analysis and relocation provided high-resolution image of the activated fault segments (Papadimitriou et al., 2015). The NE–SW activity inside the caldera, with dextral strike slip motion, was rapidly diminished after the activation of an offshore area to its southwest. Normal faulting activity expanded to the northeast offshore area, near Anydros, where the 2025 swarm is manifested. Since 2012, the activity inside the caldera was low and with relative quiescent periods, whereas near Columbo it has been more frequent and continuous (Karakostas and Papadimitriou, 2025).

High–precision earthquake locations

We used the NLL algorithm (Lomax et al., 2000, 2014) and the multiscale high precision NLL–SSST–coherence procedure (Lomax and Savvaidis, 2022) to relocate a manually picked set of earthquakes with data taken from the bulletins from the Geophysics Department of Aristotle University of Thessaloniki (doi:10.7914/SN/HT) and National Observatory of Athens (doi:10.7914/SN/HL) and a set of picks obtained with machine learning (ML). For the relocation of the manually picked earthquakes the recordings of 31 seismic stations were used. Fourteen of them were in operation on Santorini Island since the beginning of our study (January 2024). Seven stations were installed or started their operation after long interruption in February 2025 [Anydros (Feb. 03), Anafi and Amorgos (Feb. 04), Gavrilos (Feb. 07), Astypalaia (Feb. 10), Ios (Feb. 12), Christiana (Feb. 26)]. For the ML picking we analysed waveform data during 1 January–28 February 2025, from 21 broadband stations located in distances up 120 km from the seismicity centroid (https://eida.gein.noa.gr/). The earthquake detection and phase picking were performed by Phasenet (Zhu and Beroza, 2018), a deep–neural–network–based arrival-time picker. Phase picks are then associated using the REAL software (Zhang et al., 2019). REAL is a grid–search phase association algorithm that performs phase association and an initial location of earthquakes, primarily through counting the number of P

and S picks that appear within a travel–time curve threshold determined by the user and secondarily from travel time residuals (Zhang et al., 2019).

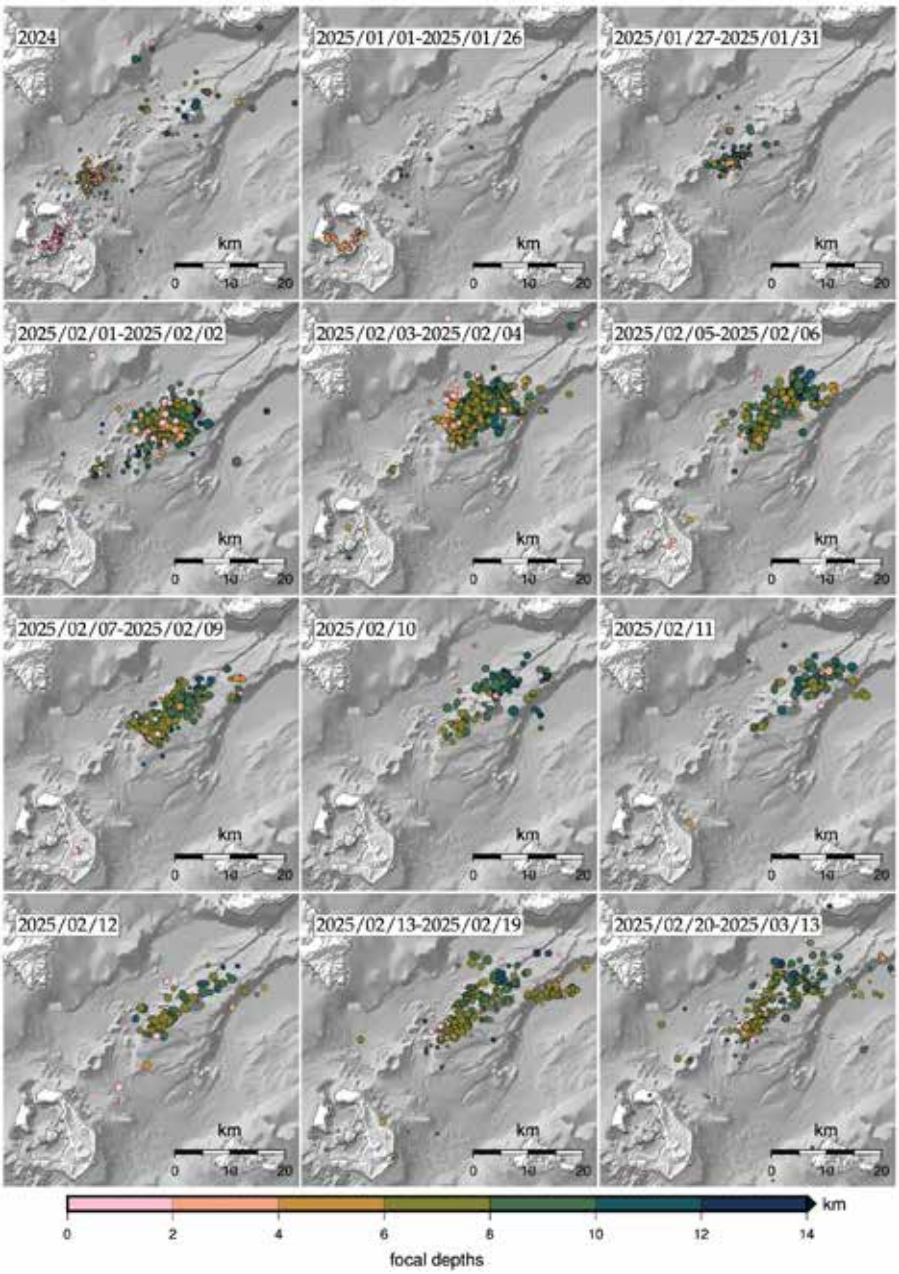

Figure 1. Seismicity evolution in map views for consecutive time windows as indicated inside each snapshot. The size of the symbols is proportional to the earthquake magnitude.

Relocated manually picked seismicity is shown in the maps of Figure 1, covering consecutive time intervals. Background seismicity during 2024 exhibits quite shallow clustering inside Santorini caldera (pink symbols), more dense clustering around the Columbo reef (offshore area NE of Santorini Island) with seismicity up to ~10 km deep, and a third cluster, along with sparse activity, to the northeast and around Anydros islet with focal depths in the brittle crust (5–15 km, inside the seismogenic layer of the back–arc Aegean area, Hatzfeld et al., 1999; among others) with the majority of them getting focal depths between 6–12 km.
With the Machine Learning detection and picking we obtained a catalog with 34442 earthquakes. We relocated the detected seismicity using the same procedure as the manually picked catalogue (Figure 2).

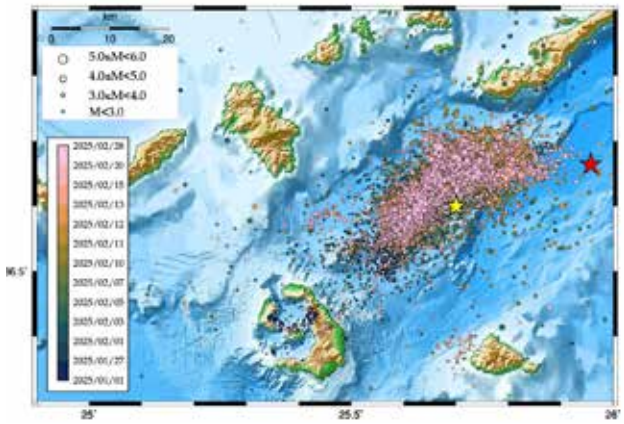

Figure 2. Relocated seismicity during 01/01/2025–28/02/2025 using machine learning detection and NLL–coherence location. The red and yellow stars depict the epicenters of the 1956 M7.7 and M6.9 main shocks, respectively (Bondar et al., 2015; ISC, 2024).

Discussion

Seismic activity intensified during the first weeks of 2025 (1–26 January), including mainly small magnitude seismic activity within the caldera at shallow depths. The main activity abruptly jumped to the northeast offshore area during 27–31 January. Beginning on 1 and up to 4 February, an unusually high number of moderate magnitude earthquakes occurred, the most intense ever reported during the instrumental era anywhere in Greece, with three earthquakes of M≥5.0 and eighty with M≥4.0. The activity formed a ~20 km–long NE–SW trend, in accordance with the strike of the 1956 second main shock (M6.9).

The epicentral area of the 2025 swarm was strictly confined within the Anydros basin, which is bounded on both sides by NE–SW striking normal faults. It appears that further migration of the activity along the Amorgos fault zone almost ceased. The shallower focal depths occupy the southwestern part of the seismicity zone, where NE–SW trending small volcanic cones are also located. Over the next two days (on 5 and 6 February) the main seismicity to the northeast became slightly more compact, with 47 (forty–seven) M4+ earthquakes, and around 10 km depth, whereas activity near Columbo decreased. Between 7 and 9 February, 39 (thirty–nine) M4+ earthquakes were concentrated in an even more localized area, but sparser seismicity extends as far as 40 km NE of Santorini. Two additional M5+ earthquakes struck on 10 and 12 February, with the M4+ occurrence rate appearing to decline. The main concentration of activity from 10–11 February migrated and jumped to over 10 km NE of Anydros Island, before rapidly returning back to the SW of Anydros by 12 February. During these last days, when the M4+ activity was more constrained we could distinguish multiple small structures within the fault network that hosts the seismicity burst.

By 13 February, seismic activity had dramatically decreased, to only a few M4+ earthquakes per day, and the last recorded M5+ earthquake on 17 February. From 13 February and through at least 13 March (Figure 1), small clusters took place to the north and eastern edges of the activated area.

Coulomb seismicity–stress imaging of the swarm

The 3D, scalar ΔCFS field due to finite–fault slip or dike opening can be obtained through integration over the fault or dike of the point–source ΔCFS field of stresses due to a point shear dislocation or tensile opening in an elastic half–space (Haskell 1964; Kikuchi & Kanamori 1982; Okada 1992; King et al. 1994; Materna & Wong 2023). This procedure is a forward calculation, with the resulting ΔCFS field often assessed by how well it agrees with the surrounding distribution of seismicity. The corresponding inverse problem is to infer a distribution of finite–fault slip or dike opening given the 3D distribution of aftershocks or other seismicity and the physics of the Coulomb failure stress criteria. Here we infer the space–time distribution of fault slip or dike opening through an imaging methodology: for specified point source slip or dike opening and receiver fault orientations, we obtain 3D maps of extended slip or dike opening through correlation of point–source ΔCFS kernels across the spatial distribution of seismicity. This seismicity–stress procedure finds a 3D distribution of relative fault slip or dike opening which can explain, in accordance with the physics of the Coulomb failure stress criteria, the surrounding distribution of seismicity.

We performed Coulomb seismicity – stress imaging (Lomax, 2025) of the 2025 Santorini – Amorgos earthquake swarm to determine whether the swarm activity could be driven by ΔCFS either from pure normal faulting source (Figure 3) or a vertical dike source with tensile opening (Figure 4). The results for the normal faulting source (Figure 3) show broad lobes of maximum source potential which are separated from and extend far to the northwest and southeast of the swarm seismicity, and which are

not parallel to the steep, 65°SE dip of the target normal faulting source. Seismicity-stress imaging supports a given source and receiver configuration when the maximum source potential is a) concentrated within the seismicity distribution and in areas of no or low seismicity, and b) flattened and extended parallel to a source fault or fracture plane orientation. Thus, these seismicity-stress imaging results do not support extended normal faulting as a driver of the swarm seismicity.

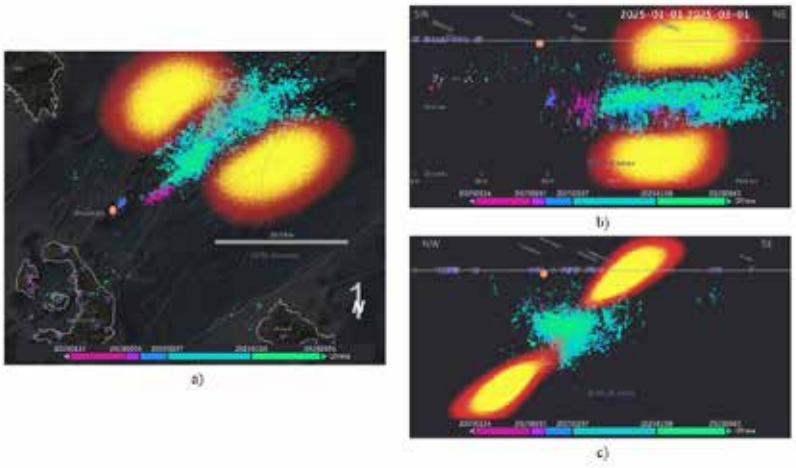

Figure 3. Seismicity-stress imaging of the 2025 Santorini-Amorgos swarm seismicity using a pure normal faulting source specified by a representative mechanism for the M_w7.7, 1956 Amorgos earthquake from Brüstle et al. (2014; strike N36°E, dip 65°SE, rake -102°). 3D density clouds of relative amplitudes of the high-potential portions of the imaged seismicity-stress finite-source fields (yellow and red show normalized correlation ≥ 0.8 and ≥ 0.7, respectively) are shown in a) map view, b) profile view from the SE, and c) profile view from the SW. Dots show NLL-SC-ML relocated swarm seismicity from 2025-01-01 through 2025-02-28, color coded according to occurrence time. Light red lines show mapped surface faults (NOAFaults v6.0); blue inverted pyramids show seismic stations used for ML picking and NLL-SC relocation.

In contrast, the 3D maps of seismicity-stress imaging over the swarm seismicity for a vertical tensile source (Figure 4) show an elongated volume of highest source potential that is mainly below and partly surrounded by the seismicity, abuts high-density limits of the seismicity, is aligned parallel to the trend of the swarm, and is flattened towards a vertical plane. All of these characteristics are compatible with and support a vertical, opening fracture or dyke as a stress source that causes the swarm seismicity.

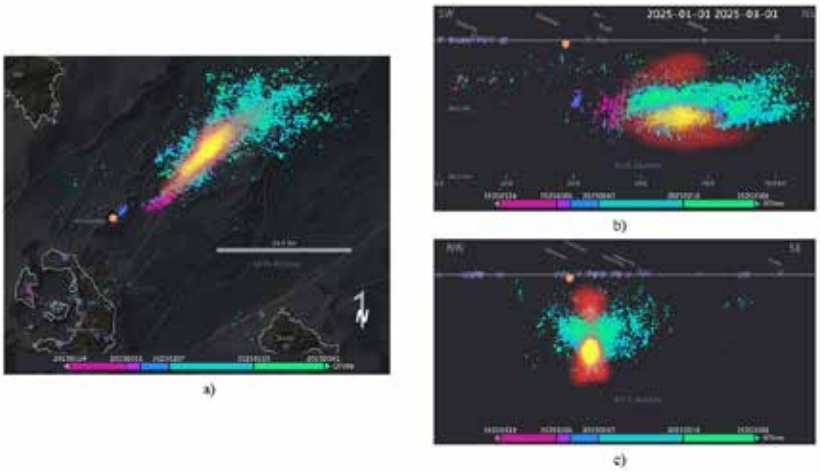

Figure 4. Seismicity-stress imaging of the 2025 Santorini-Amorgos swarm seismicity for a dike source with tensile opening on vertical planes. 3D density clouds of relative amplitudes of the high-potential portions of the imaged seismicity-stress finite-source fields (yellow and red show normalized correlation ≥ 0.8 and ≥ 0.7, respectively) are shown in a) map view, b) profile view from the SE, and c) profile view from the SW. Dots show NLL-SC-ML relocated swarm seismicity from 2025-01-01 through 2025-02-28, color coded according to occurrence time. Light red lines show mapped surface faults (NOAFaults v6.0); blue inverted pyramids show seismic stations used for ML picking and NLL-SC relocation.

Climate changes, neglected and emerging diseases.

P. Karanis[1]

(1) Department of Basic and Clinical Sciences, University of Nicosia Medical School, Cyprus, karanis.p@unic.ac.cy

The climate crisis is one of humanity's most pressing challenges and has visible and widespread impacts on public health. The presentation links the climate crisis to disease distribution, research, and control. From rising temperatures and the increasing frequency of extreme weather events to the emergence of climate-related diseases and nutritional inequalities, the climate crisis seriously threatens the health and well-being of the population. Using the interdisciplinary approach, we report on the challenges emerging, reemerging, and neglected diseases arising and being influenced by the climate crisis and how they affect our health and everyday life.

Climate change is expected to significantly impact neglected tropical diseases (NTDs), affecting their transmission patterns and geographic distribution. Vector-borne NTDs are particularly susceptible to environmental changes, as climate influences vector biology and habitat. Rising temperatures and altered rainfall patterns may lead to the emergence and re-emergence of NTDs in previously unaffected regions. Current NTD mitigation strategies, including mass drug administrations, are vulnerable to global events like the COVID-19 pandemic. There is a need for improved surveillance, monitoring, and research to understand better and address the complex interactions between climate change and NTDs. We will highlight the synergistic effects and advocate for a One Health concept by integrating insights from climate science, ecology, geology, water resources and medicine to address the interdisciplinary relation and the gaps to strengthen the resilience of Mediterranean health systems.

Neglected tropical diseases (NTDs) are diverse tropical infections caused by various pathogens, including viruses, bacteria, protozoa, and parasitic worms or helminths. Globalization and increased international trade and travel bring vectors and pathogens together, even where they are limited and prevalent. Climate change is another force driving the expansion of NTDs. A warmer and wetter climate has made the continent more welcoming to vectors of debilitating and sometimes deadly pathogens.

Although the impact of these diseases is not on the same scale in any country compared to tropical countries, cases of vector-borne diseases have become endemic in countries where they were not prevalent before, and they are on the rise. No one country long thought itself safe from NTDs is free. Old certainties that antibiotics and drugs will defend against the risks have evaporated. As Earth warms, the creatures that spread neglected tropical diseases are gaining a foothold in many countries.

Climate, demographic, geological, and geopolitical changes and floods pose new challenges in surface water quality monitoring. They bring forth usual or unusual pathogens, thus requiring new test designs. This demands the development of faster and easier tests to control the quality of drinking or reusing treated wastewater at all points, from plants to end users.

NTDs are also characterized by inequity, which is closely associated with poverty. This inequity has given rise to neglect. Wealthy countries must prepare themselves for more cases. We will discuss and propose options for action and innovative approaches that we can adopt to address these challenges and safeguard public health in an era of climate uncertainty and existing, emerging, reemerging, and neglected diseases related to water supply and vector disease distribution.

One of the most concerning impacts of climate change on human health is the rising prevalence and altered distribution of vector-borne diseases greatly influenced by environmental factors. Tick-borne diseases represent a particularly pressing threat, as climatic shifts influence pathogen transmission dynamics, host-vector interactions, and the geographic spread of key vector species. Ticks are blood-feeding ectoparasites found in mammals, birds, and reptiles worldwide. Unlike nest-dwelling tick species, non-nidicolous ticks are found on vegetation, such as grasses and bushes, onto which they climb and wait to attach themselves to their prey. They feed by sucking blood from their hosts, which can be pets, farm or wild animals, and humans. Ticks are known as carriers for a wide range of pathogens, including viruses, bacteria, protozoa, and helminths, and therefore, numerous tick-borne diseases are transmitted through their bite. Ticks, like mosquitoes, are recognized as the leading global arthropod vectors of human diseases and of primary medical and veterinary importance. Beyond these immediate concerns, ticks are vectors for pathogens that significantly increase morbidity and mortality, amplifying rising public health costs and disease management challenges.

Greece is a popular summer destination for tourists worldwide. Tourists and immigrants represent a melting pot of human activities that brings many people from all over the world together and potentially serves as a source of contamination that can cause endemic infectious diseases on the islands and the whole country. During their

visit, they overconsume diverse water resources by swimming, drinking a lot of water, and eating a lot of fresh produce with minimal preparation, especially salad ingredients and leafy greens. The objective evaluation of the epidemiological status is complex due to the unknown levels of pathogenic contamination in the water supplies, the degree of swimming pool contamination, and the distribution of contaminated food irrigated with contaminated water. Environmental pressure thereby is created and affects both humans and wildlife.

The annual average temperature increases (°C) in four Mediterranean basin countries (Greece, Cyprus, Italy, and Tunisia) from 1960 to the present. Since the 1990s, temperatures in the region have accelerated, with projections suggesting further increases, particularly in the summer months. Under different climate scenarios, the temperature could rise by 2 to 6°C by the end of the century, with a potential summer temperature increase of up to 3°C if global temperatures rise by 2°C. These warming trends are expected to lead to more frequent and intense heat waves, which will pose significant challenges to humans.

Infections have been reported, although outbreaks have been reported in limited numbers. The absence of outbreak documentation indicates the lack of an efficient screening and detection system and that these threats are not on the authorities ' alarm agenda until an outbreak occurs. Global warming negatively influences public health, the environment, and wildlife. Responding to these One Health threats promptly is critical. Specific pathogens were the leading etiological agents of waterborne and foodborne outbreaks. The parasites ' dormant and transmissive stages can infect a broad host range with multiple transmission routes. Consumption of various vegetables, direct or indirect contact with infected food products and ingesting contaminated water through drinking or swimming can lead to a foodborne and waterborne outbreak. Food and water safety are critical global health concerns, with specific foodborne and waterborne pathogens threatening human and animal health and environmental stability. Addressing the detection and monitoring challenges to water resources, leafy greens, and water supplies will overlap two questions.

Climate change and its influence on emerging disease transmission threaten public health and countries ' economies. This perspective emphasizes a critical knowledge gap by exploring how climate-induced environmental changes interact synergistically with disease transmission dynamics to heighten disease risks in Mediterranean countries. Research on the combined effects of climate change and disease transmission will establish bridges and fill the gaps, offering an integrated perspective on the interconnected pathways through which climate change affects public health. By integrating climate science, ecology/ecological modelling, geology and public health aspects, research efforts will advance existing part of knowledge by developing a holistic framework for assessing climate-driven threats. It underscores the necessity of adaptive strategies, including improved disease surveillance, integrated disease management, and climate-informed policy interventions. One Health approach is a cornerstone of the proposed solutions, fostering cross-sectoral collaboration to enhance resilience against climate-driven emerging risks

(2) National Technical University of Athens, Athens, Greece
(3) Technische Universität Berlin, Germany

Introduction

Landslides are among the most pervasive and destructive natural hazards, threatening lives, infrastructure, and ecosystems worldwide. Triggered by factors such as intense rainfall, earthquakes, volcanic activity, and human-induced changes, landslides are inherently complex phenomena influenced by dynamic interactions between geological, hydrological, and climatic conditions. Effective prediction and risk mitigation are critical to minimizing their societal and environmental impacts. However, traditional modeling approaches, which often rely on deterministic or statistical frameworks, face significant limitations in capturing the multifaceted and nonlinear processes underlying landslide occurrence. In recent years, artificial intelligence (AI) has emerged as a transformative tool in addressing complex problems across various scientific domains (Catani, Nava, and Bhuyan 2025). In the field of landslide modeling, AI-driven approaches leverage machine learning (ML), deep learning (DL), and advanced data analytics to process large, heterogeneous datasets, uncover hidden patterns, and make predictions with unprecedented accuracy (Sun, Bocchini, and Davison 2020). These technologies offer new opportunities to improve landslide susceptibility mapping, hazard assessment, and early warning systems.

The integration of AI into landslide modeling is particularly timely given the increasing availability of high-resolution remote sensing data, real-time sensor networks, and global climate models. These data sources provide the foundational input for AI algorithms to identify correlations and interactions among diverse variables such as slope angle, soil properties, rainfall intensity, and vegetation cover. Moreover, AI's adaptability allows models to evolve with changing environmental conditions, making them highly suited for long-term hazard management in a rapidly changing world (Dahal and Lombardo 2022). Despite its promise, the application of AI in landslide modeling is not without challenges. Issues such as data quality and availability, model interpretability, and uncertainty quantification remain significant hurdles. Furthermore, the successful implementation of AI requires interdisciplinary collaboration, bridging expertise in geosciences, computer science, and engineering, and transparency for decision-makers. Addressing these challenges is crucial to unlocking the full potential of AI in landslide risk reduction. This study aims to explore the opportunities and challenges associated with AI-driven in landslide modeling. It provides a review of methodologies, evaluates effectiveness, and highlights emerging trends and research directions.

Challenges and Opportunities

In recent years, the integration of AI with geotechnical and environmental sciences has opened new avenues for enhancing landslide modeling accuracy and effectiveness. AI approaches leverage computational algorithms to learn from data, enabling the extraction of hidden insights and the development of robust predictive frameworks (Zhao et al. 2024). Data complexity and availability remain significant barriers in landslide modeling, largely because these models require input from diverse datasets spanning geological attributes, hydrological dynamics, land cover, and climatic variables. The heterogeneity of these data sources often complicates their integration into cohesive models. Geological maps, satellite imagery, rainfall records, and field measurements vary in scale, resolution, and format, necessitating extensive preprocessing pipelines to harmonize inputs. This process can be computationally intensive and prone to errors. Additionally, data scarcity in remote or underdeveloped regions limits the accuracy and scope of modeling efforts. For instance, in areas without detailed geological surveys, proxy variables are often used, introducing uncertainties. Noise and errors in data, such as interference in remote sensing imagery due to cloud cover or inaccuracies in manually collected field data, further exacerbate the challenge. High temporal resolution data, critical for capturing dynamic triggers such as rainfall or seismic events, are frequently unavailable, reducing the model's ability to identify precursors to landslide events.

The temporal and spatial variability of landslide occurrences adds another layer of complexity. Landslides are influenced by short-term events like extreme rainfall, as well as long-term processes such as progressive slope deformation driven by climate change. AI models must therefore be capable of addressing these overlapping timescales. On the spatial front, landslides range from localized slope failures to regional mass movements, and models trained on small-scale events may not generalize well to larger-scale phenomena. Variability in lithology, vegetation, and human

activities such as deforestation and construction introduces nonlinear and region-specific interactions, complicating predictions further. Capturing these dynamics requires multi-scale modeling approaches capable of representing both broad regional trends and localized instabilities (Dahal, Huser, and Lombardo 2024). Uncertainty in AI-driven landslide models is another critical challenge, stemming from both the inherent unpredictability of landslides and limitations in data and algorithms. Quantifying uncertainty is essential for practical applications, as decision-makers must understand the confidence level of predictions. Probabilistic approaches, such as Bayesian neural networks or ensemble methods, can address this need but often demand substantial computational resources. Validation of model outputs against historical landslide inventories is another challenge, as such inventories are frequently incomplete or biased toward more visible events. This bias can reduce the reliability of model predictions. Furthermore, high-dimensional AI models risk overfitting to limited training data, underscoring the importance of rigorous cross-validation and feature selection to ensure generalizability.

Despite these challenges, AI offers transformative opportunities for advancing landslide modeling. One of the most significant benefits is enhanced prediction accuracy. AI algorithms can analyze large, complex datasets to uncover intricate patterns and nonlinear relationships that traditional methods often overlook. For example, deep learning models can extract geomorphological features indicative of slope instability from high-resolution satellite imagery, leading to improved landslide susceptibility mapping. These models also provide insights into the relative importance of input variables, such as rainfall intensity versus slope angle, which can guide future data collection and mitigation strategies. The scalability of AI further enables the development of regional and global models with unprecedented detail. Real-time monitoring and early warning systems represent another area where AI can have a profound impact. By integrating with data sources such as Internet of Things (IoT) sensors (Mendoza-Cano et al. 2021), AI models can continuously update landslide risk assessments in near real-time. Advanced algorithms, including recurrent neural networks and long short-term memory networks, excel at detecting anomalies in time-series data, serving as early indicators of potential slope instability (Zhao et al. 2024). These systems can also facilitate community engagement by delivering timely warnings through mobile applications, empowering at-risk populations to take preventive action and minimizing casualties. AI-driven models are inherently adaptive, evolving with new data inputs and changing environmental conditions. This adaptability is particularly valuable in the context of climate change, where shifting weather patterns and land-use practices continuously alter landslide dynamics (Ajraoui et al. 2024). Continuous retraining ensures that models remain relevant and accurate over time. AI can also simulate hypothetical scenarios, such as the impact of land-use changes or extreme weather events, aiding long-term planning and resilience building. Moreover, by automating data analysis and hazard mapping tasks, AI reduces the cost of landslide risk management, making advanced solutions accessible even to regions with limited resources. Numerous open-source libraries e.g. for R and python, such as the Scikit-learn library, and the implementation of AI algorithms in GIS platforms or Google Earth Engine make AI methods highly accessible. AI is being used in a variety of ways to improve landslide modeling, including data collection and integration, real-time monitoring, predictive modeling and early warning systems.

Figure 1. Conceptual schematic plot of landslide modeling where different conceptual elements are integrated (created in Gemini).

Discussion

This review has examined the burgeoning field of AI-driven approaches for landslide modeling, highlighting their potential to revolutionize our understanding and management of these geohazards. We have observed a growing body of research demonstrating the superior performance of AI algorithms, particularly deep learning models, in capturing complex non-linear relationships within landslide datasets. This has resulted in improved accuracy, enhanced prediction capabilities, and the ability to handle high-dimensional and heterogeneous data. However, several critical challenges persist. Data scarcity and heterogeneity remain significant hurdles, hindering the development and validation of robust AI models. The lack of standardized data collection and sharing protocols exacerbates these issues. Furthermore, the inherent "black-box" nature of many AI models raises concerns regarding interpretability and the potential for unintended biases. This lack of transparency can hinder trust and limit the widespread adoption of AI-based landslide prediction systems. Despite these challenges, the potential benefits of AI are substantial. AI-driven approaches can significantly enhance early warning systems, enabling more accurate and timely predictions of landslide events. This can facilitate proactive evacuation procedures and minimize human casualties. Moving forward, several key research directions are crucial.

- **Data-centric workflows:** Prioritizing the development of robust data acquisition and sharing frameworks, including initiatives to improve data quality, standardize formats, and enhance data accessibility.
- **Cognitive AI:** Developing and implementing techniques to enhance the interpretability of AI models, such as feature importance analysis, visualization methods, and rule extraction algorithms.
- **Hybrid approaches:** Exploring hybrid models that combine the strengths of AI with traditional geotechnical and statistical methods, leveraging the interpretability and domain expertise of traditional approaches while benefiting from the predictive power of AI.
- **Real-world applications:** Focusing on the practical implementation of AI-based landslide models in real-world settings, including their integration into operational systems and decision-making processes.

Ultimately, the successful application of AI in landslide modeling requires a multidisciplinary approach. Collaboration between researchers, practitioners, policymakers, and the public is essential to address the challenges, maximize the benefits, and ensure the responsible and ethical development and deployment of AI-based landslide prediction and mitigation systems.

Evaluation of Greek clay for pottery applications

Karountzou G.[1], Panagiotaki M.[1], Semitekolos D.[1], Charitidis C[1]

(1) Research Lab of Advanced, Composite, Nano-Materials and Nanotechnology (R-NanoLab), School of Chemical Engineering, National Technical University of Athens, 9 Heroon Polytechniou St., Zographos, Athens 15780, Greece, karountzou@chemeng.ntua.gr

Abstract

The use of clay in the ceramics industry is significant, because the properties influence greatly the final product's quality and performance. Greece has clay deposits that remain underexploited for artisanal and handicraft applications and imported clays are predominantly used. This study aims to evaluate the suitability of specific clayey raw materials for ceramic applications such as pottery, through characterization and mechanical testing. The research involves granulometric analysis, particle size analysis, and determination of Atterberg limits to assess plasticity. Experimental clay specimens are manufactured and subjected to mechanical strength tests, including flexural, tensile and compression testing, at two different firing temperatures. Additionally, mineralogical characterization is performed on both clayey raw materials and sintered specimens to investigate phase transformations. Particle size analysis and other complementary techniques are employed to further understand the material's behavior. Raw material prospection and sampling were undertaken, in accordance with the data provided from Mineral & Aggregate Resources Division of Greek Ministry of Environment, Energy and Climate Change. The clay samples are sourced from active quarries in Greece, specifically from Central Euboea, Central and Western Macedonia, and Central Greece, as potential material sources for pottery applications. The results will provide critical insights into the clay's applicability in ceramic production, highlighting its structural integrity and performance under different conditions. Additionally, these findings will promote the use of Greek clays in pottery applications.

Introduction

Clay-based ceramics have been extensively used in artistic and functional applications due to their durability and versatility. However, the performance of ceramic products depends on the properties of the clay raw materials. This study focuses on evaluating the suitability of selected clay sources for pottery through a comprehensive characterization approach. The main objective is to determine whether the studied Greek clays have the required mechanical and mineralogical properties for industrial use.

Methodology

The methodology consists of several steps. Initially, granulometric analysis is conducted to determine the textural properties and particle size distribution of the clay samples. Atterberg limits are measured to evaluate plasticity, which are critical for workability in artisanal applications. Then, the selected clay materials are processed into standard experimental specimens, which undergo mechanical strength testing. To study the influence of temperature on material properties, the specimens are fired at two different temperatures. Furthermore, mineralogical characterization using X-ray diffraction (XRD) and other techniques are performed to identify phase transformations occurring before and after firing. Additional particle size analysis and complementary characterization methods provide further insights into the structural and functional suitability of the clay for artisanal pottery applications.

Expected Results and Discussion

This study will reveal critical information regarding the development of clay materials during the ceramic production process. The impact of particle size distribution and mineral composition on mechanical strength is expected to be significant. The results will offer insights into how firing temperature influences phase transformations and overall material performance.

Conclusion

This study will contribute valuable data on the potential application of selected clays in pottery industry. Future work may include further refinement of processing parameters and extended mechanical testing to improve ceramic product development.

Abstract

The 2025 volcano-tectonic crisis of Santorini and Kolumbo volcanoes in the Greek Aegean Sea has provided unprecedented insights into the complex, interconnected magmatic systems beneath these neighbouring volcanic centres. Through the integrated analysis of seismological data and geodetic measurements, the migration of magma prior to and during this significant event has been reconstructed. The crisis began with a gradual deformation of the ground within the Santorini caldera from July 2024, with an uplift of about 45-50 mm detected by GNSS and satellite data, accompanied by increased H_2 and CO_2 gas emissions. On 27 January 2025, an intense earthquake swarm initiated 10 km northeast of Santorini, near Kolumbo volcano. The seismic activity continued for a period of over 30 days, during which time the intensity fluctuated. The seismic activity can be subdivided into distinct phases, beginning with deep seismicity (12-18 km) accompanied by strong tremors. This was followed by northward migration of increasingly shallow earthquakes towards Anhydros Island at velocities of approximately 1 km/h. The identification of at least 12 seismic surges, characterised by sharp increases in seismicity rate, magnitude intensification, and concurrent tremor activity, followed by lateral migration of seismic fronts, underscores the complexity of the crisis. A thorough analysis of 180 earthquake moment tensors for events with MW>3.6 revealed a consistent NW-SE-oriented tension axis perpendicular to the earthquake migration path, consistent with normal faulting patterns typical of dike intrusions. Our high-resolution earthquake catalogue, which contains over 28,000 events, shows a segmented, laterally ascending complex dike intrusion characterised by incremental, non-uniform and rapid expansion. Furthermore, periods of dike growth coincided with intense seismicity and large-magnitude earthquakes (MW>5) concentrated at the advancing dike tip. Between surges, when the dike boundary was stationary, seismicity was predominantly lower magnitude (MW 1-3), consistent with gradual pressurisation due to continuous magma inflow. Joint inversion of ground deformation data suggests two primary sources: a volume decrease within a mid-crustal reservoir beneath Kolumbo volcano and a uniform opening along a ~13km long dislocation between Kolumbo and Anhydros, representing the emplacement of a dike. The deflation source has been estimated at a depth of ~7.6 km beneath Kolumbo, with an inferred volume decrease of ~0.08 km³. In contrast, the volume increase in the dike has been calculated at ~0.3 km³. Following the initiation of the dike, there was a rapid increase in the magma inflow rate, which peaked between 4-12 February, with average inflow rates exceeding 200 m³/s, before decreasing to almost zero by 24 February, which is likely to mark the end of the intrusion. The sequential timing of these events – shallow magma chamber inflation at Santorini, followed by dike intrusion into the Anhydros Block with concurrent deflation at Kolumbo – points to coupling between reservoirs of both volcanoes. The interaction between the reservoirs likely occured through crustal stress transfer or pressure changes within the fluid plumbing system at depth, while there is no evidence for direct

connection between the shallow magma reservoirs.

EXTENDED ABSTRACT 140

The role of painting as historical evidence of relative sea-level change: a review

Karymbali Th.[1]
(1) School of Humanities, Hellenic Open University, Patras, Greece, theodorak2000@gmail.com

Background

Certain artworks can provide important perspectives on historical environmental and climate changes and may be used by scientists as proxies in measuring such changes. The extent to which they can be utilized depends greatly on the nature of the artwork, ranging from abstract and interpretive to strikingly precise, and the specific climate phenomenon being studied (Smithers, 2011). For instance, the variety of animals depicted in prehistoric cave and rock art offers clues about the prevailing climate at the time, though such interpretations must account for critical limitations. Pieter Bruegel's paintings, while inconclusive, have been linked to evidence of the onset of the Little Ice Age (Mann, 2002), while Mid-19th-century depictions of glaciers serve as useful benchmarks for assessing modern glacial retreat. Additionally, analyses of sunsets in various artworks have provided precise data on the atmospheric effects of volcanic eruptions (Zerefos *et al*., 2007).

When studying mean sea-level fluctuations, geomorphological data are valuable for identifying long-term rates of relative sea-level change, while historical data and records can be used to study local sea-level variations over recent centuries. By identifying and locating these indicators and determining their age and elevation relative to present-day sea-level, changes in relative sea-level can be established.

Geomorphological sea-level indicators can have the form of erosional landforms (such as marine notches, sea caves, arches, shore platforms, and marine terraces) or depositional landforms (such as beachrocks, beach ridges, tidal flats, and coral formations) (Vacchi, 2016). When these erosional or depositional features become inactive (fossilized) and appear above or below the current level at which similar landforms are currently forming, they provide evidence of sea-level changes since the time of their formation. In addition, various organisms (corals, algae, various types of shells, worms etc.) or their remnants that, when alive, inhabited known specific tidal levels, can now be found fossilized at different elevations. These biological sea-level indicators reflect changes in sea level that occurred after the organisms' death. The fossils mark the location of the ancient shoreline, representing the time when these organisms lived (Karymbalis, 2010). Sea-level indicators may also include archaeological evidence, such as ancient coastal cities or harbor structures that are now situated above or below the current sea-level (Kolaiti *et al.*, 2024). These findings demonstrate that during their period of peak activity, sea-level was at a different position than it is today.

Historical data and records often serve as valuable indicators of more recent sea-level changes. These include written documentary evidence, as well as old tidal gauge measurements, which span over 100 years but are available for only a few regions worldwide (such as northwestern France). Additionally, old high precision paintings that accurately depict coastal landscapes, whether natural or urban, can serve as historic sea-level indicators, providing valuable insights into the sea-level's position at the time they were created.

An example of using paintings to study changes in relative sea-level and the geomorphological evolution of a coastal area is the work by Mattei *et al*. (2020). Among the various geomorphological and historical elements they interpreted to reconstruct the relative sea-level variations and associated morpho-evolutive trends of the Naples coast since the mid-Holocene, they utilized five paintings created between 1790 and 1836 by different artists. However, the most notable example of how paintings can be successfully used to reconstruct recent relative sea-level changes is Venice. For centuries, Venice has long wrestled with the effects of subsidence and the rising sea-level, well before the onset of the industrial era and has abundant evidence of rising sea-level and historical evdence of past high waters. High precision 18th century paintings have been systematically used by Camuffo *et al*., 2017, Camuffo and Sturaro (2003), and Camuffo (2001; 2021)to identify water levels in Venice in the period before instrumental records were kept.

This review paper explores how sea-level evidence on buildings in Venice, as well as architectural features captured in paintings, serve as powerful witnesses to geological and climatic processes. These indicators reveal the recent rise in sea-level driven by both global eustatic sea-level rise and local land subsidence caused by natural and human forces. It primarily focuses on how the height of algae line on palaces, accurately depicted by two painters, has been used as a sea-level proxy over the last three centuries, demonstrating how art and geomorphology can collaborate in reconstructing past sea-level fluctuation.

Methodology

The methodology for this study is based on a comprehensive review of existing literature on the topic. A systematic approach was employed to identify key studies addressing long-term land subsidence and relative sea-lever rise, as well as the use of historical evidence depicted on paintings in Venice. The literature search led to a series of papers and book chapters on the

topic published mostly by Dario Camuffo and his co-authors who have been exhaustively studying these types of historical sea-level indicators in Venice over the past few decades.

Venice

Venice is located in northeastern Italy and is the capital of the Veneto region (Figure 1). It rests atop a network of 127 islands, interconnected by 472 bridges and divided by canals and open waterways. These islands are nestled within the shallow Venice Lagoon, a sheltered bay located between the mouths of the Po and Piave rivers. The lagoon has been a hub of human activity since pre-historic times, with early inhabitants relying on its rich resources for fishing and hunting. By the Neolithic period, the area was already settled, and by the Bronze Age, significant communities, such as Altinum, had emerged. From its very origins, Venice's identity has been inseparable from water. The lagoon offered natural protection against invaders and served as a vital lifeline for its people. Yet, life in this extraordinary setting has always demanded resilience, as Venetians have faced and adapted to the challenges of land subsidence and shifting sea-level.

Carminati *et al*. (2003) assessed a long-term subsidence rate of 0.7–1.0 mm/yr for the greater Venice area, which aligns closely with the slightly lower rate of 0.5 mm/yr estimated by Kent *et al*. (2002) for the past 2.6 million years. The geological-scale subsidence affecting Venice is primarily driven by the subduction of the Adriatic plate beneath the Apennines (Carminati and Di Donato, 1999), as the city lies at the northeastern edge of the Po Plain, which is the foreland basin for two fold-and-thrust belts: the Northern Apennines and the Southern Alps (Cuffaro *et al*., 2010). A natural subsidence rate of 0.45±0.09 mm/yr has also been calculated for the last 124 ka (Rovere *et al*., 2024), consistent with all the above-mentioned long-term rates. However, it is important to note that subsidence rates in regions as geologically complex as the Venice lagoon and its surrounding coastal plain can vary significantly over space and time. Holocene subsidence rates appear to be greater than those observed over extended geological periods. Tosi *et al*. (2009) offer a possible explanation for this difference, suggesting that sediment compaction could be a contributing factor. They propose that this process significantly impacts Holocene sediments, whereas its effect on older sediments is minimal.

Figure 1. Location of Venice (Source: Google Earth).

Paintings as historical relative sea level change indicator

While geological data are essential for determining long-term rates of relative sea-level change, accounting for eustatic, isostatic, and tectonic components, understanding localized sea-level fluctuations over recent centuries is particularly critical for a city like Venice. This period spans both the pre-industrial and post-industrial eras, the latter marked by accelerated ice melt and rising sea-level driven by human-induced greenhouse gas emissions (Fox-Kemper *et al*. 2021). For the past century, modern tools such as tide gauges and satellite altimetry have provided accurate sea-level measurements. Venice presents a unique case study as its centuries-old architecture, constructed in close proximity to the water's edge, combined with artistic depictions of the city by painters, allows the reconstruction of sea-level changes dating back as far as 1300 CE (Camuffo, 2021). This rich historical and cultural record offers insights unavailable in most other coastal locations.

The contributions of the paintings by two prominent Venetian painters, Antonio Canal (better known as Canaletto, 1697–1768) and Bernardo Bellotto (1722–1780) were of great importance in sea-level change reconstruction (Camuffo, 2001). Born in Venice on October 18, 1697, Canaletto grew up in a family of artists. He initially worked as a theatrical scene painter but eventually embraced a new artistic direction that shaped his legacy: veduta, or "view painting." This genre, which originated in the 17th century, focuses on exceptionally detailed portrayals of cityscapes and urban landmarks (Kowalczyk, 2018). Drawn to this style, Canaletto turned his attention to capturing the essence of daily life in Venice through his meticulously crafted cityscapes and architectural views often referred to as "veduta". In his paintings, Venice is portrayed as a grand theatrical production, with the

Grand Canal serving as the stage, the buildings forming the curtains, and the intricate architecture creating the backdrop of the scenery (Kowalczyk, 2018). Bernardo Bellotto (1721–1780) was a nephew and pupil of Canaletto known also for his stunning "veduta" painting. He even signed some of his works as "Bernardo Canaletto", capitalizing on his uncle's fame. However, Bellotto developed his own distinct style, marked by highly detailed and often large-scale depictions of cities, dramatic lighting, and a cooler palette (Kowalczyk, 2016).

To discuss the role of paintings as indicators of sea-level change, it is essential to understand the concept of the "Comon Mark" ("CM") or "Marine Common Level" in sea-level reconstruction studies, both generally and specifically in the context of Venice. The "CM" refers to reference benchmarks used to measure and monitor sea-level changes. These benchmarks might include tidal markers, which are physical markers set at specific locations that serve as references for mean-sea level, tidal datums, or other standardized elevations for data comparison (Rovere *et al*., 2024). Essentially, common marks agreed-upon reference points or datasets that allow for consistent comparisons across different regions or time periods. The role of the "CM" in sea-level change studies is crucial because it provides consistency across locations. A shared CM or "common level" ensures that measurements are comparable on a global scale. Additionally, using standard baselines allows researchers to track global sea-level rise and its impacts on coastal regions making "CM"s indispensable for understanding long-term trends.

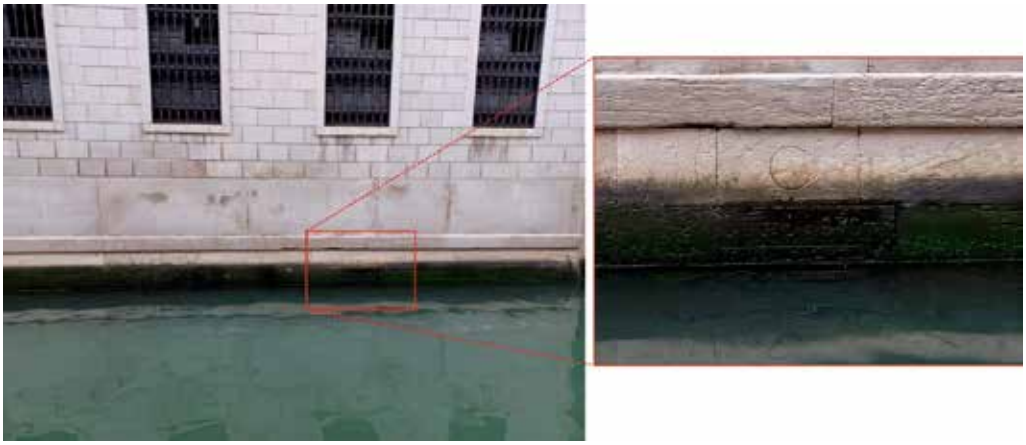

Figure 2. Photo showing the present brown-green microorganisms mark on a building wall facing a canal and the letter "C" (the official sea-level reference engraved when the benchmark was made in 970).

In the case of Venice, the "CM" refers to the distinctive dark green-brown belt formed by photic algae that grows on buildings, walkways, and bridges throughout the city (Rovere *et al*., 2024). This belt's elevation is slightly above the high tide level, influenced by the standing waves generated by boats during calm days in the lagoon. As noted by Camuffo (2023), the ancient Venetians sometimes formalized this marker by engraving it onto walls as "CM" or simply "C", designating it as an official sea-level reference at the time the benchmark was made (Figure 2). The use of the "CM" as a benchmark for water level in Venice has been well-documented in historical sources, including a 16th century book by Cornaro, (1560) and the writings of Temanza (1761).

Canaletto and Bellotto achieved an almost photographic precision in their depictions of urban landscapes, faithfully reproducing buildings down to the smallest details, a realism made possible by their use of the camera obscura (Camuffo and Sturaro, 2003). The camera obscura, an early precursor to the modern camera, functions by allowing a beam of light to pass through a lens or small opening, it is then reflected by a mirror or prism and subsequently projected onto a glass surface (Figure 3a). The painter would position a canvas or sheet of paper over the glass surface to trace the outlines of the projected image, creating a highly detailed, almost "photographic" rendering. Although the overall proportions of the scene might not always be maintained, Cannaleto and Bellotto meticulously reproduced intricate details, including the "CM" on buildings. This technique enabled painters to achieve remarkable detail and realism in their cityscapes. Canaletto's camera obscura, is kept at the Correr Museum in Venice (Figure 3b). The accuracy of detail in Canaletto and Bellotto's works can be tested by scaling and comparing elements across multiple paintings of the same building, all created using a camera obscura. Although these paintings are often regarded as copies of an original, the varied patterns of minor discrepancies suggest that the two artists likely revisited the site at different times to produce fresh sketches of the same structure. The precision in depicting even the smallest details highlights that their paintings are faithful, high-quality representations of the real world rather than imaginative or fictional compositions.

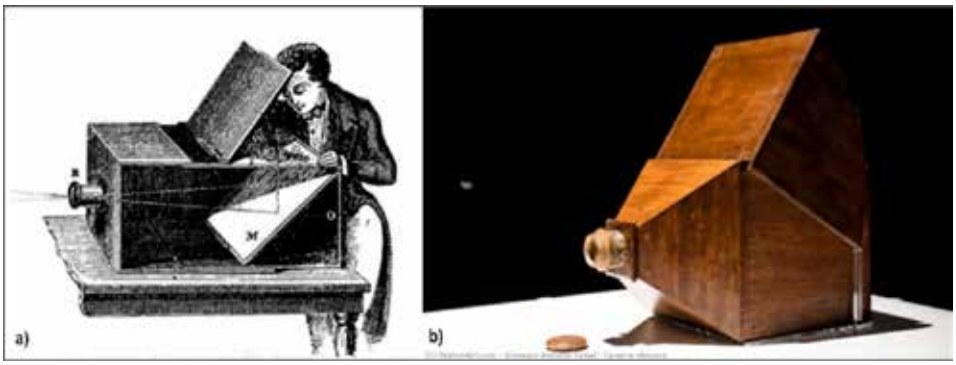

Figure 3. (a) An artist sketching from life using a 19th century camera obscura. The device includes: B (lens), M (mirror), and O (the path of light if unobstructed by the mirror). The artist used thin tracing paper to outline the image, then transferred it onto canvas, board or paper to complete the drawing. (Source: Wikipedia Commons) (b) A camera obscura made, or perhaps simply owned, by Canaletto, as revealed by the inscription.

From the above it is clear that it becomes possible to reconstruct the sea-level at the time the painting was created. Although the exact tidal stage during the painting's execution cannot be determined, both Canaletto and Bellotto incorporated the "CM" into their works, providing a reliable reference point. The process begins by identifying the precise location of the "CM" in the painting, relative to recognizable architectural features. Next, the site is visited, typically by boat, to locate the building, where the "CM" (level reached by algae) from the painting is compared to the current algae line on the structure. The difference between the two levels indicates the rise in relative sea-level from the time the painting was made to the present. Before arriving at a final estimate, several adjustments must be made. Key factors, such as the difference in wave patterns created by motorboats today compared to those caused by the rowing and sailing vessels of the 18th century, as well as the amplification of tidal wave due to dynamic effects, must be carefully taken into consideration (Rovere *et al*., 2024). The analysis of eleven paintings of Canaletto and Bellotto (Figure 4) revealed that the "CM" has risen on average by 69±11 cm since the early 18th century (Camuffo and Sturaro, 2003) as shown in Figure 5a.

Figure 4. Four of the paintings of Canaletto and Bellotto that were used as historical relative sea level change indicator (a) "The Punta della Dogana" by Canaletto (1727); (b) "View of the Grand Canal at San Stae" by B. Bellotto (1740); (c) "The Grand Canal, Venice, Looking East from the Palazzo Flangini to the Palazzo Venramin Calergi" by B. Bellotto (1741); (d) "Grand Canal From the Campo Santa Sofia Towards the Rialto Bridge" by Canaletto (1730-31). (Source: WikiArt, Visual Art Encyclopedia).

Beyond changes in the "CM" elevation shown in paintings, another architectural feature that can act as a proxy for relative sea level is the positioning of steps in front of residential buildings or leading to canal walkways. Camuffo *et al*. (2017) explored this proxy, grounded in the principle that stairs were designed for practical use—allowing people to descend from buildings into boats, and vice versa. To facilitate this, the lowest step was typically aligned with the boat's gunwale (side level), ensuring it was free of algae, meaning it was positioned slightly above the "CM".
By integrating evidence from paintings, staircases, and historical written documents detailing changes in "CM" elevation relative to known architectural features, Camuffo *et al*. (2017) reconstructed trend in relative sea-level from 1300 to around 1800 CE. Camuffo *et al*. (2017) and Camuffo (2021; 2022a) identified an exponential rise in relative sea-level from 1350 to the present. This acceleration in sea-level rise is also exponential, indicating the importance of long-term processes (such as melting continental glacier, isostatic adjustments, and tectonic movements) alongside climate change. While the precise mechanisms driving this exponential trend remain to be fully understood, they likely involve a complex interaction of Glacial Isostatic Adjustment, historical subduction, and post-industrial sea-level rise. Over the entire period from 1350 to 2016 CE, the average local sea-level change is estimated at 1.9±0.1 mm/yr. A key unresolved issue lies in the significant discrepancies between historical records and geological data reported by Vacchi *et al*. (2016). These differences suggest the possibility of substantial pre-industrial sea-level fluctuations that remain unexplained. Bridging the gap between geological and historical relative sea-level data is essential and represents a promising direction for future research in understanding long-term sea-level dynamics.

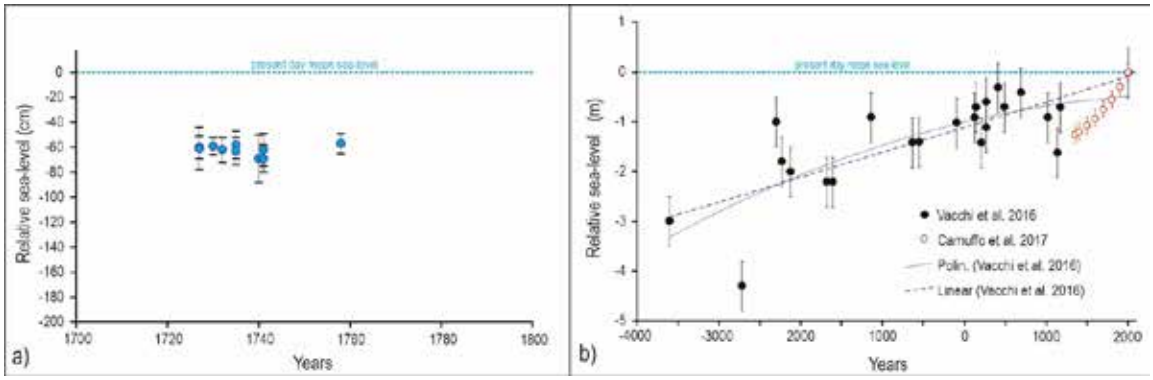

Figure 5. Data on relative sea level (RSL) changes in Venice through multiple sources. (a) The graph illustrates RSL trends based on estimations derived from the paintings of Canaletto and Bellotto (white dots with error bars, covering 1727–1758). The RSL values from the paintings were inferred by comparing the algae belt's position depicted in the artwork to its present-day level; (b) a long-term reconstruction of relative sea-level rise over the past 6000 years. Black dots represent data from natural proxies as compiled in Vacchi *et al*. (2016), while red circles indicate sea-level estimates reconstructed by Camuffo et al. (2017). (Source: Camuffo *et al*. (2022b).

In the context of climate change, the study area is expected to face significant challenges due to both short- and long-term sea-level rise (Tosi et al., 2002; Zanchettin et al., 2021; Lionello et al., 2021).
Taking into account the spatial distribution of vertical land movement (1–3 mm/year of subsidence, with peak values reaching 7 mm/year) and tide gauge data, projections indicate that by 2150, more than 112 km² could be at risk of flooding under the SSP1-2.6 low-emission scenario, with this figure increasing to 139 km² under the SSP5-8.5 high-emission scenario. During extreme high-water events—driven by the combined effects of astronomical tides, seiches, and atmospheric forcing—the relative sea-level rise (RSLR) in 2150 could temporarily reach up to 3.47 m (Andizei et al., 2024, 2025). These findings emphasize the urgent need for local communities to strengthen flood resilience strategies to mitigate the projected impacts of RSLR by 2150, particularly in the UNESCO-listed city of Venice and its ecologically significant lagoon (Alberti et al., 2023; Andizei et al., 2024).

Closing Remarks

Painting and other forms of art have emerged as significant proxies for understanding climate change impacts including sea-level rise. Venice, with its continuous habitation and unique coastal environment characterized by significant interaction between water and buildings, stands out as a one-of-a-kind region globally where painting can play a pivotal role in studying sea-level changes. The distinctive technique and faithful depiction of the city's urban landscape by painters such as Canaletto and Bellotto have significantly contributed to the investigation of relative sea level changes since the early 18th century, making Venice one of the finest examples of the collaboration between

painting and geomorphology, yielding impressive results. While paintings can help reconstruct historical sea-levels from the time they were created, several critical factors that further complicating accurate interpretations must be taken into account. In the case of Venice such issues include significant differences in wave patterns generated by modern motorboats compared to those produced by the rowing and sailing vessels of the 18th century, as well as the amplification of tidal wave due to dynamic effects.

The integration of artistic expression with scientific data allows for a unique communication of climate change, particularly in relation to sea-level rise. Beyond utilizing works of art to study changes in relative sea-level, art can also motivate audiences to consider the implications of climate change more seriously. Artists often depict landscapes threatened by rising waters, creating a visual narrative that underscores the urgency of climate change and the need for a sustainable future.

Challenges and Opportunities in the AI Era: Promoting Earth Science Education for Deaf and Hard of Hearing Students

Katheri M.[1], Koumoutsakou O.[1], Antonarakou A.[1]

(1) Department of Geology and Geoenvironment, Kapodistrian University of Athens, Ilisia, Greece, mar.katheri@hotmail.com

Introduction / Background

The formal education of Deaf and Hard of Hearing (DHH) students has a long and often controversial history, particularly in Earth Sciences. Despite the legal guarantee of equal education for DHH students, its practical implementation often lacks inclusivity. Many students, while physically present in the classroom, are academically and socially excluded due to deficiencies in the education system (Howerton-Fox & Falk, 2019), though these deficiencies may vary by region or institution. Considering inclusion, accessibility, and the greater representation of persons with disabilities in science and engineering fields (NCSES, 2023), including Earth Sciences, the need for redesigning Earth Science teaching at all educational levels becomes evident, especially in the new AI era.

The Challenges of DHH Students in Geosciences

DHH students are often discouraged from participating in Earth Science due to practical constraints and social biases (Connors, 2023). Fieldwork, which is a cornerstone of Geosciences (Whitmeyer & Mogk, 2009), presents significant difficulties. Challenges such as outdoor communication difficulties, insufficient educational materials, and the absence of sign language for specialized terms create significant barriers to equal participation.

At the same time, inclusive pedagogical approaches often omit deafness as a key factor, ignoring the need for tailored solutions. The responsibility for accommodation is often placed on DHH students, burdening them with additional stress and challenges (Carabajal *et al.*, 2017). The challenges faced by DHH students considering intersectionality (e.g., gender, ethnicity, socioeconomic status) may compound these challenges.

Assistive Technologies and Innovations

Today, technology is providing new opportunities to support DHH students. Tools such as Communication Access Real-time Translation (CART) and sign language interpreters improve communication (NAD, 2023). However, these tools often have limitations, such as incomplete coverage of specialized terms in Earth Sciences. Newer technologies like real-time AI-based sign language generation, tactile feedback devices, virtual and augmented reality education platforms, and AI tools and datasets reflect recent innovations (Kouremenos & Ntalianis, 2025; Hossain, 2024; Ulrich et al., 2024).

In addition, initiatives such as the Signing Earth Science Dictionary (SESD) offer access to approximately 750 Earth Science terms for DHH students (Vesel & Hurdich, 2014). Similar efforts are being extended to British Sign Language, with the addition of terms related to biodiversity and ecology. Thus, maintaining and expanding such dictionaries and similar efforts to address evolving terminology remains a challenge.

Innovative Pedagogical Methods

Virtual technologies provide unique teaching opportunities in Earth Sciences. Research projects, such as the use of virtual worlds, have demonstrated that virtual fieldwork can effectively simulate the experience of outdoor teaching (Allison & Miller, 2012) especially for students who might not have access to physical field experiences due to disabilities or other constraints. Moreover, devices such as the deformational sandbox demonstrate that hands-on learning can be effectively adapted for DHH students, enhancing their understanding of complex geological processes (Kahn *et al.,* 2013).

Fieldwork and Inclusive Education

Fieldwork remains a critical area for adaptation to support DHH students. Despite these barriers, educators have developed practices to improve accessibility in field experiences. Virtual field applications, while not a full replacement for the experience, offer significant support and learning opportunities (Guillaume *et al.,* 2023).

The Role of Inclusion in the Earth Sciences

Inclusion in geoscience is not only about DHH students' access to education but also about creating a more diverse and welcoming science environment. Research shows that the presence of minority faculty encourages students to remain in the field, fostering a sense of community (Dutt, 2020). Peer support networks, accessibility policies, and inclusive course design, also play a significant role in retention and fostering community.

Conclusions and Perspectives

Addressing the challenges DHH students face in geosciences requires a multi-dimensional approach. From the development of assistive technologies and customized pedagogies to the creation of inclusive learning environments, progress in this area is essential. An education system emphasizing intellectual abilities over physical limitations can unlock the full potential of DHH individuals and enrich Earth Sciences with diverse perspectives and ideas. In addition, wider social and professional barriers, including funding challenges, recruitment biases, and the need for more mentoring programs need to be taken seriously.

Research Highlights
GNSS campaign measurements conducted in February 2025 reveal measurable displacements across the Santorini caldera, with patterns consistent with low-level magmatic deflation. Comparison with 2012 benchmark data confirms ongoing deformation and underscores both the value and the limitations of campaign-based observations relative to continuous GNSS monitoring.

Introduction

The Santorini Island complex, located in the southern Aegean Sea, is one of the most active volcanic regions in the Eastern Mediterranean. It forms part of the Hellenic Volcanic Arc and comprises several islands, including Thera (Santorini), Therasia, and Nea Kameni, which collectively outline a partially submerged caldera formed during the catastrophic Minoan eruption around 1600 BCE (Friedrich et al., 2006; Druitt et al., 1999). Volcanic activity in the region is driven by the subduction of the African plate beneath the Eurasian plate, resulting in both tectonic and magmatic processes that have shaped the morphology and evolution of the caldera (Nomikou et al., 2014; Pyle & Elliott, 2006).

In recent years, the Santorini complex has experienced a period of renewed geophysical unrest, marked by increased seismic activity, observed ground displacements, and subtle geochemical anomalies (Parks et al., 2012; Bagnardi et al., 2013). This ongoing activity—reminiscent of the 2011–2012 unrest episode—has raised concerns about the potential reactivation of the volcanic system. Early detection and monitoring of ground deformation are therefore essential for understanding subsurface processes and assessing potential volcanic hazards (Newhall et al., 2000).

This study presents preliminary results of ground displacements associated with the most recent seismic and volcanic activity in the Santorini Island complex. Our analysis is based on a combination of continuous GNSS (cGNSS) data from permanent stations established and maintained by various Institute, Universities and private companies and measurements from GNSS campaign surveys conducted at selected pillars of the National Triangulation Network of Greece, established and maintained by the Hellenic Military Geographical Service, across the island complex. By comparing recent observations with historical GNSS datasets, we detect and quantify ground deformation patterns related to the ongoing unrest. The aim is to identify spatial trends, evaluate the magnitude and direction of surface displacements, and explore possible links to underlying volcanic and tectonic processes. These results contribute to a better understanding of Santorini's geodynamic behavior and provide valuable input for hazard monitoring and risk assessment in the region.

Previous Measurements (2011–2012 Unrest)

During the period of increased volcanic unrest in the Santorini Island complex between 2011 and 2012, an extensive geodetic campaign was conducted to detect and quantify ground deformation. The network consisted of ten permanent GNSS stations established progressively across the islands, with dense spatial coverage especially after mid-2011 in response to the signs of volcanic reactivation. Key stations were operated by several institutions including the Dionysos Satellite Observatory of the NTUA, the University of Patras, the University of Oxford, UNAVCO, and the University of Athens. To enhance spatial resolution, the permanent network was supplemented by 19 non-permanent (campaign) stations, measured during two epochs: the first in September 2011 and the second between January and early October 2012. These campaigns allowed for the detection of short-term displacements by comparing coordinates between the two time periods. GNSS data were processed using the Gamit/Globk software package (10.4), with results validated against independent solutions produced using the Bernese software (Version 5.0) at the Dionysos Satellite Observatory (Dimitriou, 2013).

The analysis revealed measurable displacements across the caldera, particularly evident in the radial outward motion and uplift consistent with magmatic inflation processes. Linear velocities and coordinate time series were derived for both campaign and permanent stations, referenced to the ITRF08/IGS08 Reference Frame (Altamimi et al., 2012), using IGS stations to ensure geodetic consistency.

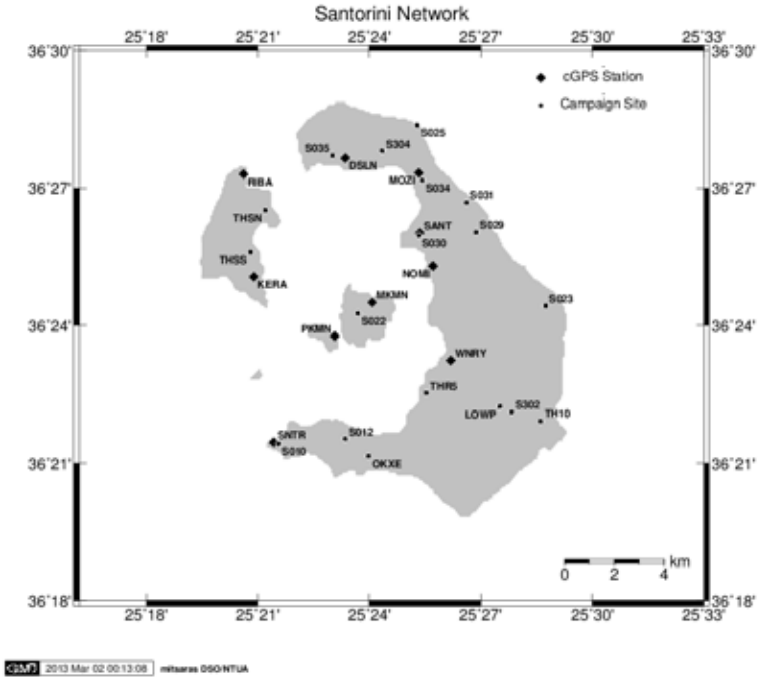

Figure 1. Santorini GNSS Network (Dimitriou, 2013)

3. Recent GNSS Campaign

In the framework of the current study, GNSS measurements were carried out at 16 benchmarks that had originally been observed during the 2012 measurement campaign (Fig. 2). The 2025 observations were conducted using dual-frequency GNSS receivers, with each session lasting at least two hours to ensure high-precision positioning suitable for geodetic applications. The measurement campaign was conducted over the period 6 – 13 February 2025, a period of time during which the seismic phenomenon was in full swing. The raw data were processed using the Bernese GNSS Software (Version 5.2) via the AUSPOS service, which delivers precise coordinate solutions in the ITRF2020 reference frame (Table 1 & 2).

However, the coordinates of the benchmarks measured at 2012 were originally computed in the IGS08 reference frame. To allow a reliable and rigorous comparison between the two epochs, a dedicated transformation and alignment procedure was implemented to bring both datasets into a common reference system and epoch.

3.1 Methods of data analysis

To achieve compatibility between the two datasets, the 2012 coordinates in IGS08 were first transformed into the ITRF2020 reference frame using the official seven-parameter Helmert transformation, including both positional offsets and their associated rates (Altamimi et al., 2023). Additionally, to ensure that the coordinate comparisons reflect only the true displacements between the two measurement epochs, both datasets were referred to a common epoch. This step is critical because the 2012 and 2025 observations are separated by more than a decade, during which secular tectonic motion could contribute significantly to the apparent coordinate differences. For this purpose, the velocity field of Bitharis et al. (2016)—which provides high-resolution horizontal and vertical velocities for the Hellenic region based on long-term GNSS observations—was used to propagate the transformed coordinates forward in time to the epoch of the 2025 campaign. This allowed the separation of long-term tectonic trends from potential volcanic or local ground deformation signals between the two periods (Figure 3).

Once the coordinates of the campaign of 2012 were transformed into the ITRF2020 frame and propagated to the epoch of the 2025 measurements, the coordinate differences between the two epochs were computed for each benchmark. These differences were initially expressed in geocentric Cartesian coordinates (X, Y, Z), but for geophysical interpretation, they were further transformed into topocentric displacements, in the local North, East, Up (NEU) reference frame.

This transformation allows a clearer visualization and analysis of horizontal and vertical displacements relative to each station's location on the Earth's surface. The NEU components were computed using each station's geodetic latitude and longitude, following standard local frame rotation techniques. This step enables the detection of meaningful surface movements such as uplift, subsidence, or horizontal spreading that may be associated with magmatic or tectonic processes in the Santorini volcanic complex.

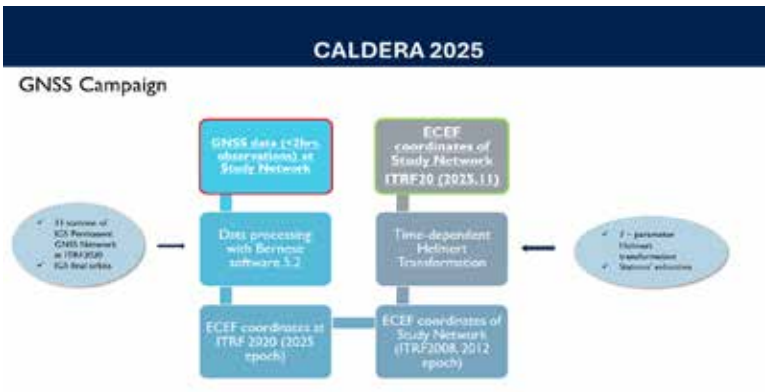

Figure 3 - Schema of the methodology for the data analysis

3.2 Preliminary Results

The comparison between the two GNSS campaign data revealed measurable displacements at the benchmarks across the Santorini Island complex. The displacements are presented both in terms of horizontal (East–North) and vertical (Up) components. The horizontal displacement vectors exhibit a radial pattern centered around the north part of the caldera, with the largest motions observed at stations located near Nea Kameni and the northern part of the island. The magnitude of horizontal displacements generally ranges from 2.5 cm to over 9 cm, suggesting a subtle but coherent deformation field (Figure 4).

Vertical displacements also show spatial variability, with most of the stations inside the caldera experiencing subsidence of up to 15 cm, while peripheral stations remain stable or exhibit minor uplift. These patterns are consistent with low-level deflation of a magmatic source beneath the caldera (Figure 5).

In addition to the comparison between the 2012 and 2025 campaigns, a short-term repeatability test was conducted to assess the internal consistency and reliability of the recent GNSS measurements. Specifically, three benchmarks were successfully re-measured with a time difference of only five days during the February 2025 campaign. These repeat measurements refer to the same reference frame (ITRF2020) and the same epoch, thus eliminating the need for any transformations or epoch propagation. Although limited in number, these observations provide a more detailed snapshot of the ongoing deformation, free from long-term tectonic signals or processing-related uncertainties. The high internal consistency between the repeated measurements enhances confidence in the reliability of the broader displacement patterns observed in the full network.

Figure 4 - Horizontal Displacements (2012-2025)

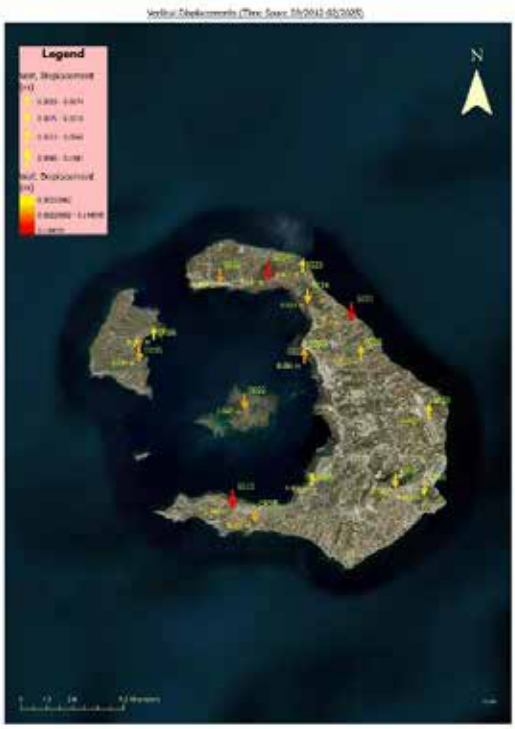

Figure 5 - Vertical Displacements (2012-2025)

The displacements derived from these short-term measurements provide an internally consistent snapshot of ongoing deformation. The horizontal displacements at these three sites range between 2.4 cm and 6.3 cm, indicating significant surface motion over just a few days. In the vertical component, the measurements revealed distinct vertical behavior: no vertical displacement at the caldera center, uplift at the southwestern station, and subsidence at the northeastern station. This spatial variation suggests that deformation is not driven by a simple, symmetric source. Instead, it may reflect a heterogeneous deflation process, possibly involving lateral magma migration or localized hydrothermal activity. The absence of uplift at the caldera center further supports the interpretation of a deflating or stabilizing magmatic system with distributed or compartmentalized subsurface dynamics. Similar patterns of spatially variable deformation were observed during the 2011–2012 unrest and attributed to complex pressurization processes within a multi-level magmatic system (Parks et al., 2012).

Figure 6 - Horizontal Displacements (2025)

Figure 7 - Vertical Displacements (2025)

4 cGNSS station analysis

The data described above were analyzed using the Bernese GNSS Software (v. 5.2) (Dach et al., 2015). Both GPS and
GLONASS observations were used when available. IGS20 was used as the frame of reference, using a set of 19 IGS stations for alignment. CODE final products were incorporated in the analysis, consistent with the frame of choice. The key parameter of interest was station coordinates (Anastasiou et al., 2024).

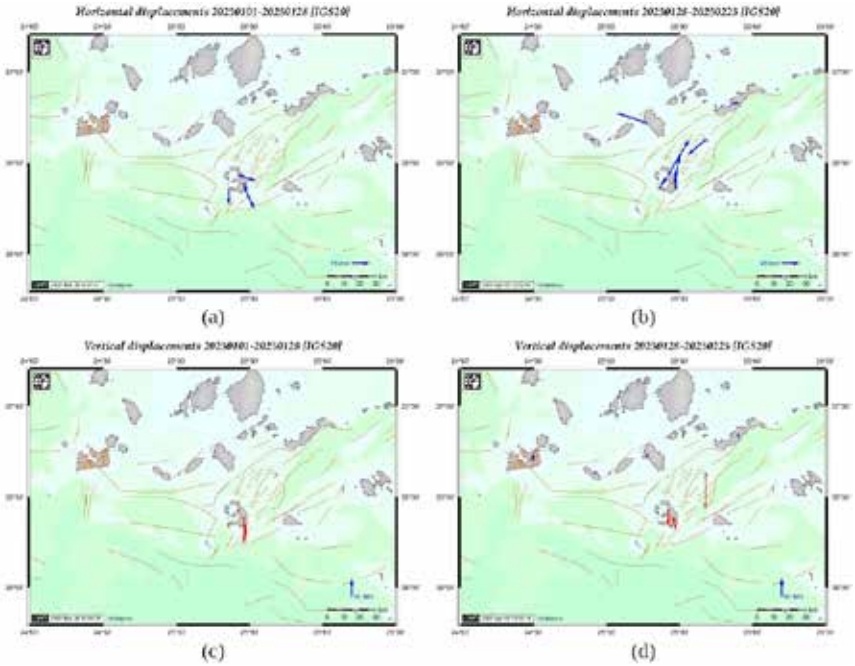

Figure 7 - Horizontal Displacements and vertical displacement of cGNSS stations for two different phases a,c: 01.01.2025-28.01.2025 and b,d: 28.01.2025-25.02.2025

Position time series analysis depicts the different movement of the stations that occurred toward the end of January 2025. Figure 7 illustrates the station displacements in different phases. In Figure 7a, a radial motion of the stations is observed up until the end of January, while in Figure 7b, the stations on Santorini Island are moving in a northeastward direction. A southwestward displacement is observed for the islet of Anydros, and displacements are also estimated on the islands of Amorgos and Ios.

Conclusions

This study presents preliminary results of ground deformation in the Santorini volcanic complex based on a comparison between GNSS campaign measurements from February 2025 and a previous geodetic campaign conducted during the 2011–2012 volcanic unrest. The data analysis, following rigorous transformations and epoch adjustments, revealed coherent displacements in both horizontal and vertical directions, indicating ongoing low-level deflation of a magmatic source beneath the caldera.

While the campaign-based measurements provided valuable spatial coverage and enabled the detection of long-term displacements, the approach has certain inherent limitations when compared to continuous GNSS (cGNSS) monitoring. Continuous GNSS stations offer high temporal resolution, allowing for the detection of short-term deformation transients, long-term trends, and episodic events that may be missed during isolated campaign observations. Moreover, cGNSS data are less affected by field-related errors such as antenna setup inconsistencies, multipath, or variations in session duration—factors that can introduce uncertainty into campaign-based results.

In contrast, the campaign method, while logistically simpler and cost-effective, captures only snapshots in time, making it less suitable for detecting subtle temporal variations or dynamic deformation processes. Nevertheless, it remains a useful tool for benchmarking long-term change, especially when co-located with cGNSS stations for cross-validation.

Future work should aim to integrate campaign results with continuous time series and InSAR data, enabling a more complete and time-resolved picture of the geodynamic processes at Santorini. Expansion of the permanent GNSS network and reoccupation of additional historical benchmarks will further improve spatial resolution and strengthen long-term volcanic monitoring in the region.

Acknowledgements

We thank the GNSS data providers NOA, NKUA, University of Patra, Hellenic Cadastre, Metrica, and JGC. These institutes and private companies provide RINEX data of permanent stations free of charge.

Managing volcanic risk encompasses a multifaceted and crucial field, aimed at reducing the hazards posed by volcanic eruptions to human life, infrastructure, and the surrounding environment. This endeavor includes preparedness planning, monitoring, and responsive actions, with continuous monitoring of volcanic activity using state-of-the-art technology and geophysical tools being the first and most essential step (Katsigera et al., 2024).

SANTORY is a state-of-the-art project aiming at submarine volcanic hazard monitoring in the Aegean Sea. Focused on the Kolumbo submarine volcano NE of Santorini Island, this cutting-edge observatory combines advanced imaging, geophysical and geochemical measurements, and real-time monitoring technologies to address one of the region's most important volcanic threats (Nomikou et al., 2022).

For the operation of the observatory, three oceanographic cruises were conducted, during which specialized scientific instruments were deployed inside the crater for several months (Figure 1), later retrieved to collect data, and subsequently re-deployed. These instruments included: the SANTORY underwater observatory, which comprised sensors for collecting acoustic data, temperature (T°C), CO_2, H_2S, O_2, pressure, electrical conductivity (EC), pH, and turbidity; tilt current meters for measuring marine currents within the crater; specialized thermometers for monitoring temperature changes in the polymetallic chimneys of the hydrothermal field; optical cameras positioned in front of active polymetallic chimneys to record hydrothermal fluid flow; and advanced underwater recording stations for measuring physical parameters in water, such as turbidity, temperature, conductivity, pressure, and oxygen levels. Additionally, the ROV was equipped with the following instruments for real-time data collection: a multispectral and stereo camera ("THEIA") for capturing the texture of the seafloor with multispectral data; the gSniffer device for real-time γ-radiation measurements; the γ-radiation imager ("SUGI") for real-time γ-radiation imaging; and a UV camera ("CHERI") for detecting Cherenkov radiation, marking a global first in underwater applications (Figure 2).

Over the past two years, SANTORY has provided unprecedented insights into Kolumbo's geological dynamics and volcanic activity. High-resolution 3D mapping revealed steep slopes, mass-wasting deposits, and hydrothermal vent fields, critical for assessing seafloor instability and potential eruption risks. Novel hyperspectral imaging and autonomous video systems have captured persistent vent activity, bubbling plumes, and environmental changes, thus providing the most complete assessment of hydrothermal processes to date and establishing a baseline for potential tracking of underlying volcanic processes.

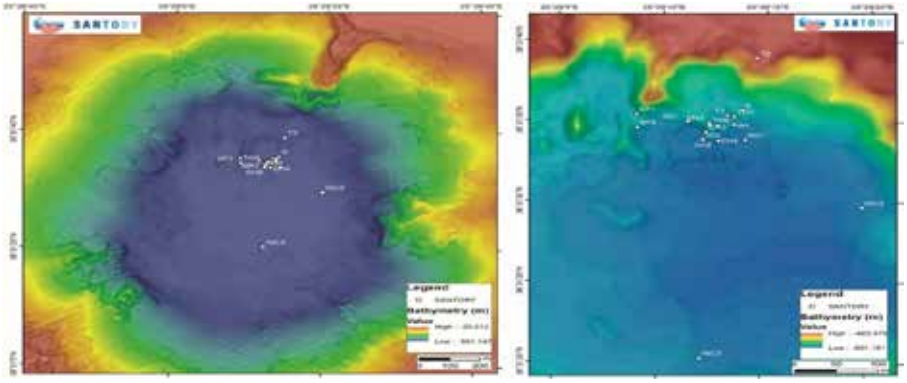

Figure 1. Bathymetry map of Kolumbo crater. Bathymetric data were collected by GEOMAR's autonomous underwater vehicle (AUV) Abyss during mission POS 510 (Hannington et al, 2018). The points indicate the location of the SANTORY observatory and its instruments along the hydrothermal vent field.

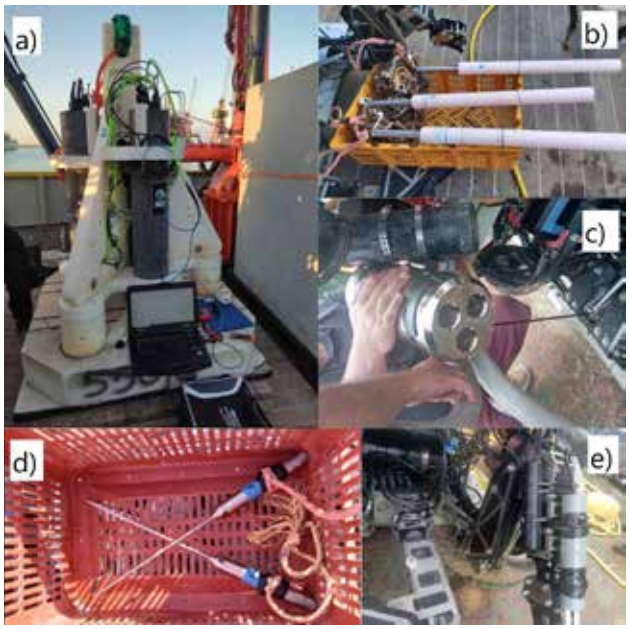

Figure 2. Photographs showing a) the SANTORY observatory, b) The tilt current meters of SANTORY placed in the Kolumbo crater, c) the multispectra and stereo camera "THEIA", d) the sensitive high-temperature thermometers and e) gSniffer for real-time γ-radiation measurements, conducted for the first time on a global scale.

Autonomous sensors deployed on the crater floor have been monitoring hydrothermal outflow temperature, pressure, and chemistry of fluids; these parameters will help quantify chemical fluxes, and reveal periodic variations driven by tides, in addition to magmatic activity. Datasets revealing these hydrothermal fluctuations may thus be critical in detecting precursor signals of volcanic unrest (e.g., changes in subsurface permeability, magmatic degassing). Chemical and isotopic analyses of hydrothermal fluids have revealed the degassing of CO_2-rich fluids characterized by a mantle-like 3He/4He signature. These findings highlight Kolumbo's potential for hazardous eruptions and its classification as a high-risk volcanic system.

Through the program, innovative results emerged, highlighting the uniqueness of the Kolumbo submarine volcano. Acoustic data collected every 30 minutes included one-minute recordings that revealed local hydrothermal events and bubble activity related to CO2 release in the 4000-8000 Hz range (Figure 3). Algorithms were developed to differentiate hydrothermal noise from environmental background noise, identifying bubble radii primarily in the range of 0.20-0.54 mm. Persistent and active bubble activity was observed within the hydrothermal field, with high temperature recordings (232°C) inside hydrothermal chimneys. Local hydrothermal events and fluid dynamics were identified, showing synchronized variations and anomalies in current meters, significant cooling phenomena, and high-velocity currents regulated by tidal forces.

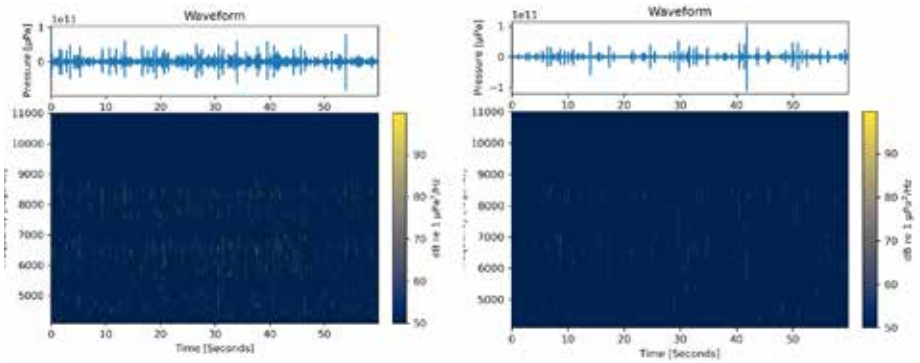

Figure 3. Bubble activity recording from the SANTORY observatory. Bubble activity was detected in the range of 4000-8000 Hz. Due to the presence of ambient noise overlapping the same band, a specialized algorithm was developed to better isolate bubble noise events.

Geochemical analysis confirmed acidic and slightly reducing conditions on the crater floor, helium isotopic composition indicating mixing of atmospheric and magmatic sources, and high concentrations of mercury (Hg) and methylmercury (MeHg) pointing to potential natural pollution. CO2 concentrations were extremely high (96%). Water samples collected at various depths showed anomalies in magmatic/geothermal gases, while trace elements such as Mn, Cs, and Hg exhibited significant deviations. A pH decrease above active chimneys was observed between December 2022 and October 2023, with the lowest value recorded during the last expedition (pH=5.33; 10/2023).

For the first time, natural radioactivity data were recorded within the Kolumbo hydrothermal field. The typical radioactivity measurement rate recorded away from the seafloor and known hydrothermal fields ranges around 1–2 counts per second. In contrast, radioactivity near the hydrothermal chimneys of Kolumbo reaches an impressive level, approximately three orders of magnitude higher, with a maximum of 996 counts per second (Figure 4).

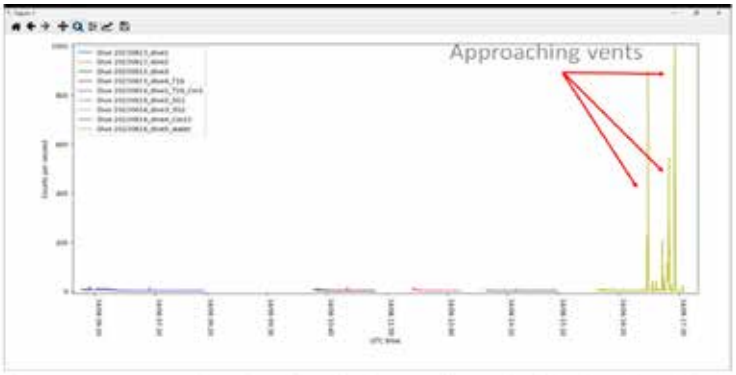

Figure 4. Radioactivity measurements inside the Kolumbo crater. Radioactivity near the hydrothermal chimneys reaches an impressive level, approximately three orders of magnitude higher, with a maximum of 996 counts per second.

Additionally, isolation of microorganisms from Kolumbo's extreme environment was achieved, where these microorganisms are of particular interest for biotechnological applications as they possess unique mechanisms for adapting to extreme conditions. Microbial data also unveiled diverse communities thriving in hydrothermal vent systems, offering insights into their metabolic pathways and resilience mechanisms. Metagenomic analyses uncovered new information about the carbon and methane cycles, which directly impact our planet's climate.

The project results provide valuable information for assessing volcanic hazards, contributing to the protection of the region from natural disasters, safeguarding human lives, and supporting the local economy. SANTORY is more than a research project—it is an initiative for developing a protocol for volcanic hazard mitigation that can be extrapolated to other submarine systems. By integrating cutting-edge technologies and multidisciplinary expertise, the project delivers actionable insights to improve early warning systems and protect vulnerable coastal communities. SANTORY sets a new benchmark in safeguarding against submarine volcanic threats.

All scientific data are accessible through the SANTORY Open Data Hub platform, available to both the residents of the Municipality of Thira and the scientific community. https://santory-open-data-hub-nom.hub.arcgis.com/

Acknowledgements

We are thankful to the International Ocean Discovery Program (IODP), the technical staff of the JOIDES Resolution, and all of the shipboard personnel for a great expedition. We also thank the member organizations of IODP for financial aid, and the Municipality of Thera for help in preparing for the expedition.

Flash drought assessment: insights from Lesvos island, Greece

Katsora, C.[1], Leivadiotis, E.[2], Tzoraki, O. [1], Papadopoulou, N.[1]
(1) University of the Aegean, Mytilini, Lesvos, Greece, geoha23008@geo.aegean.gr, ckatsora@gmail.com
(2) University of Thessaly, Volos, Greece

Traditional drought definitions characterize them as prolonged periods of below-average precipitation, resulting in gradual soil moisture depletion (Wilhite & Glantz, 1985). However, the emergence of flash droughts (Christian et al., 2021), characterized by rapid onset and intensification, challenges this traditional view. While a universally accepted definition remains elusive, key characteristics include rapid soil moisture depletion, often within days or weeks, and significant impacts on agriculture, livestock, and water resources (Oetkin et al., 2018).

Effective flash drought monitoring is crucial for early warning systems and mitigation efforts (Pakkasagi et al., 2023). Monitoring techniques (Lisonbee et al., 2021) encompass satellite remote sensing for soil moisture, vegetation health, and precipitation; ground-based observations from weather stations and soil moisture networks; meteorological models for forecasting; and drought indices such as the Standardized Precipitation Index (SPI) (McKee, 1993), the Evaporative Demand Drought Index (EDDI) (Li et al., 2024), and the Standardized Precipitation Evapotranspiration Index (SPEI) (Spinani et al., 2017).

This study investigates historical flash drought occurrences on Lesvos island (Figure 1a), Greece, an island characterized by a hot-summer Mediterranean climate (Csa), that experiences significant seasonal and spatial rainfall variability, high temperature oscillations, and an average annual temperature of 17.78 °C. The island exhibits diverse vegetation types, reflecting its natural environment and historical agricultural practices (Figure 1b), which can influence vulnerability to flash drought events.

The historical flash drought events have been identified by employing two indices, requiring minimal datasets while yielding reliable results: the Standardized Precipitation Evapotranspiration Index (SPEI) and Soil Moisture (SM).

Figure 2 provides a graphical illustration of the methodology employed for FD identification using the SPEI. This represents a simple climatic water balance (i.e. difference between precipitation and potential evapotranspiration (PET). Meteorological data, comprising precipitation and temperature records from the Agia Paraskevi, Akrasi, and Sigri stations (Figure 1a), were analyzed using R scripts to identify historical flash drought events. This analysis identified forty flash drought events within the past 15 years (Figure 3), with a peak occurrence between March and June (Figure 4a) and an average duration of approximately eight pentads (Figure 4b). The years 2018 and 2012 experienced the most intense (Figure 4c) and severe (Figure 4d) flash drought events within the northeast and north regions, respectively.

Hourly soil moisture data from the ERA5 reanalysis dataset (1950-2024) were used to evaluate the spatial extent, frequency, magnitude, and intensity of flash drought events across Lesvos island. Following the methodology outlined in Figure 5, the results show a higher frequency of flash droughts in the northern part of the island (Figure 6a). The most severe events, characterized by higher magnitude and intensity (graphically presented as percentages), were also observed in the north-northeastern region (Figure 6b,c).

Given the success of this methodology, which integrates meteorological data (precipitation and temperature) with satellite-derived soil moisture, it has the potential for application in other Mediterranean regions with similar climatic characteristics. This approach can be valuable for identifying flash drought occurrences, assessing associated risks, and developing effective mitigation and adaptation plans.

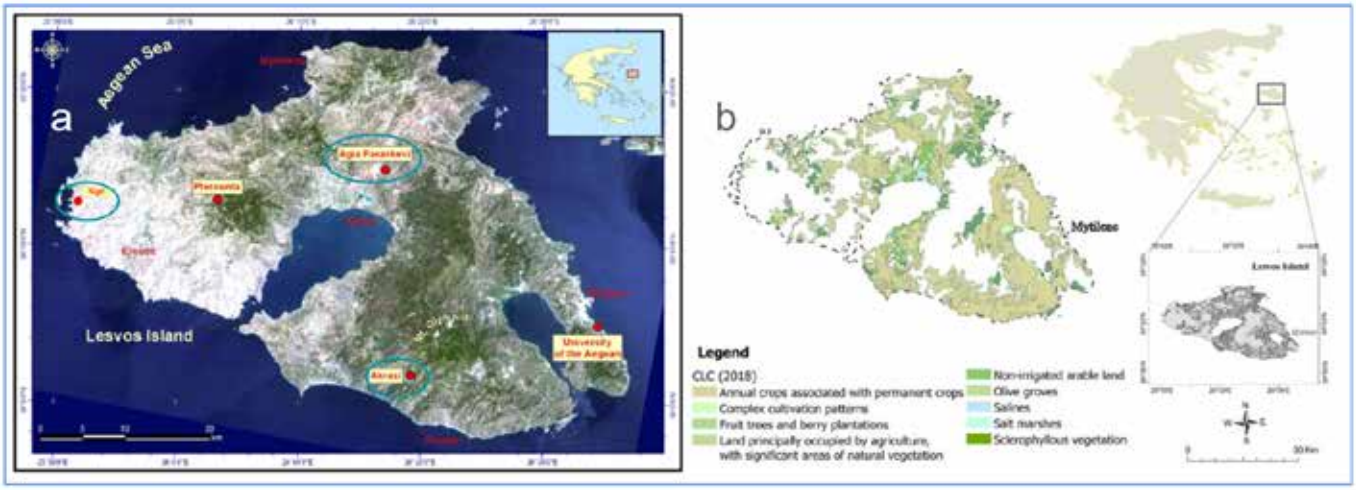

Figure 1: a. Area of interest with available meteorological stations, b. Vegetation types in Lesvos (Palaiologou *et al.*, 2012)

Step 1

Prepare data (precipitation, maximum temperature and minimum temperature):

- remove missing values,
- define the analysis period,
- aggregate the daily data into pentads (five-day periods).

Step 2

Calculate SPEI for each pentad:

- calculate potential evapotraspiration (PET), using Thornthwaite method,
- compute the water balance as the difference between precipitation and PET (Precipitation - PET).

Step 3

Identify flash drought events when SM value falls between the 40th and 20th percentile, with event durations up to 8 pentads (40 days):

- exclude events shorter than 4 weeks from further analysis,
- focus on detecting valid endpoints of FD events that meet the defined criteria,
- remove overlapping onset-endpoint pairs to ensure independent event identification.

Step 4

Calculate flash drought characteristics:

- Frequency: Calculate the total frequency of the FD events,
- Duration: calculate the duration of each FD event, as the absolute value between the start and end pentad, divided by 5 (expressed in days),
- Magnitude: calculate the magnitude of each FD events as the absolute difference between the endpoint and the SPEI value at the onset,
- Intensity, calculate the intensity of each FD event by dividing the magnitude by the duration.

EXTENDED ABSTRACT 145

Rainfall-induced landslides in Corfu island: effectiveness of the regional scale landslide susceptibility map

Kavoura K.[1], Konstantopoulou G.[1], Paschos P.[1]
(1) Hellenic Survey of Geology and Mineral Exploration, Acharnaes, Greece, aikavoura@eagme.gr

Research Highlights

Introduction

A long term investigation on landslide phenomena in Corfu Island, consumes that the majority of them are strongly connected with rainfall events hit Western Greece and Ionian Sea islands, annually. The last years an increasing number of precipitation events occurred in Greece are characterized by meteorologists as extreme events, with a large amount of rain falls in a short time. Depending on the geomorphological and geological conditions of a specific area, this kind of events usually induce soil erosion moreover lead to landslides and floods. For Corfu island, according to the Hellenic National Meteorological Survey the mean annual rainfall is around 1100mm, while high rainfall frequency between October and November is recorded. Additionally, the abundance of recent landslides occur in this period. Based on the landslide database of the Hellenic Survey and Mineral Exploration (H.S.G.M.E.) from 1959 to 2022, 203 landslides in a 592 km^2 area have been officially recorded and mapped into a multi-temporal landslide inventory map.

Analyzing the landslides inventory some interesting results are extracted about landslide features. It is shown that 77% of the landslides are hosted in Neogene sediments followed by Quaternary formations and artificial fills while several rockfalls occur in limestones. Serious instability phenomena are often observed as rotational or translational slides (80%), while in some cases complex landslides occur. Moreover, soil creep often be an important process on extensive areas of the island. Almost 85% of the recorded landslides are located within residential areas and road network, while the rest within forests and cultivated lands (Konstantopoulou *et al*., 2019). In addition, it is stated that rainfall consists the main triggering factor of landslides in this area.

In general, the study area is prone to landslides, but where? Landslide susceptibility assessment is an important tool for identifying areas prone to landsliding. A preliminary landslide susceptibility map of the Corfu Island was presented by Konstantopoulou *et al*., 2022, using the Frequency Ratio (FR) statistical model and four commonly used predisposing factors (lithology, land use, slope, distance from road network). That assessment had a very good ability to classify landslides in susceptibility zones with ROC curves analysis give an AUC=0.895. A newer landslide susceptibility assessment was presented by Kavoura *et al*., 2024 using FR model and six predisposing factors (lithology, land use, slope, road network density, distance from rivers, distance from faults).

An important stage in landslide susceptibility assessment is to evaluate the effectiveness of the produced landslide susceptibility map by transparent validation. The standard evaluation approach is to analyze the agreement between the resulting map and observed data (Corominas *et al*., 2014). This study discusses the quality of the final landslide susceptibility map highlighting the transparency and the acceptance of such maps.

Objectives

Many techniques have improved in order to evaluate the quality of landslide susceptibility models. In this study besides the ordinary validation checks, such as Receiver Operating Characteristics (ROC), the actual predictive performance of future landslide phenomena also be assessed.

The objective of this study was to provide a coordinated approach for quality assessment of landslide susceptibility analysis by focusing not only on the calculation, but also on the evaluation process, even if the landslide susceptibility assessment was prepared under a statistical based method (FR model). More precisely, this approach uses retrospective data from landslides to examine the predictive performance of landslide susceptibility map (Fleuchaus *et al*., 2021). The predictive performance of the susceptibility map was evaluated based on different landslide events triggered by heavy rainfall events between 2022 and 2024.

Methods

For the assessment of susceptibility at regional (1:50,000) scale, six key-role predisposing factors were selected that are often used in such analyses based on literature review and experience in landslide studies. The factors were chosen to reflect the general geological, topographic and environmental settings in the study area:

1. Road network density, represents the impact of road network in occurrence of landslides (Figure 1a)
2. Slope angle, is a fundamental factor in slope stability analysis leading also the landslide mechanism (Figure 1b)

3. Land cover, this factor is associated with human activities. Changes in land uses bring changes to landslide susceptibility (Figure 1c)
4. Geotechnical units, one of the most important factors while failure occurs because the force of gravity becomes greater than either friction or the internal strength of the rock or soil (Figure 1d)
5. Distance from faults, refers to the geotechnical quality of rockmass and soil formations (Figure 1e)
6. Distance from hydrographic network (Figure 1f)

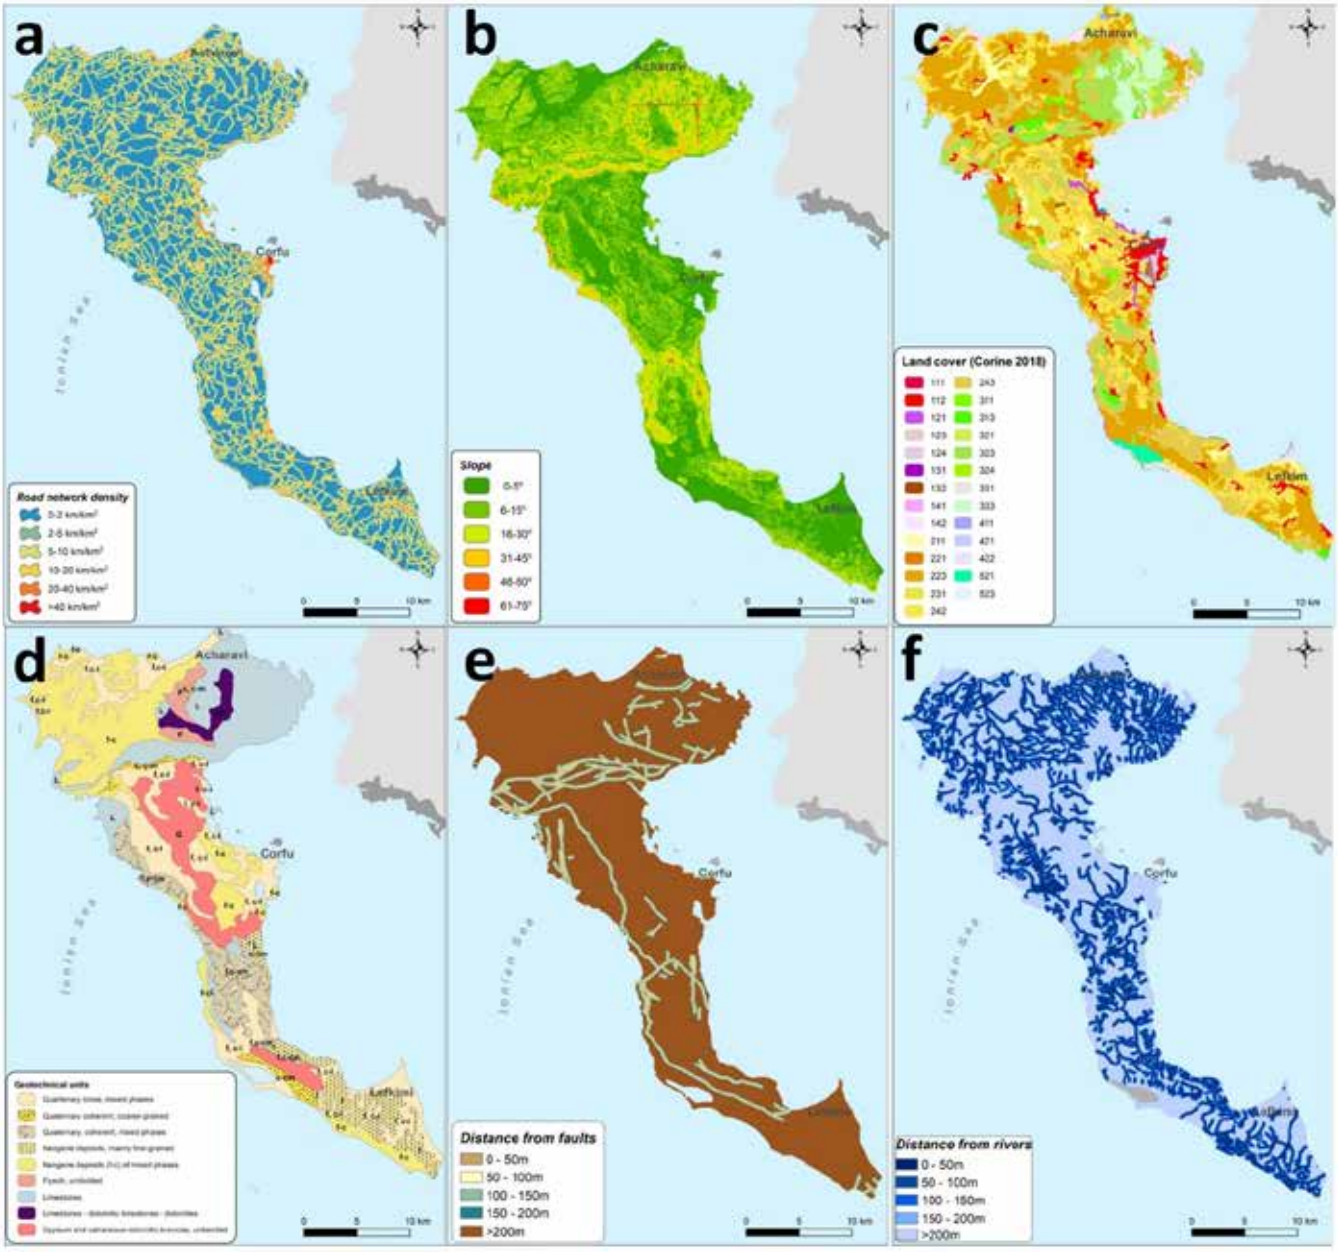

Figure 1. Predisposing factors a) Road network density, b) Slope angle, c) Land cover, d) Geotechnical units, e) Distance from faults and f) Distance from hydrographic network

The Frequency Ration (FR) model was applied to define weights for each factor, using the ratio of the per-centage of landslides in a class of the selected factor to the percentage of the area of this class in the study area. The classification of the susceptibility level is given in a percentage scale of 10%, so that each class differs from the next in terms of the degree of susceptibility, i.e. the probability of a landslide occurring in the area according to the conditions of the area, by 10%. The lower the percentage the lower the susceptibility level (Figure 2).

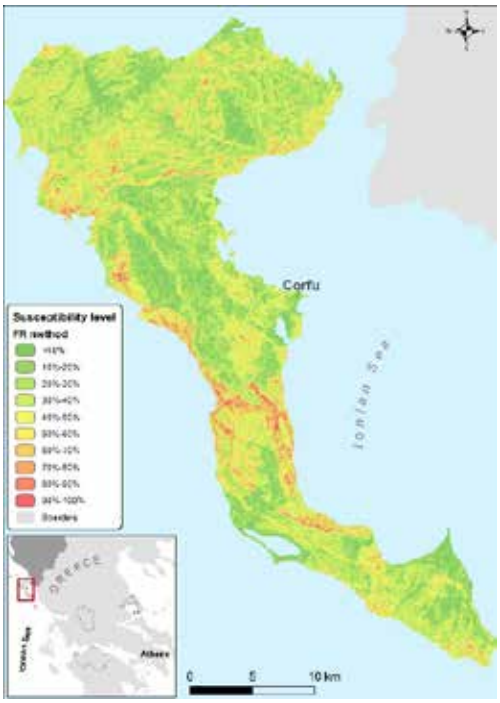

Figure 2. Landslide susceptibility map of Corfu Island

Receiver Operating Characteristic (ROC) curves were used, firstly for checking the reliability of the proposed model (success rate curves) as well as to check the ability of the model to pinpoint landslide-prone areas (prediction rate curves). In the first face, the model was checked using a training set of landslides (landslides were activated before 2020) and an equal number random set of points free of landslides. The process was repeated for the validation set of landslides (landslides were activated after 2020) in order to find if these independent landslide occurrences were correctly adapted in different susceptible areas. It is indicated that in Corfu Island the model can correctly predict the susceptible areas while AUC value is approximately 0.9 ($AUC_{success}$= 0.893 and $AUC_{predict}$=0.906).
Although the study achieves an AUC value higher than 80%, the landslide susceptibility map is subject to the predictive power of landslides activated after 2022, considering the impact of inaccurate input data or the over- and underestimation of causative factors. For this reason, a brief search was made in the local press to find unrecorded landslides in the HSGME database that were activated after 2022. This resulted in the identification of four independent rainfall – induced landslide events in different parts of the island according toTable1.

Table 1. Landslide events after 2022

Landslide event	Rainfall event	Rainfall[1]	Area
1st	8-13/12/2022	57.4 mm	Agios Dimitrios – Chlomos
2nd	19/8/2024	19.4 mm	Ano Garouna
3rd	9-10/9/2024	133 mm	Sinarades – Agios Gordios
4rth	8/1/2025	19.2 mm	Episkepsi (Megas Lakkos)

1: Weather station of Gouvia, Corfu (National Observatory of Athens network).

Results and Conclusions

The posterior validation of the landslide susceptibility map was performed based on the distribution of landslides for individual susceptibility classes (Pareek *et al*., 2024). According to Figure 3a, the majority of landslides are located along slopes in the Chlomos area predicted as being highly susceptible to landslides over 75%. Both landslides of 2024 were activated in Ano Garouna village (Figure 3b) and Sinarades – Agios Gordios (Figure 3c) area were well predicted and plotted into the susceptibility class of 70%-80%. The most recent landslide occurred in January 2025 on a slope of a mountainous road in North Corfu. As illustrated in the Figure 3d the phenomenon is closely linked to a highly susceptible zone along the road.

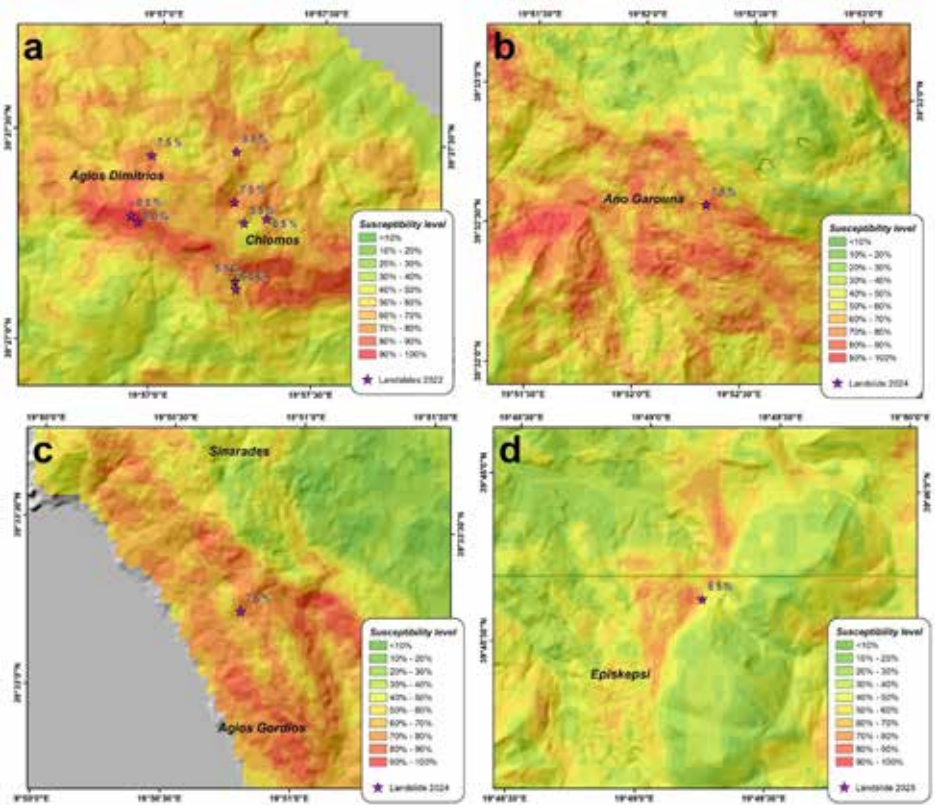

Figure 3. Evaluation of landslide susceptibility map abstracts with overlaid recent landslides at a) Chlomos and Agios Dimitrios villages, b) Ano Garouna village, c) area between Sinarades and Agios Gordios and d) wider area of Episkopi village

The retrospective validation presented in this study revealed significant correlation of the landslide susceptibility map of Corfu Island with respect to recent landslides for the period 2022 – 2025. In particular, the 60 % of the landslides, were activated into the susceptibility class of 70%-80%. This work highlights that the retrospective validation approach could be a promising assessment tool in the field of landslide susceptibility evaluation. While HSGME serves the Nation by providing reliable scientific information and thus minimizing loss of life and property from natural disasters, this research could be a basic tool for managing a sustainable hazard and risk mitigation program in landslide prone areas

EXTENDED ABSTRACT 146

Origin of nitrate pollution in groundwater of Mygdonia Plain, Greece

Kazakis Nerantzis[1*], Sideri Ioanna[1], Ntona Maria Margarita[2], Stavropoulou Vasiliki[1], Lampropoulou Dimitra [3], Zagana Eleni[1], Voudouris Konstantinos[2]

(1) Laboratory of Hydrogeology, Department of Geology, University of Patras, Faculty of Natural Sciences, 26504 Rion, Patras, Greece, nkazakis@upatras.gr (2) Laboratory of Engineering Geology & Hydrogeology, Department of Geology, Aristotle University of Thessaloniki, 54124 Thessaloniki, Greece (3) Department of Chemistry, Aristotle University of Thessaloniki, 54124 Thessaloniki, Greece

Research Highlights

- The highest concentration of nitrate is 208 mg/L occurring during the dry period.
- Dual nitrate isotopes in groundwater samples from deep boreholes indicate manure and sewage as primary nitrate sources.

Introduction / Background

Groundwater and surface water nitrate pollution constitute an important environmental issue worldwide. The primary source of nitrate pollution is usually human activities, particularly in regions heavily influenced by agriculture and livestock farming (Kazakis *et al*., 2020). In numerous aquifers across Greece, nitrate concentrations exceed the maximum permissible limit for drinking water (50 mg/L), raising significant concerns due to their potential adverse impacts on human health (Daskalaki and Voudouris, 2008). This research was conducted in a Mediterranean region affected by nitrate pollution where the groundwater originates from porous, karsts and fractured rock aquifers.

This study is focused on the administrative boundaries of DEYA Oraiokastrou due to the elevated concentrations of nitrate in drinking water. The determination of nitrate origin and regime in the porous aquifer is of utmost importance in order to map the polluted aquifer layers and locate zones with nitrate concentration below the permitted drinking limit (50 mg/L).

Study area

The study area is located in Mygdonia Basin, northern Greece. It has a typical Mediterranean climate with a mean annual rainfall of 496 mm for the period of 2015-2022, while the minimum and maximum values observed were 391 mm and 550 mm, respectively. The temperature varies from 11.9 ˚C to 20.6 ˚C with a mean annual temperature of 15.8 ˚C (data from meteo.gr). From a geotectonic perspective, the basin includes two major structural zones: the central and eastern parts are associated with the Serbo-Macedonian Massif, while the western region, where the study area is located, belongs to the Circum Rhodope Belt (Meinhold and Kostopoulos, 2013). The geological substratum comprises Paleozoic two-mica gneisses and amphibolites of the Serbomacedonian Massif, along with Mesozoic phyllites, quartzites, clay-schists, marbles, and granites of the Circum Rhodope Belt (Mountrakis *et al*., 2006). Neogene deposits, primarily red clays, overlay these bedrock formations, with extensive Quaternary materials, including sandy clays, sands, and gravels, dominating the geological formations of the area (Figure 1). The study site is hydrologically divided into two sub-catchments: Koronia sub-basin and Volvi sub-basin. The study area belongs to the 10th Water District of Greece (GR10) and mainly falls within the Cholomontas – Oraiokastro and Koronia Groundwater Systems. According to the second revision, the qualitative and quantitative status of the Koronia Groundwater System is characterized as poor. The aquifer systems in the basin exhibit considerable heterogeneity, with alluvial deposits hosting both shallow unconfined and deeper confined aquifers, while fractured rock aquifers with variable permeability are found within the metamorphic formations (Mylopoulos *et al*., 2007; Devlioti *et al*., 2023).

This complex geological and hydrogeological setting highlights the importance of the Mygdonia Basin as a critical area for tracing nitrate sources in groundwater. The land use in the study area, based on the data from the Corine land cover, is provided in pie diagrams of Figure 2. Based on these data the landscape is primarily allocated to agriculture, with moderate forest coverage and limited urban and industrial development. Agricultural land is the dominant land use, with non-irrigated arable land constituting the largest portion (62%), followed by complex cultivation patterns (26%). Forested areas are primarily broad-leaved forests (45%) and coniferous forests (42%), with smaller contributions from natural grassland and other vegetation types. Artificial surfaces cover the minimum part of the study area and are mainly composed of discontinuous urban fabric (41%) and industrial or commercial units (27%).

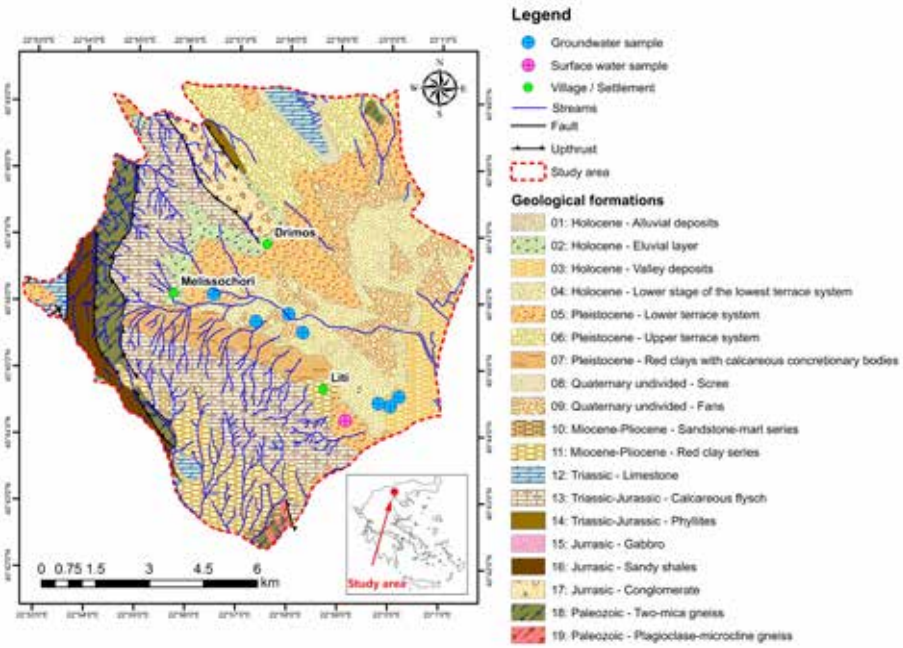

Figure 1. Study area with the groundwater and surface water sampling points.

Methodology

Groundwater and surface water samples were collected from the Mygdonia Basin during two field campaigns conducted in June and September 2023. Sampling locations were strategically selected following a judgmental sampling approach, as described by Ntona *et al.* (2023). The collected samples were analyzed to determine the concentrations of major ions and to perform stable nitrate isotope analyses of $\delta^{15}N\text{-}NO_3^-$ and $\delta^{18}O\text{-}NO_3^-$. Prior to collection, the sampling equipment was thoroughly cleaned with distilled water. Groundwater samples were collected from the well monitoring points and filtered through 0.45 μm filters to remove particulates. The filtered samples were then divided into aliquots, for isotopic analysis. The isotopic data was analyzed to distinguish between different nitrate sources, including synthetic fertilizers, animal manure, and organic matter decomposition. The chemical analyses of water samples were conducted by a private laboratory. The nitrogen isotopes in water ($\delta^{15}N$ and $\delta^{18}O$) were measured in the Isotopic Biotechnology Laboratory of the University of Ghent.

Results and discussion

The results of the chemical and isotope analysis provide important information to understand and investigate the hydrogeological regime of the groundwater in the study area. The water samples have been categorized in various diagrams providing their suitability for human consumption and irrigation purposes. Based on the Durov (Durov, 1948) diagram (Figure 3a), specifically in the square section, in most samples the predominant ions are HCO_3^- and Ca^{2+}, usually indicating rapid water recharge. The rest of the samples plotted higher with primary ions Ca^{2+} and Mg^{2+}, are due to the ion exchange processes. Referring to the Piper diagram (Piper, 1944), in the anion triangle, all samples are concentrated in the HCO_3^- section, while in the cation triangle, all groundwater samples are projected towards Ca^{2+} and the surface water samples have no dominant type (Figure 3b). Most samples are characterized as Ca^{2+}-Mg^{2+}-HCO_3^- water type, while the surface water sample collected in June is separated from the rest samples with higher concentrations of sodium compared to calcium.

The EC values of the same sample vary from 837 to 880 μS/cm, while the pH is 8.1 in the sampling periods. Regarding the suitability of water bodies for irrigation purposes, the Wilcox (Wilcox, 1995) diagram (Figure 4a) was used, which depends on the sodium percentage against electrical conductivity, and indicated that water is of good to permissible quality for irrigation, while only one groundwater sample collected in September showed good to excellent quality. In addition, Richard's plot (Richards, 1954) (Figure 4b) was applied to classify water samples in terms of the degree to which they can cause difficulty in the permeability of soils and the infiltration process, based on their electrical conductivity and the sodium adsorption ratio. Most samples are classified as high salinity hazard and low sodium hazard, indicating that the water

quality is medium and not suitable for semi-tolerant crops (Jafar Ahamed, 2013). Some samples collected in September are categorized as having medium salinity hazard and low sodium hazard, which means they do not require special measures for managing salinity.

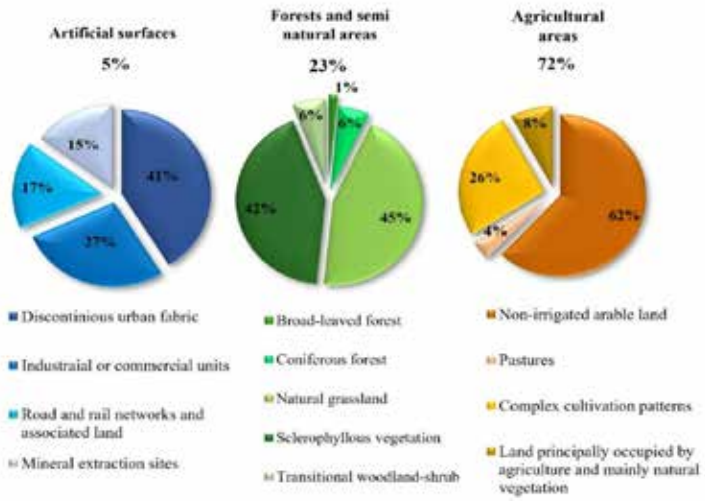

Figure 2. Pie diagrams with the percentages of land use in the study area.

The results of the physicochemical analyses (Table 1 and Table 2) on the samples showed that the pH values in June 2023 ranged from 7.3 to 7.7 and in September 2023 from 7.4 to 7.7 characterizing the groundwater as neutral to alkaline. Electrical conductivity (EC) varies from 831.0 to 1315.0 μS/cm and 734.0 to 1315.0 μS/cm during wet and dry periods, respectively. It is noted that the wider area is characterized by the presence of geothermal fields (Chantzi and Dotsika, 2016).

Nitrate concentrations for the two sampling periods showed a range from 47.8 mg/L to 154.0 mg/L in June and from 49.3 mg/L to 208.0 mg/L in September. The average concentration increased from 100.9 mg/L in June to 128.6 mg/L in September, representing a 27.5% rise.

In addition, almost all samples exceeded the permissible limit of nitrate concentration in drinking water (50 mg/L), with the exception of two samples, one for each period, which are quite close to this limit. With regard to the remaining nitrogen species, NH_4^+ appeared in all the samples with values lower than the detection limit of 0.06 mg/L, while NO_2^- concentration values were below the detection limit of 0.03 mg/L in almost all samples, with maximum values of 0.3 mg/L and 0.1 mg/L for June and September, respectively.

Land use data and field surveys highlight several potential anthropogenic sources of nitrate, including the extensive application of fertilizers, both manure and chemical types, as well as sewage effluent and solid waste disposal practices. To enrich the current results, the dual nitrate isotopes have also been utilized to investigate the contributors of nitrate pollution in the study area (Table 3). The dual nitrate isotope cross-plot diagram (Figure 5) serves as a key analytical tool for identifying the predominant nitrate sources.

Maximum	1315.0	7.7	164.0	39.3	1.5	50.3	154.0	77.7	88.8	437.0
St. Deviation	149.4	0.2	19.66	6.3	0.3	8.4	35.89	12.3	22.7	25.7

Table 2. Statistical analysis of the groundwater samples during the dry period of 2023.

Parameter	EC	pH	Ca^{2+}	Mg^{2+}	K^{+}	Na^{+}	NO_3^-	SO_4^{2-}	Cl^-	HCO_3^-
Values	µS/cm		mg/L	mg/L	mg/L	mg/L	mg/L	mg/L	mg/L	mg/L
Minimum	734.0	7.4	110	19.6	0.5	24.0	49.3	37.7	22.4	375.0
Average	934.0	7.5	136.9	29.0	0.9	39.6	100.7	57.3	53.2	414.3
Maximum	1315.0	7.7	187.0	41.7	1.2	53.7	208.0	74.4	112.0	442.0
St. Deviation	183.9	0.1	26.0	7.4	0.2	9.7	49.4	12.2	29.2	26.6

The results indicate that the majority of the groundwater samples fall within the isotopic range of manure and sewage nitrate sources, as the primary contributors to nitrate pollution in the Mygdonia Plain aquifer. In contrast, chemical fertilizers and soil organic nitrogen were found to play a key role in sample OR1.

The source identification of pollutants such as nitrate constitute the first step for the detection of unaffected aquifer layers. It is obvious that in the study area, chemical fertilizers and manure were excessively used neglecting the protection of groundwater. The upper layers of the aquifer are characterized by extensive nitrate pollution. The next step to secure the water supply for domestic use in the site is the isolation of these layers and pumping from deeper zones. Additionally, the assessment of groundwater vulnerability to nitrate pollution and pollution risk mapping constitutes a further step for water resource management and protection in the wider area of Mygdonia basin.

Table 3. Nitrate concentrations and isotopic composition of groundwater samples.

Sample	$d^{15}N\text{-}NO_3$	$d^{18}O\text{-}NO_3$
	‰	‰
OR1	5.6	3.5
OR2	11.2	4.0
OR3	9.9	3.5
OR4	8.4	4.0
OR5	9.9	3.8
OR6	9.90	3.70
OR7	8.60	4.40

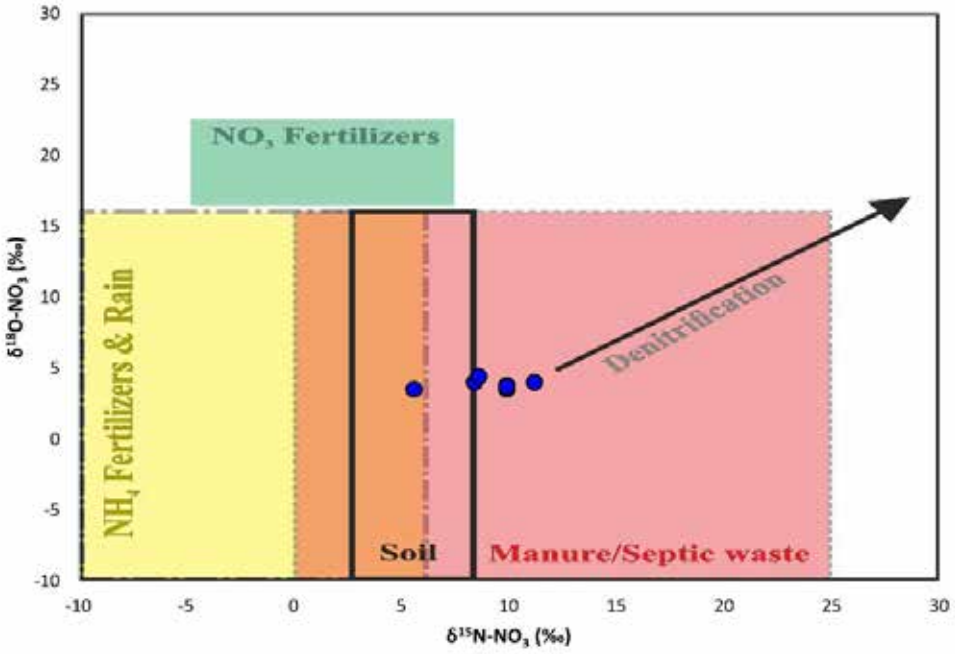

Figure 5. Cross plot of $\delta^{18}O\text{-}NO_3$ and $\delta^{15}N\text{-}NO_3$ of groundwater samples (Kendall, 1998).

Conclusions

This research provides a robust basis for tracing nitrate sources and enhances understanding of groundwater nitrate pollution in the Mediterranean region. The groundwater and surface water samples were collected during June and September 2023, revealing nitrate concentrations that reached up to 154.0 mg/L and 208.0 mg/L, respectively. Using stable nitrate isotopes on groundwater samples plotted on a Kendall diagram, nitrate sources were identified. The main nitrate pollution sources in the Mygdonia Plain aquifer are due to manure and sewage. The hydrochemical analysis of groundwater samples and the plot of water samples on the Piper diagram reveals the Ca^{2+}-Mg^{2+}-HCO_3^- water type of samples.

Further investigation into the role of the geothermal fields on groundwater quality should be implemented in the wider area. Management strategies to mitigate nitrate pollution from these identified sources and protect groundwater quality in the area are of paramount importance. This requires a systematic and continuous monitoring of groundwater quality in Mygdonia Basin.

Acknowledgments

This research was carried out within the framework of the project entitled “Water resources research and nitrate origin in groundwater of the Municipal Unit of Mygdonia” and was funded by the Water and Sewage Management Company of Oraiokastro (DEYAO).

EXTENDED ABSTRACT 147

Micropaleontological and paleoenvironmental study of carbonate intercalations within Boeotia (Greece) clastic formations

Khan S.A[1,2], Tsourou Th.[1], Skourtsos E.[1], Soukis K. [1], Michailidis I.[1], Skampa E.[1], Triantaphyllou M.V.[1]

(1) National and Kapodistrian University of Athens, Department of Geology and Geoenvironment, Athens, Greece, mtriant@geol.uoa.gr (2) Department of Earth Sciences, University of Lille 1, Villeneuve d'Ascq, France

This study aims to define the age and the paleoenvironmental depositional conditions of various carbonate facies within the Western Boeotia-Thessaly Unit in the broader area of Boeotia, central Greece, through the integration of calcareous nannofossil biostratigraphy and sedimentary microfacies analysis.

The existence of an Upper Jurassic–Lower Cretaceous "flysch" spread across multiple paleogeographic regions, both neritic and pelagic, is the main distinctive characteristic of the Western Thessaly–Boeotia unit that belongs to the outermost part of the Internal Hellenides (Papanikolaou, 2013; Papanikolaou, 2021).

The study area (Figure 1) is comprised of the outcrops of the Western Thessaly-Boeotia and the Parnassos units in Central Greece. The Western Thessaly–Boeotia, Late Jurassic–Early Cretaceous Boeotian flysch is followed by Late Cretaceous pelagic breccia limestones of the Thymiama facies, in contrast to the other more internal units, which remain below the Late Cretaceous transgression (e.g., Papanikolaou, 2021). The investigated successions are mainly composed of carbonate intercalations within the clastic sequences of the Boeotian flysch and the limestone of Thymiama. A selection of samples has been analyzed for the present research (Historical Geology and BioGeosciences Laboratory; National and Kapodistrian University of Athens), representing the carbonate intercalations and/or carbonate sequences from the various geological units and facies defined in the fieldwork campaign. Emphasis has been attributed to the calcareous nannofossil biostratigraphic assignment of the sampled clastic sequences (Figure 2).

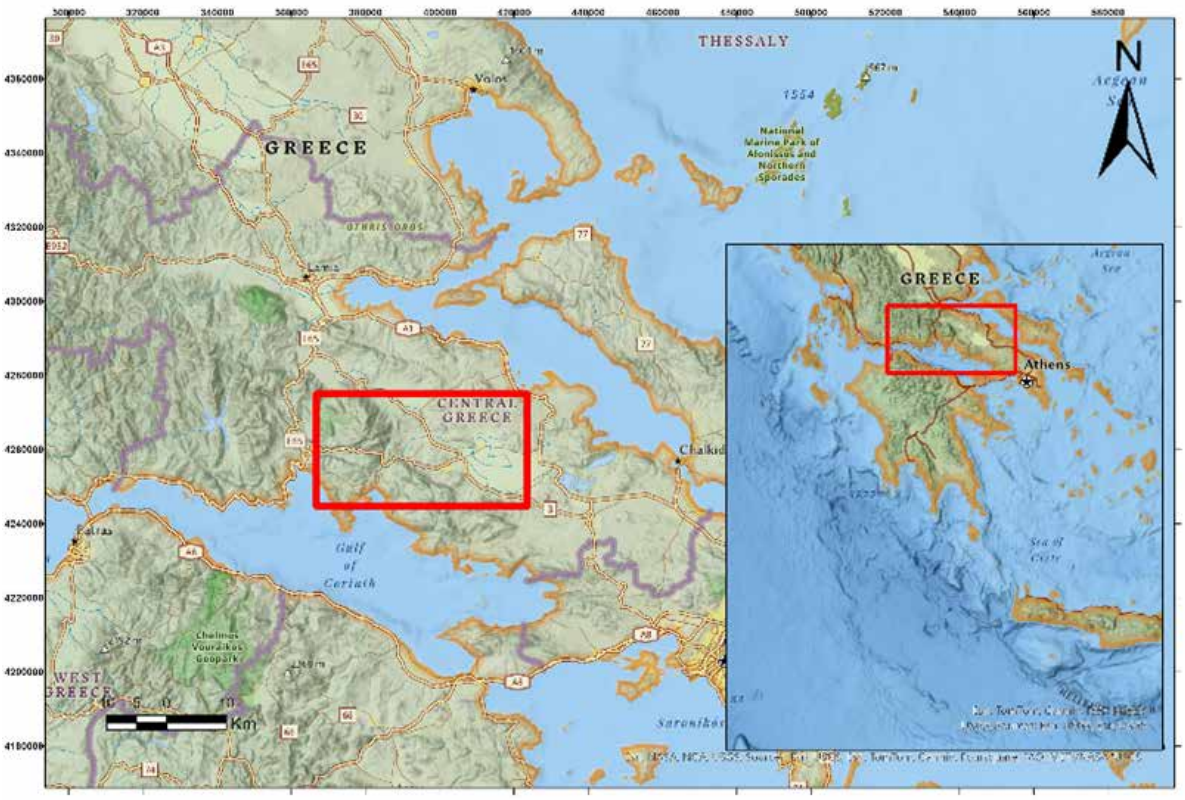

Figure 1. Location map of the study area in Central Greece.

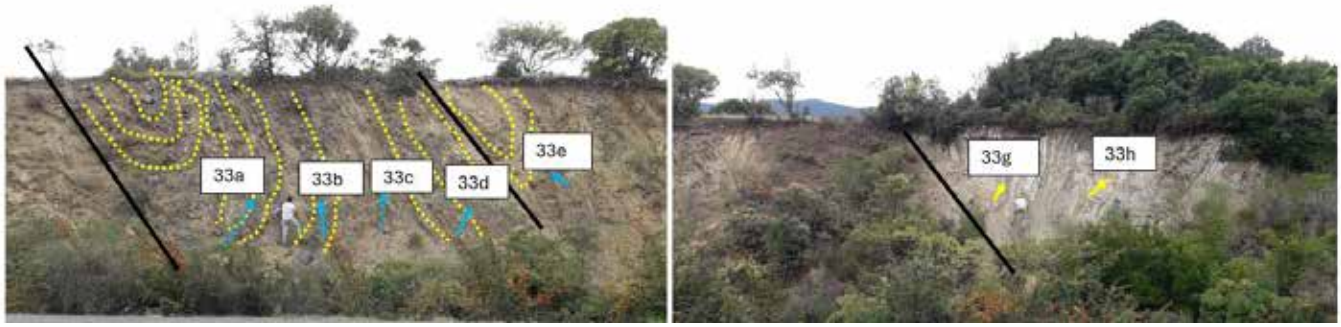

Figure 2. Studied outcrop showing the carbonate intercalations within the clastic sequences of the Boeotian flysch in Karakolithos section.

The nannofossil-based biostratigraphy performed in the clastic sequences being either intercalated or in contact with the studied carbonate samples, suggests that the samples from the Boeotian flysch are of Early Cretaceous age (Berriasian-Valanginian up to Aptian; Nirta et al., 2015; present study). The intercalated carbonate sequences of the Early Cretaceous age Karakolithos section comprise of pelagic biota. Based on the microfacies details, the sediments of the Boeotian flysch have been deposited in toe-of-slope to deep shelf setting in low-energy conditions (FZ-2 and FZ-3). This is evident by the intense presence of radiolarian and planktonic foraminifera within pelagic lime mud.

The Thymiama limestones in Boeotia represent reworked sediments from a reef or platform-derived environments as evidenced by rudist fragments and echinoderms. These have been transported during multiple sedimentary cycles and were redeposited to deeper settings (FZ-4), i.e., a low-energy gradient slope setting, also supported by the occurrence of Orbitolinidae. The nannofossil-based biostratigraphic results from marly intercalations within the Thymiama-type brecciated limestones suggest Turonian age. Also, the Aptian-Cenomanian has been identified in other locations, supporting an overall Aptian-Turonian age for the Thymiama limestones in the Boeotia area.

EXTENDED ABSTRACT 148

" Vikos-Aoos Geopark: Toponyms as a Link Between Geological Heritage and Culture"

Georgia Kitsaki[1], Christos Stergiou[2], Haritakis Papaioannou[3]

(1) Vikos-Aoos UNESCO Global Geopark - Development Agency of Epirus S.A. (EPIRUS S.A.), Ioannina, Greece, gkitsaki@epirussa.gr (2) Stergiou C.L., Faculty of Geology, Aristotle University of Thessaloniki (AUTH), Thessaloniki, Greece / Vikos-Aoos UNESCO Global Geopark, Ioannina, Greece (3) Vikos-Aoos UNESCO Global Geopark - Development Agency of Epirus S.A. (EPIRUS S.A.), Ioannina, Greece

The Vikos-Aoos Geopark serves as a unique example of the interaction between geological formations, the natural environment, and culture, highlighting the enduring relationship between geological heritage and human activity. The region's geodiversity, characterized by designated geosites and a wide variety of geological formations, provides evidence of long-term geodynamic processes that have significantly shaped local ecosystems and biodiversity. At the same time, these geological features have been utilized by local communities, contributing to the development of a biocultural heritage, where the geoenvironment and human activity have jointly shaped the landscape and cultural identity of the area.

The integration of the geological environment into the daily lives of local communities extends beyond the mere exploitation of natural resources, such as the use of rocks in traditional architecture. Instead, it is deeply embedded in the toponymic tradition, the process by which geographical features are named, allowing communities to attribute distinct characteristics and meaning to the landscape. Toponyms are not merely linguistic data; rather, they function as carriers of valuable information across multiple disciplines, including history, archaeology, geology, and folklore. Geology, by examining the gradual transformations of the Earth's surface, contributes to the understanding of geographic and cultural migrations of populations, as well as the selection of specific sites for human settlement. Meanwhile, folklore studies investigate how toponyms encapsulate religious beliefs, local traditions, and ritual practices, establishing a profound connection between inhabitants and their natural surroundings, transforming the landscape from a natural into a humanized space.

Research Methodology and Objectives

The present research aims to identify and highlight examples that demonstrate the dynamic relationship between geological formations and human activity, illustrating the connection between geological heritage and cultural identity. Additionally, it seeks to enhance the participation of local communities in the management and promotion of the Vikos-Aoos Geopark, recognizing the significance of local knowledge in preserving both natural and cultural heritage. To collect, analyze, and interpret data, a qualitative research methodology was applied, aiming at an in-depth investigation of experiences and social processes related to the region's geological heritage. Data collection techniques included:

- Literature review and content analysis of scientific and historical sources.
- Interviews with local residents of the Geopark to document local perceptions and oral traditions.
- Participant observation through field research in locations of particular geological and cultural interest.

As part of the field research, studies were conducted in the community of Pyrgos in Konitsa, where an on-site visit was carried out with its President, Mr. Christos Papadimitriou, and in the village of Laista in Zagori, where data was collected in collaboration with the President of the Laista Mountaineering Association, Ms. Toula Poala.

Findings and Conclusions

Preliminary research findings indicate that the Vikos-Aoos Geopark hosts numerous locations of significant geological interest and designated geosites that have been incorporated into the collective memory of local communities through toponymic tradition. Notable examples include "Nterti", "Vrachos tou Chodza" ("Hodja's Rock"), "Kokkino Lithari" ("Red Rock"), as well as the well-known Dragon Lakes of Smolikas and Tymfi. These findings suggest that diverse geological formations—ranging from steep cliffs to crystalline springs—have acquired profound significance for local populations, becoming an integral part of their cultural heritage.

This exploration of the interplay between geology and culture underscores that geology is not merely a science that interprets the Earth's past but also a bridge to sustainable development and cultural empowerment. The Vikos-Aoos Geopark serves as a living example of the intricate relationship between the natural environment and human activity, emphasizing the need for holistic approaches in the management and promotion of geological heritage.

Prospects and Management of Geocultural Heritage

The management of the region's geocultural heritage aligns with the principles of UNESCO, fostering the systematic

interpretation of geological and cultural heritage while promoting sustainable development. Strengthening the connection between humans, nature, and culture through the management of the Vikos-Aoos Geopark is a priority, ensuring the preservation of the geological and cultural elements that make the area unique.
Thus, understanding the relationship between geological structures and cultural practices not only contributes to scientific knowledge but also plays a crucial role in reinforcing local identity and ensuring the sustainable development of the region.

EXTENDED ABSTRACT 149

A Duration Model for Strong Seismic Motions of Intermediate-Depth Earthquakes in the Southern Aegean and its implication for stochastic simulations

Kkallas Ch.[1], Papazachos C.[2], Margaris B.[3]
(1) Aristotle University of Thessaloniki, Thessaloniki, Greece, chkkalla@geo.auth.gr
(2) Aristotle University of Thessaloniki, Thessaloniki, Greece, kpapaza@geo.auth.gr

Introduction

The southern Aegean subduction zone experiences the highest active deformation rates along the entire Africa-Eurasia collision zone, accounting for over 60% of Europe's seismicity. The Aegean microplate is moving southwestward at an average velocity of ~35 mm/yr relative to Eurasia, while the nearly stalled Mediterranean-Nubian plate system moves slowly toward Europe at ~5 mm/yr (Reilinger et al., 1997; Papazachos et al., 1998; Papazachos, 1999; McClusky et al., 2000; Ganas and Parsons, 2009) (Figure 1). This subduction process of the Eastern Mediterranean lithosphere beneath the Aegean microplate leads to the presence of partial melt in the mantle wedge above the subducting slab. As a result, P and S waves from intermediate-depth earthquakes (depths >45-50 km) are strongly attenuated along the South Aegean volcanic arc, while body waves from in-slab events that propagate toward the outer Hellenic arc experience high-frequency amplification (Skarlatoudis et al., 2013). The attenuation of seismic wave energy observed in the recordings appears to affect the durations of their seismic records. The ground motion duration is usually defined using the segment of the seismogram corresponding to the 0% (or 5%) to 95% energy range, as determined by Husid plots (Husid, 1969). A typical example is presented in Figure 2 which shows the corresponding Husid durations at a back-arc station (KOSI) and along-arc station (KAPA) for the 09 July 2016 **M**4.6 intermediate-depth earthquake. As we can see from both plots, there is a notable difference in the duration between the back-arc and along-arc stations, with the back-arc region exhibiting longer durations compared to the along-arc stations. This variation highlights the influence of the geotectonic setting on seismic wave propagation and attenuation. In this study, we examine the variation of strong ground motion duration as a function of hypocentral distance for intermediate-depth earthquakes. Previous attempts to correlate epicentral distance with quantitative measures of recorded ground motion duration have been performed by several researchers (e.g. Papazachos et al., 1992; Koutrakis et al., 2002; Tselentis and Danciu 2008), using shallow earthquake data (typically h < 50 km) for the broader Aegean area. No such relationships have been proposed for intermediate-depth earthquakes, mainly due to the limited data available.

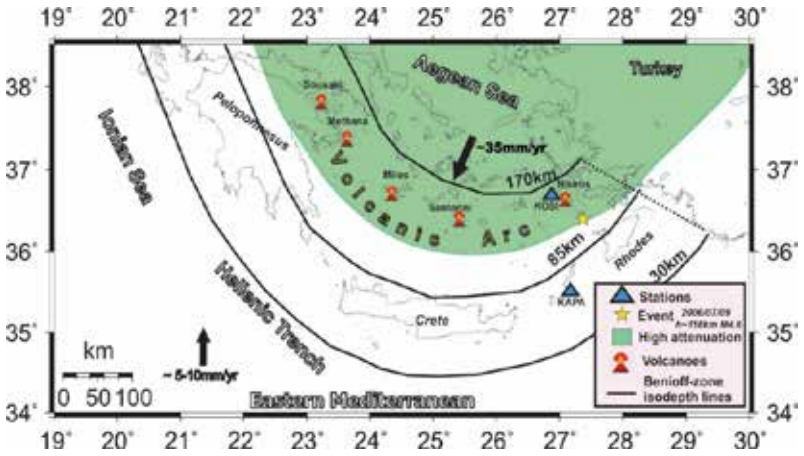

Figure 1. Schematic geotectonic map of the southern Aegean Sea subduction (southern Greece). Plate motions relative to stable Europe are shown with solid vectors. Indicative Benioff-zone isodepths are also indicated. The shaded area identifies the high-attenuation back-arc region (Skarlatoudis et al., 2013). We also present the 09 July 2006 M4.6 intermediate-depth earthquake with a yellow star, while the stations of Fig. 2 (KOSI and KAPA) are depicted with blue triangles.

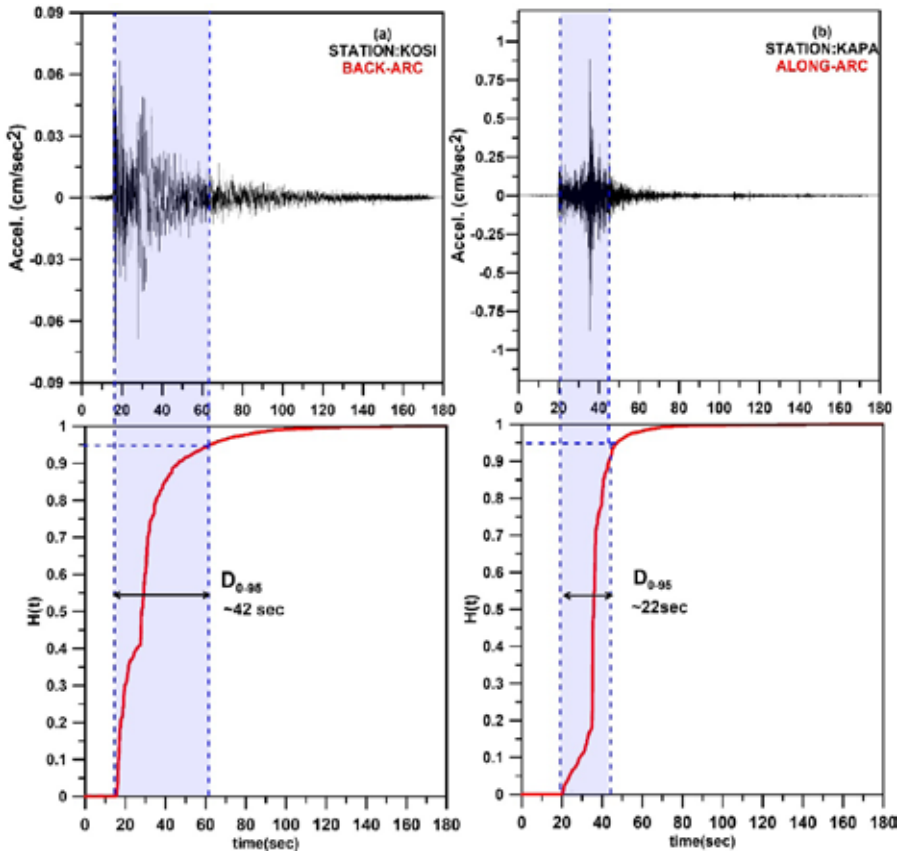

Figure 2. Husid duration for the 0%–95% range of the Arias intensity computed only for S-waves, for a back-arc station (KOSI) and a along-arc station (KAPA) [2006/07/09 M4.6 earthquake, h~118 km]. Although the stations are located at approximately the same epicentral distance, the back-arc station (KOSI) shows a significantly longer duration compared to the along-arc station (KAPA).

Data and method

We estimated the Husid duration for back-arc and along-arc area using a larger number of instrumental recordings based on previous works (Kkallas et al., 2018 and Skarlatoudis et al., 2013). Waveform data were collected and processed for the Southern Aegean subduction, providing the basis for a detailed study of the duration model, using information provided by horizontal components. To calculate the ground motion durations, we used waveform data from both acceleration and broadband-velocity sensor instruments for intermediate-depth earthquakes (depths >45km) with **M**4.5-6.7 that occurred along the southern Aegean Sea Wadati-Benioff zone. We considered the "significant" duration, as this was examined for the energy range 0% –95% of the Arias intensity of both P and S wavetrains. It should be noticed that the selection of 0% rather than the 5% often used refers to our choice to define a duration that starts exactly at the arrival time of the S (or P) waves, indicating the onset of the wave under study. We also excluded data from very large hypocentral distances (R^{hyp} > 450km), as the data for very large distances showed a very large scatter and corresponded to very small levels of ground motions.

Data from intermediate-depth earthquakes were analyzed and grouped into three categories based on their focal depths (≤60 km, 60–100 km, >100 km). This classification enabled us to quantitatively examine a possible correlation between S-wave durations and hypocentral distance. Figure 3a depicts a characteristic example, illustrating the spatial variation of Husid durations observed for the 09 July 2006 **M**4.6 intermediate-depth earthquake. Longer duration values are recorded in the back-arc region, at stations more than 100 km from the epicenter, driven by significant back-arc attenuation for events with depths >100 km. Figure 3b shows the variation of strong seismic motion duration, as defined by Husid diagrams, with respect to hypocentral distance. These differences are clearly due to the presence of the mantle wedge, characterized by a low Qs quality factor (Ventouzi et al., 2018), as well as low Vp and Vs velocities (Papazachos and Nolet, 1997), which primarily accounts for the strong attenuation of S-wave energy.

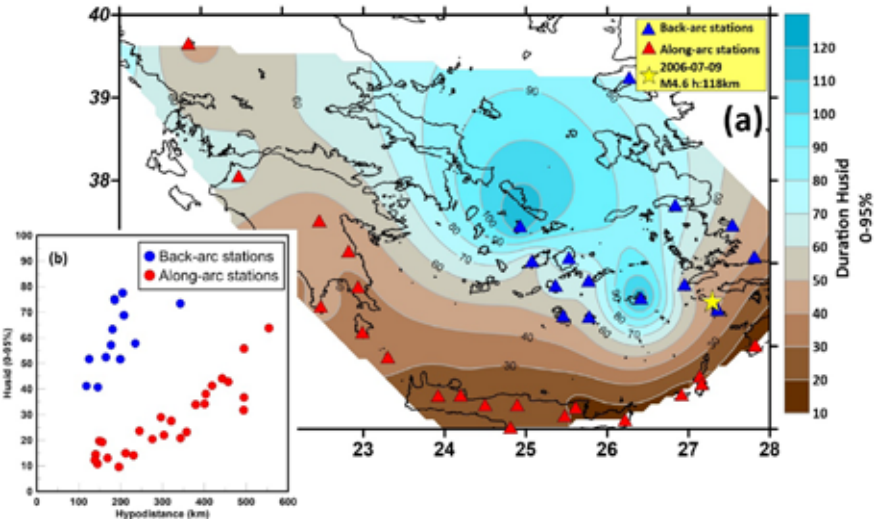

Figure 3. a) Spatial variation of the 0-95% Husid duration for S-waves for the 09 July 2006 M4.6 intermediate-depth earthquake, showing significant spatial variability between the outer Hellenic arc and the back-arc area. b) Variation of the same duration as a function of the hypocentral distance and back-arc/along-arc location of the recording station, showing a ~4 times larger durations for back-arc stations.

Figure 4 shows the variation of the strong motion duration, as defined by Husid diagrams, against the hypocentral distance for the three focal depth intervals (Figures 4a, 4b, 4c). Significant differences in the S-wave duration for earthquakes with focal depths greater than 100 km are identified between stations in the back-arc region and stations along the Hellenic Arc, leading to different linear regressions between duration and hypocentral distance (Figure 4d). This was not the case for shallower intermediate-depth events, where back-arc and along-arc stations exhibit rather similar durations.

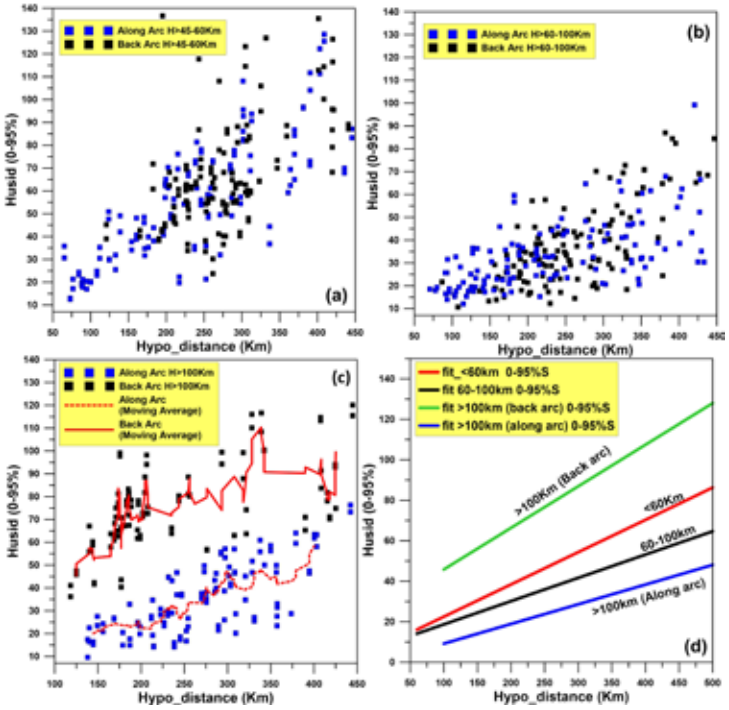

Figure 4. Variation of S-wave significant duration measures (Husid 0%-95%) with hypocentral distance for along-arc and back-arc seismic stations, categorized by depth: a) h≤60 km, b) h:60–100 km, c) h>100 km. d) Linear regression between duration and hypocentral distance for along-arc and back-arc stations, based on the depth classification.

The final relations regarding the duration of strong seismic motion (S-waves) are:

$$S-wave\ durarion(h,R_{hyp})=\begin{cases} if\ 45km \le h < 60km \\ 0.1594 * (R_{hyp}) + 6.5355 \\ if\ 60km \le h < 100km \\ 0.11493 * (R_{hyp}) + 7.1973 \\ if\ h \ge 100km \\ [Back-arc]\ \ 0.2053 * (R_{hyp}) + 25.293 \\ [Along-arc]\ \ 0.0972 * (R_{hyp}) - 0.53475 \end{cases} \quad (1)$$

It should be noticed that no magnitude term is included in the linear equations (1), which may appear rather strange, considering that the input data span a rather wide moment magnitude range (**M**4.5-6.7). However, attempts to simultaneously solve for both distance and magnitude terms using an appropriate linear formulation rendered a very weak dependance on moment magnitude, which is equivalent to a total difference of ~4 sec for the aforementioned magnitude range. Due to the very poor control on the magnitude effect on durations we decided to use the simple form of eq. (1), until a larger dataset is available for intermediate-depth events of the southern Aegean area. We should consider that eq. (1) corresponds to significant durations, which do not reflect the actual level of seismic motions, but rather the time interval within which the largest part of S-wave energy is released by the mainshock. As a result, it is expected that the event magnitude is less critical and that the duration increases with the coda envelope that critically depends on the hypocentral distance.
The results in eq. 1 can be employed in a stochastic simulation scheme to determine synthetic but realistic waveforms using the stochastic approach of Motazedian and Atkinson (2005), as adapted by Boore (2009), and implemented in the EXSIM algorithm. It is important to emphasize that EXSIM does not determine ground motion duration using peak-based or threshold-based criteria, such as the time interval during which acceleration exceeds a fixed value commonly referred to as “strong-motion duration.” Instead, EXSIM adopts a more physically meaningful approach by utilizing energy-based duration metrics, which are derived from Husid plots. These plots represent the cumulative energy of the ground motion over time, allowing the modeled duration to reflect the overall energy content of the seismic signal, rather than being influenced by isolated acceleration peaks or arbitrary thresholds. We used the method as adapted by Kkallas et al. (2018) for the southern Aegean Benioff zone. Moreover, we used the same approach to generate P-wavetrains, using the travel-time curves for intermediate-depth earthquakes of Ventouzi et al. (2013) to deternine the S-P duration, which we considered as the duration of longitudinal (P) waves. The final seismogram was created as the superposition of both P and S waveforms. A typical example is presented in Figure 5 for the 24 July 2015 **M**5.0 Nisyros earthquake (h=133 km). The waveforms (containing both P and S waves) from the stochastic simulation modeling are quite similar with the actual records for stations from both the along-arc (ARG) and back-arc area (VLY), suggesting that the employed duration model can be considered as realistic.

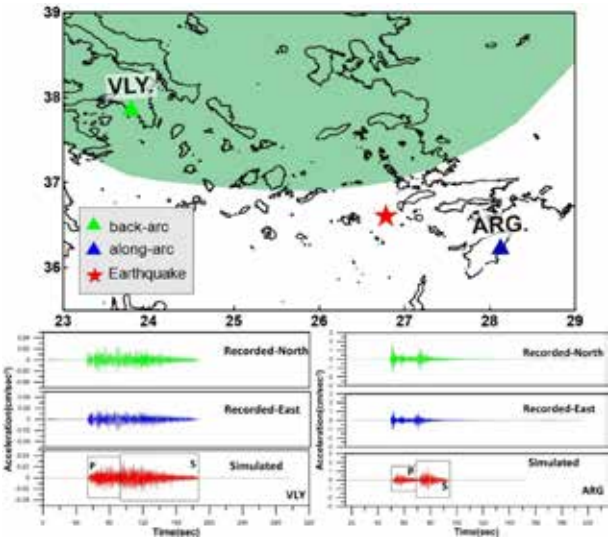

Figure 5. Synthetic acceleration waveforms (P and S waves) for back-arc and along-arc stations for the 24 July 2015 M5.0 Nisyros earthquake from stochastic simulation modeling. Notice the significant differences in the duration of strong ground motion time histories between the back-arc and along-arc stations, with the final composition of the waveforms (P and S waves) being in good agreement with the actual records for both stations (along-arc station ARG and back-arc station VLY).

Conclusions

The study of the strong seismic motion duration for intermediate-depth events of the Southern Aegean Benioff zone revealed that for earthquakes with depths greater than 100 km, the recording stations can be divided into two categories: stations along the external Hellenic Arc (along-arc) and stations in the back-arc region. Stations in the back-arc region exhibit records with longer Husid durations of seismic motion, though with low amplitudes due to the strong attenuation of S-waves caused by the presence of the mantle wedge beneath the volcanic arc. In contrast, records from stations along the Hellenic arc have significantly higher amplitudes and shorter Husid durations. On the contrary, events at shallower depths seem to have comparable significant durations for both back-arc and along-arc stations. It should be noted that this conclusion may seem counterintuitive at first, since it is known that the duration of strong seismic motions for intermediate-depth earthquakes is shorter at stations in the back-arc region compared to those in the along-arc region. However, by "duration", we define the time during which the motion accumulates the total energy of the seismic record, regardless of the level of seismic motion. Consequently, the low-amplitude back-arc records "delay" the accumulation of the total cumulative energy, leading (typically) to a longer strong duration. In contrast, records from stations along the external Hellenic Arc have significantly higher amplitudes (similar to those of shallow earthquakes), resulting in the rapid accumulation of a larger percentage of the energy in the record (shorter strong duration). As we demonstrate in this work, a simple distant-dependent duration model can be adopted and employed in stochastic simulation modeling, allowing the efficient reconstruction of wavetrains for intermediate-depth events in the Southern Aegean subduction zone. The observed weak dependence of duration on moment magnitude is most likely attributed to the limited dataset. Further clarification on the uncertainty quantification in linear regressions could be explored in the future once additional data becomes available, allowing to assess the actual influence of moment magnitude on duration.

Lunar Pits: Statistical Analysis of Morphometric and Geophysical Properties

Klimis F.[1], Sykioti O.[2], Karymbalis E.[1], Parcharidis I.[1]

(1) Department of Geography, Harokopio University of Athens, Athens, Greece, gs219116@hua.gr (2) Institute of Astronomy, Astrophysics, Space Applications and Remote Sensing, National Observatory of Athens, Athens, Greece

Background and Objectives

Lunar pits are distinct geological features scattered across the Moon's surface that offer significant insights to the subsurface structure of the Moon, potentially indicating the existence of ancient lava tubes formed by volcanic activity. Lava caves or lava tubes are formed when the external part of the a lava flow cools more quickly and makes a hardened crust over the internal lava flow. As the lava flow drains out of the tube, it leaves an empty space. The thin part of the ceiling of lava tube could then collapse to expose the entrance to the lava tube which is called a pit (Haruyama et al., 2009; Robinson et al., 2012; Hong et al., 2014; Wagner & Robinson, 2014). They vary from a few meters to several hundred meters in diameter and display differing depths. Morphologically, these pits can be broadly categorized into two types: those with a direct vertical drop (shaft-like pits) and those that slowly narrow down like a funnel (Figure 1). Lunar pits are mostly identified in near crater impact sites and within maria (large basaltic plains formed by ancient volcanic activity). Much of the original volume of most pits is now filled with debris, but some exhibit significant overhangs and may have present-day cave access (Wagner & Robinson, 2022). As these formations may be linked to subsurface lava tubes, they are not only significant for understanding the geological history of the Moon but also for future lunar exploration, water ice detection and habitat development (Zu et al., 2024; Carrer et al., 2024). According to Horvath et al. (2022), lunar tubes and caves could provide a temperate, stable, and safe thermal environment for long term exploration and habitation. Although, the investigation of pits may be challenging due to steep slopes of loose material at their walls and floors, it could help clarify their formation mechanisms and their implications for the evolution of lunar volcanic and tectonic processes (Nesnas et al., 2023).

This study carries out a statistical morphometric and geophysical analysis of 278 currently observed lunar pits in order to detect and quantify their main attributes. A dataset of morphometric and geophysical measurements was collected in order to perform descriptive statistics and correlation analysis. The analysis is performed on a 2-point axis: (1) descriptive and correlation analysis of morphometric variables, (2) descriptive and correlation analysis of geophysical variables. The main conclusions of the analyses are presented proposing future directions for the continuation of this work.

Data and method

For the purpose of this study, morphometric and geophysical data issued from various satellite and topographic measurements of the lunar surface were collected. The main data source of the morphometric variables was the Lunar Reconnaissance Orbiter Camera Planetary Data System (PDS) archive. A detailed catalogue of 278 lunar pits containing geographical, topographical and morphological data was retrieved and utilized. The Catalogue of Lunar Pits receives updates as more pits are detected manually or by the Pitscan Algorithm developed by Wanger & Robinson (2022). According to Wagner & Robinson (2022), the up-to-date observed pits are 321. However, due to the unavailability of morphometric and geophysical variables of the newly recently detected lunar pits, in this study we used the 2021 pit catalogue that includes 278 pits. The main data source of the geophysical variables was the web platform Lunar QuickMap, implemented by the collaboration between NASA, Arizona State University and Applied Coherent Technology Corporation (https://quickmap.lroc.asu.edu/). Through the QuickMap platform (the platform employs the Wagner & Robinson (2022) pit catalogue), we retrieved the files containing the geophysical variables of 278 pits (example in Figure 2, variables in Table 1).

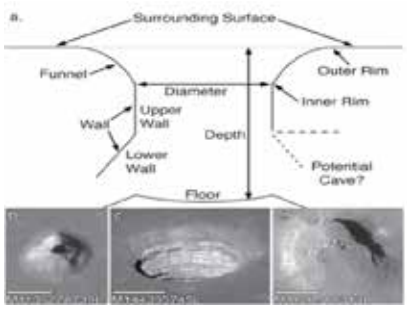

Figure 1. Cross-section of a generic lunar pit (Source: Wagner & Robinson, 2022). Not all pits exhibit all these features, or show these shapes. The inner rim is exaggerated for visibility.

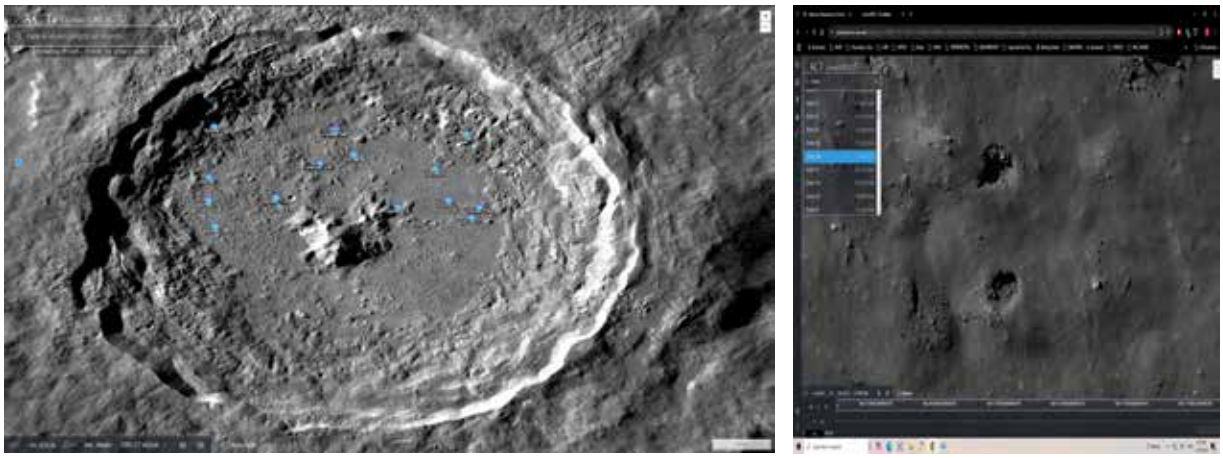

Figure 2. Tycho crater (formed 108 mya, Tycho crater has a diameter of 85km and is one among the thousands of similarly-sized craters on the Moon). Left image: screenshot featuring lunar pit locations within Tycho Crater using the QuickMap Platform (blue dots); Right image: zoom to pits Tycho 17a and Tycho 17b (located within the yellow circle in the left image). The left image scale is shown at the bottom right corner (10km) and the spatial resolution of the image is app. 100m/pixel. The spatial resolution of the right image is app. 0.6m/pixel.

All variables examined in this study are presented in Table 1. For the purpose of the morphometric statistical analysis, the variables were classified into two distinct categories, continuous and nominal variables. Statistical measures were used to provide a comprehensive understanding of the continuous variables, namely mean value, standard deviation, kurtosis and skewness. The Shapiro Wilk Test was also employed to evaluate whether the data follow a distribution. Correlation matrices were employed to determine the strength and correlation type (positive or negative) among pairs of variables such as funnel diameter, depth, slope measurements and terrain characteristics. The Jamovi open-source statistical software was utilized along with plug-ins of the R software in order to perform the correlation analysis. For the nominal variables, histograms were created to explore the distribution of categorical data, such as terrain type, host feature, and other binary indicators like the presence of an entrance ramp, overhangs, etc. Similar to the morphometric analysis, the geophysical analysis involved the use of descriptive statistics, distribution examination and correlation analysis.

Table 1. List of all morphometric and geophysical variables used in this study. The use of "?" shows the boolean character of the variable, meaning the presence or absence of a certain morphometric characteristic.

Morphometric continuous variables	Morphometric categorical variables	Geophysical continuous variables
Funnel max Diameter (m), Funnel min Diameter (m), Inner max Diameter (m), Inner min Diameter (m), Azimuth of the long axis of the inner pit (deg), Depth (m), SLDEM2015 (+LOLA) elevation (m), SLDEMDEM Slope (dynamic) (deg), SLDEM src Azimuth (deg), SLDEM src Slope (deg), Terrain Height (m), Terrain slope (deg)	Terrain type, Host feature, Geometry, Entrance Ramp ?, Overhangs ?, Nearby Pits ?, Nearby Fractures ?, Nearny Depressions ?, In Dome ?, In Depression ?, Colinear Pits ?, Colinear Depressions ?, Colinear Fractures ?, Is Copernical Crater ?, Is Mare ?, Is permanent shadow ? Results and Conclusions

Statistical analysis of pit morphometric characteristics

With the completion of the morphometric analysis, several key conclusions were drawn regarding the physical characteristics, geophysical context, and local distribution of lunar pits. The statistical results of the descriptive statistical analyses of the continuous variables (Table 1) are presented in Table 2 and examples of the distributions of pit continuous and nominal morphometric characteristics are presented in Figure 3.

Table 2. Results of the main descriptive statistical analysis of the continuous variables.

Variable	Number	Missing	Mean	Median	SD	Skewness	Kurtosis	Shapiro –Wilk
Funnel Max Diam	266	12	48.55	29.00	62.56	3.375	12.885	0.571
Funnel Min Diam	273	5	36.33	21.00	49.66	3.887	17.018	0.518
Inner Max Diam	266	12	31.00	16.00	48.78	4.328	21.931	0.483
Inner Min Diam	261	17	22.82	11.00	40.65	4.631	24.244	0.440
Azimuth	277	1	87.48	70.00	54.08	0.172	-1.364	0.927
Depth	237	41	13.15	9	13.89	3.310	13.072	0.609
SLDEM2015(+LOLA)(m)	278	0	-2008.63	-2293.34	1703.75	1.041	0.351	0.870

The results show significant skewness and kurtosis in both funnel and inner diameters, with the majority of pit dimensions ranging between 22 and 48 meters (Table 2 and Figure 3a). While most lunar pits are relatively shallow, with depths between 10 and 15 meters, there exists a subset of significantly deeper pits, indicating potential variations in formation processes or geological setting (Figure 3b). The azimuth analysis reveals a uniform distribution of pit orientations, suggesting no particular alignment or external directional influence in the formation of these pits (Table 2). Furthermore, the majority of lunar pits are found in impact melt terrains (mostly located within mare regions), and relatively few within mare and highlands (Figure 3c). This suggests a strong association between impact-related processes and pit formation. Many pits tend to cluster near other geological features, especially craters. This clustering suggests that pit formation may be influenced by nearby structural weaknesses, crustal thinning due to impacts or collapse processes related to crater formation. The study identified 28 distinct clusters of pits across various lunar regions. A significant number of pits (228 out of 278) are located near depressions, while very few are located within depressions. This distribution pattern could be related to crustal weakening in the broader area or subsurface voids influencing pit formation. Elevation data show that lunar pits are predominantly located in elevations well below the Moon's reference elevation sphere (Figure 3d).
Regarding the geometric variability, the majority of pits display undefined or elliptical or circular geometries with a variability that could be due to different collapse dynamics or variable composition of the host regolith (Table 3). Examining the overhangs, the presence of overhangs is observed only in a small percentage of lunar pits. Overhangs may be the result of mechanical weathering or collapse of pit walls due to gravitational forces. The majority of pits do not exhibit entrance ramps. Finally, no pits are observed in permanently shadowed regions of the Moon, which could be explained either by lack of data or by poor illumination conditions (e.g. areas of permanent shadow near the lunar poles and inside craters that are not directly illuminated by the sun).

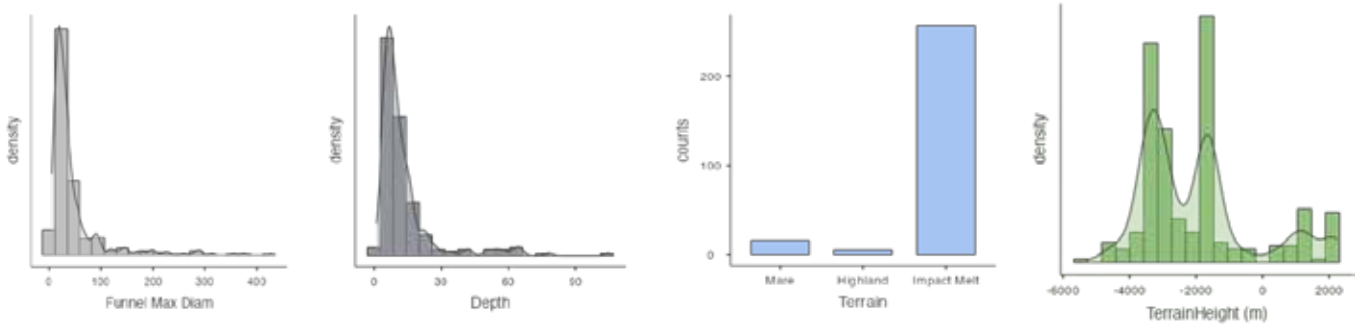

Figure 3. Examples of distributions of pit continuous and nominal morphometric variables: (a) funnel maximum diameter, (b) depth, (c) terrain type and (d) terrain elevation issued from LOLA DEM (elevation values are the distance above or below the reference sphere). Most of the pits show less than 10m funnel maximum diameter, they are rather shallow (10-15m) located in impact melts at altitudes well below the lunar reference elevation sphere.

Table 1. Most frequent pit geometries (shape) (occurrence >5% of total number of pits).

Geometry (shape)	Number of pits	% of total
Elliptical	52	18.7
Rectangular	21	7.6
Irregular	25	9.0
Triangular	19	6.8
Circular	38	13.7
Undefined	57	20.5

Concerning the linear correlation analysis, the first notable observation in the correlation matrix (Figure 4) is the strong relationship between pit dimensions. More specifically, Funnel Max Diameter and Funnel Min Diameter show a very strong positive correlation (Pearson's r = 0.94, p < .001). Similarly, both Inner Max Diameter and Inner Min Diameter show strong positive correlations with Funnel Max and Min Diameters (r > 0.9, p < .001), suggesting that the size of the inner pit is closely linked to the size of the outer funnel. Additionally, the strong positive correlation between Funnel Diameter and Inner Diameter (r > 0.7, p < .001) suggests that deep pits tend to present large diameters.

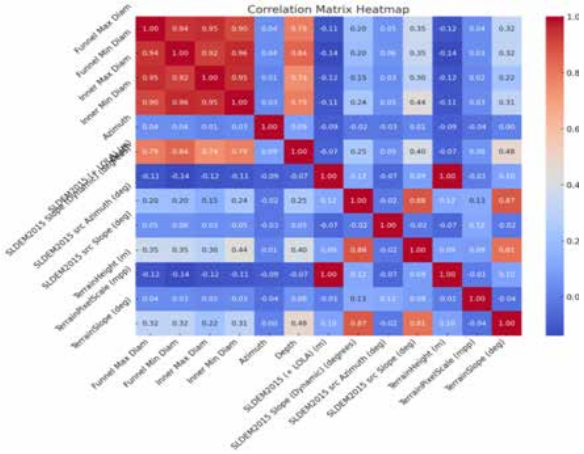

Figure 4. Correlation matrix between morphometric variables. The matrix is symmetric. The highest linear correlations are observed between the funnel diameter (man and min) and the inner diameter (max and min) of the pit.

Statistical analysis of pit geophysical characteristics

The results of the statistical analysis of the geophysical characteristics of the pit areas are in general consistent with the already known geological patterns on the lunar surface. In terms of mineralogy, maria, corresponding to secondary lunar crust formed by basaltic volcanism, exhibit the highest olivine, pyroxene (both clinopyroxene and orthopyroxene) content and the lowest content in plagioclase (32-35 wt%) (Figure 5a). Highlands, corresponding to the primordial lunar crust of anorthositic composition, present medium content in olivines and pyroxenes and a high content in plagioclase (anorthite) (62-65 wt%). Impact melts, corresponding to areas of intense cratering (where most of pits are located), present the lowest content in olivine and pyroxenes and the highest content in plagioclase (70-75 wt%). Correspondingly in terms of chemical composition, iron (Fe) and titanium (Ti) contents are high (15-17wt% and 2.5 – 3.5 wt% correspondingly) within maria pit areas, which are consistent with the maria basaltic compositions (Figure 5b). Highlands present relatively low Ti and Fe-content (7-10 wt%), which is expected due to the predominance of anorthositic rocks. Finally, pit areas within impact melts present the lowest Fe and Ti-content (7-10 wt%), which is consistent with their general low content in mafic minerals (olivines and pyroxenes). Concerning thorium (Th), it seems that maria and highland pit areas show higher Th content (3-3.5 ppm) than impact melts. Finally, impact melts present high rock abundances within regolith, low thermal intertia (0.03m) while they seem to retain higher nighttime soil temperatures (~ -271.15°C) compared to the maria and the highlands, reflecting thus a distinct thermal behavior (Figures 5c and d).

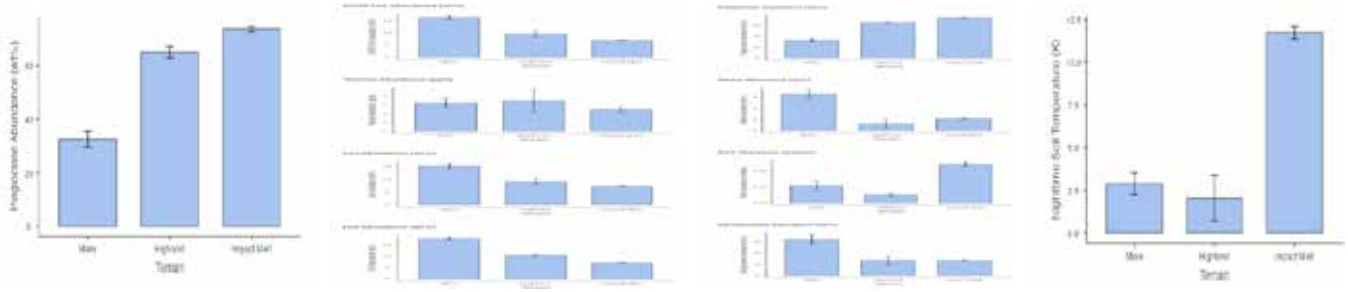

Figure 5. Examples of geophysical variables for the three different lunar terrain types (maria, highlands and impact melts; (a) plagioclase content (%wt), (b) iron content (%wt), (c) rock abundance in regolith (unitless) and (d) nighttime soil temperature (in K). Vertical bars correspond to value variations.

The linear correlation analysis reveals strong relationships between geophysical variables (Figure 6). Notably, Fe-content presents a high positive correlation with nighttime soil temperature (r = 0.92). Additionally, there is a strong positive correlation (r = 0.89) between rock abundances within the regolith and nighttime soil temperatures, which is consistent with Powell *et al.* (2023). In parallel, a significant negative correlation observed between nighttime soil temperatures and thermal inertia (Diviner H-Parameter) (r = -0.97) shows that nighttime temperatures are sensitive to the thermophysical properties of the regolith. High thermal inertia materials, such as large rocks, seem to remain warmer during the lunar night and thus result to anomalously warm nighttime temperatures (Williams *et al.*, 2017).

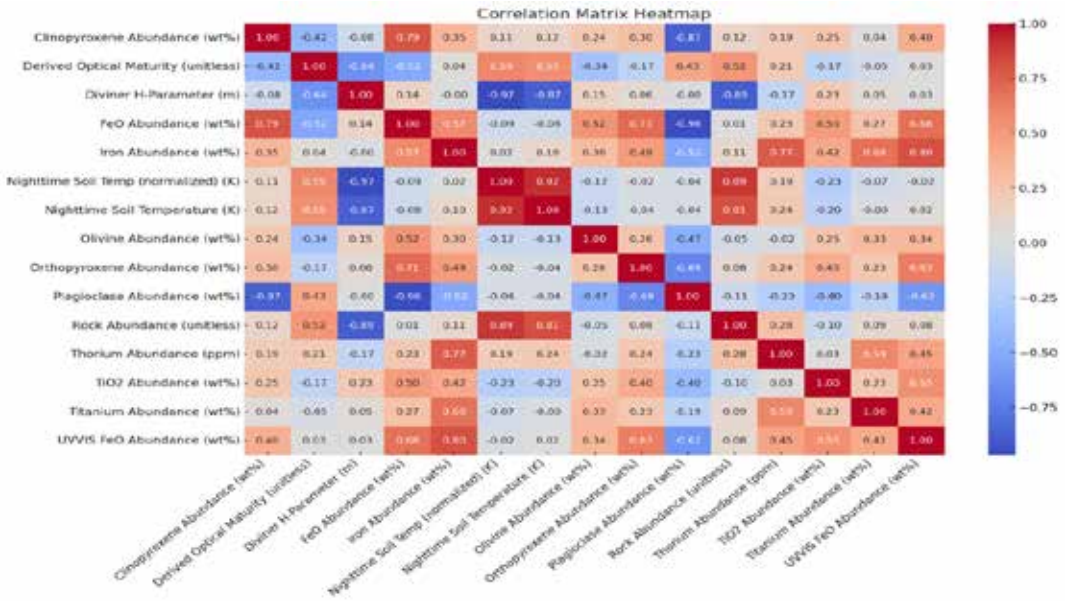

Figure 6. Correlation matrix heatmap of geophysical characteristics. The matrix is symmetric.

In conclusion, the examination of the morphometric and geophysical properties of lunar pits showed that they often have undefined or elliptical shape, varying geometry and are often present in several clusters, near depressions located within crater impact melts. Mineralogy and chemistry are consistent with the geological context of their locations. Although the spatial resolution of the current available data is often a limiting factor, the examination of their properties provides insights to the Moon's geological history, surface processes and stability. Furthermore, lunar pits are potentially linked to subsurface lava tubes or caves which could be promising sites for future human exploration, human habitats and infrastructures. Their unique structure potentially offers natural protection from extreme temperatures, cosmic radiation, and meteorite impacts, making them prime candidates for sustainable lunar bases, landing site selection and long-term lunar sustainability research.

This study is part of Mr. Klimis' BSc thesis. Future continuation of this work includes the study of the each pit cluster, comparison of different pit clusters within different geological contexts, thermal properties (outside and within pits), and the detection of new pits potentially linked to subsurface lava tubes or caves.

Utilizing engineering geological database for urban geohazard assessment: a case study from Thessaloniki, Greece

Kokkala A.[1], Marinos V.[2], Papathanassiou G.[1]

(1) School of Geology, Aristotle University of Thessaloniki, Thessaloniki, Greece, kokkalaaliki@gmail.com

(2) School of Civil Engineering, National Technical University of Athens, Athens, Greece

Introduction

This research presents an advanced engineering geological database, designed to comprehensively manage extensive geological and geotechnical data (Kokkala, 2023). Based on the Tunnel Information and Analysis System (TIAS) framework (AGS, 1999; Marinos et al., 2013), the database integrates information from numerous boreholes and geotechnical investigations conducted in Thessaloniki's urban area, northern Greece, focusing on Quaternary and Neogene sediments, as well as fill deposits. Its primary aim is to reduce geological uncertainties and address geotechnical challenges critical for urban safety and planning, by means of numerous database applications (Kokkala and Marinos, 2022). Emphasizing the utility of big data management, the study explores how geological heterogeneity, subsurface variations, and engineering geological conditions can be better understood to mitigate geohazards (e.g. liquefaction as the application example used here) and support early-stage infrastructure design.

Methods

In this study, Standard Penetration Test (SPT) and Cone Penetration Test (CPT) results were analyzed to investigate liquefaction susceptibility and potential in an area located at the vicinity of Thessaloniki airport (Figure 1), as a database application for urban geohazard assessment. Based on the outcome arisen by the geotechnical investigation, it was concluded that the subsoil profile predominantly consists of sandy clays and silts, interspersed with medium-density sand layers. Two distinct sub-areas (A and B), differentiated based on their proximity to the stream located to the south, were analyzed to evaluate in situ conditions and liquefaction susceptibility.

A series of cross-sections, such as the example shown in Figure 2, was developed to illustrate the distribution of the Soil Behavior Type Index-SBTn (Ic) based on the liquefaction susceptibility criterion proposed by Robertson and Wride (1998). Further analysis involved the assessment of the liquefaction potential index (LPI) alongside estimations of vertical and lateral displacements for each sub-area, utilizing the available CPT data. For this purpose, two distinct seismic scenarios were considered: the first one involves the activation of the Anthemoundas fault, resulting in a seismic event with a magnitude of M 6.9 and peak ground acceleration of 0.4 g, while the second scenario refers to the activation of the Gerakarou fault, generating a seismic event with a magnitude of M 7.0 and peak ground acceleration of 0.5 g (Lin and Smerzini, 2022).

Results

The analysis revealed stratigraphic differences between the sub-areas. Sub-area A exhibited a higher concentration of coarse-grained materials in places, whereas sub-area B was dominated by fine-grained deposits, reflecting variations in the depositional environment. In most soil columns, LPI values exceeding 5% were observed throughout the study area under the first seismic scenario, indicating a high to very high liquefaction potential. Additionally, vertical displacements ranged from 16 to 19 cm and lateral displacements reached up to 220 cm were estimated under both seismic scenarios for the two sub-areas.

Conclusions

This study highlights the essential role of integrating primary geological and geotechnical data into a well-structured database for detailed geohazard analysis. The proposed methodology showcases the utility of an engineering geological database in evaluating and mitigating liquefaction, providing critical insights for enhancing urban safety and optimizing infrastructure design.

EXTENDED ABSTRACT 152

Diapiric structures in evaporites of Western Greece as potential geoenergy storage areas

Kokkalas S.[1], Psarros V.[1], Koutsovitis P.[1]
(1) Department of Geology, University of Patras, Greece, skokalas@upatras.gr

Introduction-Research background

The capture and storage of CO_2 is an important process as it helps to prevent the negative impacts of CO_2 emissions in the atmosphere, such as the greenhouse effect and ocean acidification among others. On the other hand, the storage of H_2 is an environment-friendly process, as it allows for large-scale controlled and flexible energy conversion. Storage of both hydrogen and carbon dioxide in salt caverns has emerged recently as a favorable option due to its numerous benefits, such as the high withdrawal capacity, favorable mechanical properties, and enhanced safety (Tackie-Otoo & Haq, 2024). Despite the increasing demand in geo-energy storage, there is limited relevant literature, mainly on underground geoenergy storage in geological structures in Greece (Arvanitis et al., 2020; Makri et al., 2022). Triassic evaporites diapirism, which involves the buoyant uprise of large evaporite masses through piercing and displacing, are either reaching the surface or halting at a depth, as is evidenced in several seismic profiles. They mainly occur in Western Greece along the Ionian zone, such as in the areas of Aitolo-Akarnania, Hepirus, the Ionian islands, as well as in the Western Peloponnese (Underhill, 1988; Kamberis et al., 2022; Soto et al., 2024). Salt caverns provide significantly higher storage volumes compared to traditional fuel tanks, making them ideal for large-scale energy storage (Fig. 1). The geological suitability for geo-energy storage in salt caverns is determined by certain fundamental geological criteria such as: i) the depth of the storage cavities, ii) the minimum thickness of the salt formation, (iii) the mineralogical composition of the salt formations and (iv) the petrophysical properties of the host rock (i.e., low porosity and permeability, pore structure etc.), in order to ensure that the supercritical gas remains in the cavity and to prevent the potential risk of leakage.

The above criteria for geological suitability for subsurface storage were examined and evaluated in some representative areas in Western Greece, where evaporitic rock samples were collected and analyzed, by applying several laboratory techniques, upon samples from the areas of Katouna (Aitolo-Akarnania), Pagos (Corfu), and various sites in the proximity to Preveza (Kanalaki-Aidonia-Chimadio). Based on the interpretation of these preliminary results, and the percentage of coverage of the required geological criteria for underground energy storage, the prospects of underground storage in artificial cavities in evaporite rock formations are discussed and the adverse factors that require further study in the future research stages are presented.

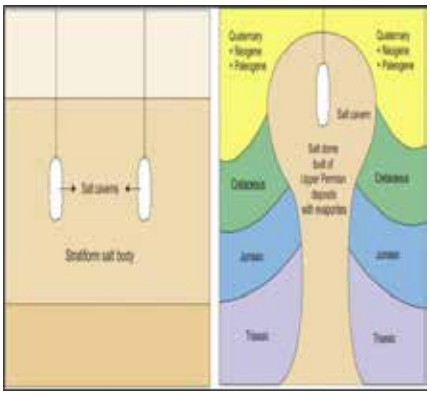

Figure 1. Salt cavern in a salt diapiric structure (Tarkowski and Czapowski 2018).

CO_2 and H_2, as representative gases for underground gas storage, exhibit significant differences in physical properties, particularly in density and viscosity. Storage of CO_2 in salt caverns is a promising solution, since it not only provides permanent storage but can also operate as a renewable and sustainable method for utilizing CO_2 as a valuable industrial resource.

For the underground storage of geoenergy, salt caverns are currently considered to offer the most promising option owing to their low investment cost, high sealing capacity, the inert nature of salt structures, and the low cushion gas requirement (Fig. 1; Caglayan et al., 2020). Rock salt properties such as permeability, porosity, and pore pressure, are crucial parameters to consider for hydrogen storage and to evaluate potential migration (AbuAisha and Billiotte, 2021).

Several sites for hydrogen storage in salt caverns in UK (Teeside), USA (Clemens Dome, Moss Bluff) operate for nearly 50 years, at depths below 1 km, demonstrating that underground storage is a technically-feasible option (Landinger and Crotogino, 2007; Tarkowski, 2019). For the Greek region a total cavern storage potential mainly onshore (within 50 km from the shore) is estimated around 10^2 TWh (Caglayan et al., 2020).

Geological setting

Although the Ionian Zone has been extensively studied, having attracted the interest for hydrocarbon exploration in Greece (Zelilidis et al., 2015), there is still much ambiguity in the deeper structures of the crust of the External Hellenides. Western Greece is considered as a region with mainly thin, or possibly coexistence of thin and thick-skinned deformation of the Mesozoic-Cenozoic succession above the Triassic evaporites and Permian sequences (Kokkalas et al., 2013). The Ionian Zone consists of sedimentary rocks ranging from Triassic evaporites at the base, to Jurassic–upper Eocene carbonates with minor cherts and shales (Karakitsios, 1995; Rigakis et al., 2007; Karakitsios et al., 2015; Bourli et al., 2019; Kamberis et al., 2022). Thick Upper Eocene to Miocene flysch deposits overlie the carbonate sequence (Avramidis et al., 2002; Vakalas et al., 2024). The Ionian Zone boundary towards the west is marked by intrusive evaporites that represent the lowest detachment level of individual overthrust sheets in the External Hellenides.

The Ionian Zone consists of three distinct stratigraphic sequences (Karakitsios, 2013): a) a pre-rift sequence (Triassic – Early Jurassic) represented by a thick evaporitic succession (with an estimated thickness that exceeds 2 km) overlain by shallow marine carbonates. Regarding the depositional environment, the alternating sulphate and carbonate constituents correspond probably to an arid and shallow depositional setting (Karakitsios, 1995). Evaporites are often related to extensive exposures of dissolution breccia of Triassic age (Triassic breccia); b) a syn-rift sequence (Early to Late Jurassic) where the basin was compartmentalized, and a half-graben geometry was favored, as reflected in variations in sediment type (pelagic carbonates and deep water clastics) and thickness (Karakitsios, 2013). During this stage, the evaporites were mobilized forming several types of diapiric structures; c) A post-rift sequence (Early Cretaceous to Eocene) marking by the deposition of pelagic limestones.

However, new insights into the evolutionary structural model of the Ionian fold-and-thrust belt in central-south Albania and Western Greece have been revealed, based on significant information provided from detailed fieldwork and new seismic data, suggesting an alternative model that places the rifting stage earlier in the Triassic and demonstrating the clear influence of salt tectonics since the Early Jurassic (Hernandez et al., 2019; Vakalas et al., 2023; Soto et al., 2024).

Methods

Fieldwork and preliminary sampling were conducted in five areas along western Greece, specifically on Corfu Island (Pagoi), in several sites of Preveza region (Aidonia, Chimadio and Tsouknida) and along a continuous road outcrop near Katouna area (Table 1). The rock samples were carefully selected to avoid areas of high dissolution and internal fracturing, in order to comply with the requirements for each of the following analytical techniques. For the determination of the mineralogical and quantitative composition of the samples, X-Ray Powder Diffraction analyses (XRD) and Fourier-Transform Infrared Spectrometry (FTIR) were conducted. For the characterization of their petrophysical properties, such as porosity, pore size distribution (PSD), permeability and specific surface area, Brunauer-Emmett-Teller (BET) analysis with nitrogen and Mercury Injection Capillary Pressure (MICP) analysis (Table 2), were carried out in parallel, in the facilities of the Department of Material Sciences and FORTH/ICE-HT (Upatras), respectively. Investigation of the sealing capacity and pore-throat-aperture size distribution in samples was conducted via mercury porosimetry using the latest Micromeritics Autopore III porosimeter, which is capable of injecting non-wetting phase (mercury) in user-defined, step-like pressure increments (0.5 to 2 psi) up to 60,000 psi (~413 MPa) into an evacuated, cleaned, and dried rock sample.

Results

The analyzed evaporite samples can generally be distinguished into those being rich in gypsum and those being rich in anhydrite (Table 1). The samples have a dominance of gypsum in the samples Pg2, KAT, KAT1, KAT2, Aid2, whereas anhydrite is the predominant phase in samples Pg1, Pg3, and Chm1b.

Mercury porosimetry showed porosity values that range from 0.17% to 5.06% (Table 2), with a wide distribution of pore diameters D (Fig. 2). The mean pore-throat diameter values in the samples indicate macroporous materials, with samples Pg2, Chm_1b and Aid2 showing the lowest mean values (0.55-0.57 μm), whereas the highest value is shown in sample KAT1 (1.10 μm). Since these samples were collected from surface outcrops, a reference evaporite sample (Mo1#7) from a borehole in southwest Montenegro at a depth of ~ 3 km, (kindly provided by Energean Montenegro Ltd.) was used for comparison; it showed a mean PSD value of 0.19 μm (Table 2). The permeability exhibits relatively low values, ranging from 0.01549 to 0.46367 mD. For comparison the reference sample Mo1#7 showed a permeability of 0.00587 mD.

Table 1. Results of XRD-analysis in the studied samples.

Samples ID	Location	Mineral content (in %)						
		Gypsum	Anhydrite	Halite	Dolomite	Calcite	Celestite	Quartz
KAT	Katouna	30	4	9	10	17	7	20
KAT 1	Katouna	35	4	13	13	21	6	5
KAT 2	Katouna	36	3	11	9	20	8	9
Aid2	Aidonia (Preveza)	98	-	-	<2	-	-	-
Chm	Chimadio (Preveza)	15	-	-	-	85	-	-
Chm_1b	Chimadio (Preveza)	4	30	<3	<3	34	<3	27
Tsk	Tsouknida (Preveza)	10	-	-	-	90	-	-
Pg 1	Pagoi (Corfu)	4	43	<3	<3	44	<3	7
Pg 2	Pagoi (Corfu)	37	<3	8	10	18	7	18
Pg 3	Pagoi (Corfu)	4	30	<3	<3	30	<3	29

In order to additionally investigate the presence and size of the micro-mesopores BET-analysis was performed, which has a different resolution capability than MICP. The BET-analysis confirmed the wide distribution of pore width ranging from micropores (width 1.6-3 nm), mainly mesopores (width 7-10 nm), and also macropores (width 50-100 nm). A mean pore diameter of approximately 3.8 nm is observed, indicating the presence of micro-mesoporosity in the samples, which would be unfeasible to determine by applying only the mercury porosimetry measurement technique. Furthermore, the specific surface area shows values ranging from 19.9 to 22.7 m^2/g.

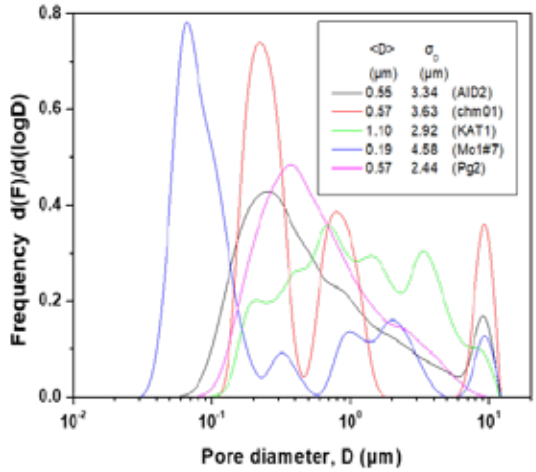

Figure 2. Pore size distribution diagram of the samples from the MICP analysis.

In the BET analyses, it is observed that all samples belong to the type III isotherm adsorption. Type III isothermal adsorption is convex on the P/Po axis throughout the entire adsorption process, and for this reason, there are no inflection points (Fig. 3). From the types of adsorption-desorption isotherm (type III), which are not common, it appears that there is little interaction between the gas and the adsorbing surface. Regarding the type of hysteresis loop, all samples exhibit an H3-type hysteresis loop, which appears only in the mesoporous structure due to capillary condensation, and this is confirmed by the pore size distribution (PSD) assessed through analytical techniques. This indicates that the pores exhibit slit-like shapes and it is considered that materials with such characteristics tend to behave as microporous materials, regardless of the PSD.

Table 2. Results from MICP-analysis in selected samples.

Sample	Pore volume, V_p (cm^3/g)	Specific surface area, S_p (m^2/g)	Porosity (%)	Mean value of PSD (μm)	Standard deviation of PSD (μm)	Tortuosity τ	$k = \varphi < D_p >^2 / (16\tau)$ (mD)
Aid2	0.0220	0.258	4.74	0.55	3.34	2.217	0.40422
Chm1b	0.0007	0.007	0.17	0.57	3.63	2.229	0.01549

Discussion-Conclusions

The porosity of the studied evaporite samples appear to exhibit a complex structure involving micro-, meso-, and macropores, and potentially interconnected pores (microcavities due to dissolution). The range of their pore size (diameter) distribution values was estimated by combining results from both BET and MICP techniques, as there is a different resolution capability between these techniques. In general, the porosity of the samples shows low values ranging from 0.17 to 5% and relatively low permeabilities (0.01-0.46 mD). Since these are preliminary data and the research is still ongoing on this subject, more data will be required from other evaporitic rock sites in western Greece to have a better overview of their petrophysical properties.

The halite (NaCl) at a percentage higher than 95%, the depth of the cavity formation (which ideally should range between a min of 800 m and max of 1300 m for the higher capacity of hydrogen storage), and the ideal thickness of the evaporite formation, in the range of 150-200 m, are some of the most important required factors for the underground geological storage of carbon dioxide and hydrogen in salt cavities to be considered.

Existing data from boreholes and seismic interpretations of salt structures (pillows, plugs and diapirs) in western Greece (Fig. 4, Kamberis et al., 2022; Soto et al., 2024), suggest that in the area of Filiates the presence of thick halite appears at a non-ideal depth of 1700 m and deeper, as anhydrite predominates at shallower depths (from 300-1600 m in Filiates-1 well). In Delvinaki, halite predominates at the desired depth (700-1000 m) with sufficient thickness (approx. 400 m) and minimal presence

of dolomite. In Tryfos, (Aitolo-Akarnania) and Parakalamos, although the formation depth is ideal, the lack of halite and the presence mainly of anhydrite-gypsum and dolostone sequence requires further investigation and analyses, mainly due to the slower dissolution of the formation compared to halite and issues of stability and sealing of the walls of the artificially formed cavity. Despite that, the visco-plastic properties of evaporitic rocks may improve their sealing function, since they have the ability for "self-sealing" the potential microfractures under cyclic stress (Lyu et al., 2023). Thus, detailed studies on the mechanical properties of the evaporitic rocks are crucial when selecting a site for underground storage.

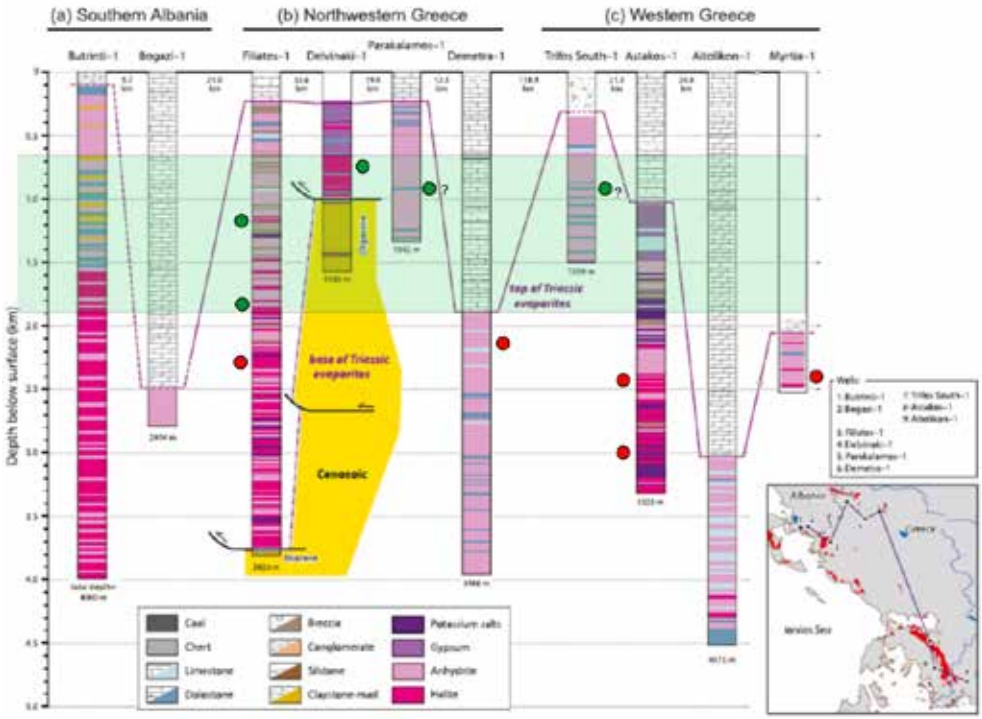

Figure 4. Triassic evaporite sequences with well correlation in north-western and western Greece and inset showing the position of wells and main outcrops of Triassic evaporites in the Ionian zone (from Soto et al., 2024). Original figure is modified showing the ideal depths for subsurface geoenergy storage with green shading, while green/red circles indicate the potential sites with favorable/unfavorable conditions for storage, respectively, based on combined depth/lithology selection criteria.

Although until recently, the construction of artificial cavities in evaporitic formations has been carried out exclusively in areas with a high percentage of halite (>95%), recent studies have shown that salt-rich gypsum rocks can also be characterized as high-quality seals for hydrocarbon reservoirs, due to their strong plasticity, and their excellent petrophysical and mechanical properties (Lyu et al., 2023). However, the effect of cyclic loading on their sealing capacity in a cavity needs further investigation, which limits progress in such storage plans (Lyu et al., 2023). Furthermore, a recent experimental study suggests that the geochemical reactivity of hydrogen with salt cavern minerals (halite-anhydrite-gypsum) is very weak at relatively low temperatures, within short period of time with hydrogen treatment, demonstrating high stability and integrity of salt caverns during short hydrogen storage cycles, with no major alterations in pore structure analysis (Fatah et al., 2024).

Based on these new published data (Fig. 4), and in conjunction with the analytical results of the present study, areas such as Pagoi (Corfu Island) and Katouna (Aitolo-Akarnania region), exhibit promising petrophysical characteristics, which, together with the aforementioned areas of Delvinaki and Filiates (mostly based on the available well data and the seismic profile interpretations; Soto et al., 2024), provide favorable prospects for further research as potential underground storage sites for H_2 and/or CO_2. The areas of Corfu and Trifos (north of Katouna) in Aitolo-Akarnania have been proposed also by Arvanitis et al. (2020), as potential H_2 storage sites, based mainly on their storage capacity (367 km^3), taking as a scenario a capsule-shaped cavern, with dimensions of 300 m height and 60 m in diameter, at a depth of 650 m.

It is also worth to mention that a significant issue in the development of such areas for subsurface storage of hydrogen is the lack of a specific legislation that regulates, based on technical-geological and economic-technical criteria, the entire process related to underground hydrogen storage, from the selection of the site to the injection process, including the monitoring and an action plan after the exploitation of the storage facility.

The Argo-Beachrock Project: web mapping and geovisualisation of beachrocks using UAS along the coast of the Argolic Gulf, Greece

Kolaiti E. [1], Soulakellis N.[2], Tataris G.[2], Mourtzas N.[3]

(1) Society for the Study of Ancient Coastlines - AKTES NPO; National Hellenic Research Foundation, Institute of Historical Research; University of Nottingham, Department of Classics and Archaeology; Chalandri, Athens, Greece, kolaitieleni@gmail.com (2) University of the Aegean, Department of Geography, Cartography and Geoinformatics Laboratory, Mytilene, Lesvos, Greece (3) Society for the Study of Ancient Coastlines - AKTES NPO; University of Nottingham, Department of Classics and Archaeology; Chalandri, Athens, Greece

Research Highlights

Web mapping and geovisualisation of beachrocks using UAS along the littoral zone of the Argolic Gulf: a methodological approach to surveying the nearshore zone, with advantages and constraints for bathymetric reconstruction.

Introduction - Background

Beachrocks are rocky coastal deposits that form during relatively short periods along the shoreline within the intertidal zone, under complex physicochemical (e.g., Ginsburg, 1953; Taylor and Illing, 1969; Moore, 1973; Hanor, 1978; Meyers, 1987) and biological (e.g., Webb *et al.*, 1999; Neumeier, 1999) cementation processes. They consist of coastal sediments, such as sand, gravels, pebbles, cobbles and other coarse materials of both clastic and biogenic origin, and even of anthropogenic origin (e.g., ancient remains), usually cemented with calcium carbonate, high/low magnesian calcite and aragonite. It is generally accepted that beachrock lithification takes place in the intertidal zone (e.g., Scholle and Ulmer-Scholle, 2003; Vousdoukas *et al.*, 2007; Mauz *et al.*, 2015). In microtidal environments such as this, in the central Aegean where the maximum and mean tidal ranges do not exceed 0.30 m and 0.15 m, respectively (HNHS, 2015), the cementation of coastal sediments exceeds the tidal range and expands into the swash, saturated, zone (Gifford, 1995; Kolaiti *et al.*, 2017; Kolaiti, 2019). Diagenesis is similar in both the intertidal and the swash and backwash zones, and the cementation results are indistinguishable (Bernier and Dalongeville, 1996). Therefore, beachrocks demarcate an ancient coast during their formation, with the base of the seaward end of a beachrock slab, in its well-preserved parts that have not undergone erosion or fragmentation, representing the mean low tide of a former sea level (e.g., Kolaiti and Mourtzas, 2023). Different sea level stands form distinct beachrock slabs at various elevations that correspond to different generations of a fossilized palaeoshoreline (e.g., Vousdoukas *et al.*, 2007; Desruelles *et al.*, 2009; Mauz *et al.*, 2015 and references therein; Mourtzas and Kolaiti, 2020). The loose, unconsolidated, sandy/sandy-gravel sediments laid on the sea bottom between two different beachrock generations represent a period of relative sea level (rsl) change (e.g., Desruelles *et al.*, 2009). Fossils, organic material or archaeological remains embedded in a beachrock are a *terminus post quem* for the beachrock formation, postdating the embedded material (Kolaiti, 2019).

The study of beachrocks provides valuable knowledge about the ancient environmental, geological, sedimentological, and geomorphological conditions that prevailed in the littoral zone during their formation process (Mauz *et al.*, 2015 and references therein). Their development along a sandy coastline contributes to mitigating the effects of marine erosion, i.e., the irreversible retreat of the coastline caused by natural (e.g., storms, waves, ocean currents, sea level rise) and anthropogenic (e.g., residential and touristic development, coastal infrastructure) processes in the coastal zone. This results in a systematic alteration of the coastscape, with the sea covering large sections of the vulnerable sandy beach. The submerged beachrock slabs in the nearshore zone due to relative sea level rise can act as natural barriers against coastal erosion, despite the loss of sediment during their initial cementation, thus changing the seascape and affecting the coastal morphodynamics (Psomiadis *et al.*, 2010). On the other hand, the rsl rise results in exposure of beachrocks along the contemporary coast (typical example from the study area: the Ververonta beachrock), which were previously buried under beach sediments, thus turning a sandy beach into rocky. This may have several social-economic impacts on the touristic exploitation of a beach and requires appropriate coastal management (Vousdoukas et al., 2009), in order to avoid inconsiderate destruction by locals (typical example from the study area: the Plaka-Drepano beachrock). As an alternative protection measure against coastal erosion, of lower

cost and more environmentally friendly than heavy engineering structures, several studies have focused on coastal ground improvement based on bio-stimulation, that is cementation of coastal sediments on the erosion-prone beach following the formation process of beachrocks and using local bacteria and seawater (e.g., Danjo and Kawasaki, 2016; Saitis *et al.*, 2022).
Due to their lateral spread and, often, their significant thickness, beachrocks contribute to the preservation of biodiversity in the nearshore marine ecosystems, effectively acting as a natural reef on the sandy seabed and a safe habitat of several species of marine life (seaweed, algae, organisms, fish, etc.).
Finally, recently initiated experimental researches attempt to link beachrocks with natural CO_2 storage exploring their role in reducing the environmental footprint of a region, as it has been demonstrated for CO_2 sequestration in sandstone reservoirs (e.g., Koukouzas *et al.*, 2018; Gholami and Raza, 2022).

Project area - Objective

The pilot area for the implementation of the Argo-Beachrock Project is the nearshore of the south Argolic Peninsula, from the southern part of the Saronic Gulf, at the eastern edge of the Hydra Strait, to the mouth of the Argolic Gulf, on the western coast of the Myrtoan Sea. The study area stretches across 255 km of coastline and includes 20 locations with beachrock formations, which collectively cover a total length of 20 km (Fig. 1).
This area was chosen partly because numerous submerged beachrock generations have already been recorded at various locations and depths, indicating distinct ancient lithified beaches formed during different periods. Notably, it includes the deepest recorded occurrence of Holocene beachrock observed in Greece to date (i.e., -8.85 m below mean sea level, Tigani coast, Tyros Bay) (Kolaiti, 2019). Additionally, it is a region undergoing systematic tourism development.

Figure 1. Map of the project area. The survey areas are indicated by red bullets.

The objectives of the Argo-Beachrock Project could be outlined as follows:

- UAV mapping and documenting of beachrock formations, including UAV and underwater survey, and depth measuring and validation.
- Analysis and processing of spatial data, production of high-resolution orthophoto maps, digital surface models (DSM), and 3D models.
- Visualisation of 2D information on an open-access web-map platform, creation of thematic maps, photographic material.
- Understanding coastal dynamics, environmental conditions, and natural processes through the comprehension and synthesis of all available data on the formation and evolution of beachrocks.
- Creating a comprehensive database (incl. location, depth per generation, mineralogical composition, if available, and absolute and indirect dating for each survey site), thus enhancing scientific knowledge and providing data available for future research.

- Disseminating the project results in order to raise public awareness of the importance of coastal protection through the study and preservation of beachrock formations, highlighting their role in mitigating erosion and preserving ecosystems. Collaboration with local communities, researchers, and stakeholders.

Methods

The submerged beachrock formations throughout the survey area have been previously mapped, their features (length, width and thickness) recorded, and the depth of the seaward and landward end of the top and base of each beachrock generation in each location were measured during previous snorkel geological surveys using customary methods. The depth measurements were subsequently corrected for tide at the time of the surveys with respect to mean sea level and for the effect of atmospheric pressure on the sea level (Kolaiti, 2019, 2024).

In this study, aerial digital photogrammetry was applied to produce high-resolution digital surface models (DSM) of the seashore and nearshore zone in all the survey areas. The low altitude imagery captured during aerial surveys conducted in two different periods (October 2024 and April 2025), under extremely calm wind conditions (<1 bf), in order to achieve the best shoreline reconstruction and avoid any distortion in the coastline position caused by sea waves and water refraction. High-resolution images have been acquired using an RTK DJI Mavic 3E with global shutter camera (FOV 84°, 24mm lens equivalent, 20MPixel, ¾ sensor size) in aerial surveys. Side overlap was set at 60%, frontal overlap at 80%, and flight speed at 4-7 m/sec. During the two survey periods 30 flights were conducted, of a maximum duration 20 min each, depending on the extent of the survey area. The relative height of the flights was 80 m with terrain follow adjustments, whereas in two sites (Tyros and Plaka-Drepano) a flight height of 60 m and 40 m was applied, in order to compare the images in shallow waters. At the 80 m-flight level, the resulting ground sample distance (GSD) was 2.2 cm/pixel, which produced a high detailed orthomosaic. A total of 4,534 images were collected, while the sum of the 20 survey areas amounts to 454 ha (4.54 km^2).

The image-based 3D modelling process was carried out using Agisoft Metashape Pro software. The GGRS 1987 coordinate system was used, with Geoid Model D applied for vertical adjustments. After the modelling process was completed, the following outputs were produced for each surveyed site: (i) 3D dense point cloud (in LAS/LAZ format) (ii) mesh (in FBX format) (iii) GeoTIFF Digital Surface Model (DSM) with a spatial resolution of 8.5 cm, and (iv) orthomosaic with a spatial resolution of 2.1 cm.

The 3D modelling workflow involved several key steps: (a) *Sparse Point Cloud Generation*: an initial sparse point cloud was created as a preliminary representation of the geometry derived from UAV-acquired imagery using the Structure from Motion (SfM) algorithm, (b) *Dense Point Cloud Generation*: high-resolution dense point clouds were generated from the aligned images using multi-view stereo algorithms, after feature detection with the Scale-Invariant Feature Transform (SIFT) algorithm. The dense point cloud enhanced model precision by capturing detailed surface features necessary for accurate representation, (c) *3D Mesh Creation*: The dense point cloud data was interpolated to construct 3D meshes, providing a continuous surface representation, and (d) *3D mesh Texturing*: the 3D meshes were textured to produce a photorealistic visual output.

This systematic approach ensured the generation of high-precision 3D models suitable for detailed analysis and visualisation (Papadopoulou *et al*., 2021, 2022).

Results - Discussion

The orthomosaics generated from the Argo-Beachrock Project's geospatial survey were used to delineate the boundaries of each beachrock generation, now submerged in the nearshore zone of each surveyed area, to assess its current situation (e.g., erosion, fragmentation), and to identify remains of ancient structures integrated into the beachrock formations.

For each surveyed area, a comprehensive suite of geospatial products has been generated, including detailed 3D models, high-resolution visualisations, orthophoto maps, and associated datasets. These outputs are integral to the project's objectives and will be made publicly available on open-access platforms by the project's conclusion. The data dissemination strategy includes the following components:

- *Web-Map Platform*: an interactive web map will enable users to visually explore all orthomosaics. This platform will allow seamless navigation, zooming, and layer toggling for enhanced spatial analysis and visualisation. The

web map will cater to diverse user needs, from researchers and planners to educators and the general public.

- *YouTube Channel for 3D models*: a dedicated YouTube channel will host a collection of 3D animated maps, providing dynamic visualisations of the generated 3D models. These animations will facilitate an in-depth visual inspection of the models, showcasing intricate surface details and the spatial relationships within each survey area. The channel will serve as an accessible resource for presentations, educational purposes, and broader dissemination to non-specialist audiences.

By leveraging open-access platforms, the project ensures that these datasets are preserved and accessible for future research, education, and practical applications. This approach promotes collaboration, supports transparency, and maximizes the impact of the generated geospatial resources.

Next, we provide an example of the photogrammetric mapping and visualisation data generated for one out of the twenty survey sites (Figs. 2 and 3).

Figure 2. Part of the orthomosaic of the Plaka beach (Drepano, N Argolic Gulf), providing a clear and detailed image of the beachrock formation extending to a depth of -1.20±0.05 m below mean sea level.

Figure 3. Part of the 3D model of the Plaka beach (Drepano, N Argolic Gulf), corresponding to the same coastal zone as Figure 2.

The depths in the nearshore zone, as derived from the Digital Surface Models (DSMs) produced in the context of the Argo-Beachrock Project, were compared with those obtained through mechanical methods during previous snorkel geological surveys. The comparison shows a good match in shallow waters (up to a maximum depth of 2 m), with deviations well below the mean tidal range. However, this comparison is not meaningful for greater depths.

Shallow-water bathymetry is a dynamic and evolving field of research, with modern drone imagery-based methods enabling unprecedented levels of detail and accuracy (Makris *et al.*, 2024 and references therein). Among the methodologies commonly employed in the literature, spectral and geometry-based approaches are predominant. These techniques are often utilized individually or in combination to enhance bathymetric accuracy and resolution.

In the context of the present study, the produced Digital Surface Models (DSMs) were utilized exclusively for geovisualisation purposes rather than as a true bathymetric dataset. This distinction aligns with prior research, where DSMs

derived from drone-based imagery are often leveraged for visual representation but they lack the precision required for accurate depth measurements in bathymetric studies, as it is widely accepted that the accuracy of DSMs decreases with increasing water depth (Sefercik *et al.*, 2024 and references therein).

Conclusions

By combining UAV image-based 3D modelling, field observations, and systematic documentation of coastal natural features and manmade structures, alongside the use of geovisualisation tools, we can better understand the extent of past marine transgression and coastline retreat driven by ongoing relative sea level rise along the entire coast of the Argolic Gulf during the Late Holocene.

Modern methodological approaches to studying the dynamic coastal system have proven invaluable tools for monitoring and managing one of the wealthiest littoral zones of the Peloponnese, which is experiencing steady tourist growth. However, this region, rich in natural geomorphs and cultural heritage, has already been significantly affected by rising sea levels over both prehistoric and historic timescales. It will face even greater challenges as sea levels continues to rise at an accelerating rate, in line with global temperature increases, a dire consequence of climate change.

Beyond the methodological aspects, the results of this fully open-access research project will assist scientists, local communities, and stakeholders to design early response systems for coastal retreat, extreme weather events, and civil protection and adaptation measures, ultimately contributing to a sustainable regional development. More analytically, integration of UAV-based remote sensing and advanced geovisualisation techniques has significantly enhanced the accuracy and efficiency of coastal monitoring and analysis. Geovisualisation platforms further enable interactive exploration and interpretation of 2D and 3D data, fostering a deeper understanding of spatial-temporal trends and facilitating data-driven decision-making for coastal management and climate resilience strategies. Finally, UAV-based mapping can serve as a foundation for the long-term monitoring of the changes in the coastal zone over time.

Acknowledgements

The Argo-Beachrock Project was implemented with the support of the Athanasios C. Laskaridis Charitable Foundation within the framework of "*Points of Support*", a co-funded programme by 10 public benefit foundations. The project was assigned to the Society for the Study of Ancient Coastlines NPO – AKTES on October 1, 2024, and was carried out in close and effective collaboration with the Cartography and Geoinformatics Laboratory, Department of Geography, University of the Aegean. It was completed on May 31, 2025. The final deliverables are displayed on the *ArcGis Enterprise Portal* of the University of the Aegean (https://sdi-portal.aegean.gr/portal/apps/experiencebuilder/experience/?id=602a22c307b34e7cb0211f0f6b58220e), uploaded on the fully open access *sketchfab platform* (https://sketchfab.com/aegean_cartolab/collections/the-argo-beachrock-project), and published on the *AKTES YouTube channel* (https://www.youtube.com/@aktes7509/playlists).

Introduction

The Corinth Canal is an artificial waterway in Greece that connects the Corinth and Saronic Gulfs. It crosses the narrow Isthmus of Corinth, a 79 m high ridge which once linked the Peloponnese peninsula to the Greek mainland, creating a natural barrier between the Ionian and Aegean Seas. The Canal extends in a straight line for 6,343 m. It is 24.60 m wide at the sea surface narrowing to 21.30 m at its bottom, while the water height in it ranges from 7.50 to 8 m (CorinthCanal). In this paper, we present an overview of the technical aspects of this admirable engineering work tracking the historical route of its opening from antiquity until the late 19th century and briefly describe the accompanying infrastructure works and the ongoing interventions, mainly driven by the geotectonic setting of the area. We argue for the monumentality of the Corinth Canal that mandate its future preservation and we propose a framework of actions to protect this prominent heritage.

The diolkos and the history of the canal

The idea of avoiding the dangerous and long circumnavigation of the Peloponnese taking advantage of the strategic position of the Isthmus of Corinth dates back to the late 7th – early 6th century BC, when ancient Corinth flourished, ruled by the tyrant Periander, having two harbours (Lechaion in Corinth Gulf and Kenchreai in Saronic Gulf) and a fleet to control maritime traffic on both seas. It was then that a paved trackway along the isthmus was constructed, the famous *diolkos*, across which goods and small boats, mainly warships, were hauled and transported on a platform (*olkos*). It followed the path of the present-day canal for a length of about 8 km. It was 3.40-6.0 m wide and carried two grooves in the middle, spaced 1.50 m apart. It ended on a paved quay on its western side, where it has been excavated for 255 m and 204 m on the Peloponnese (Kolaiti *et al.*, 2017) and Sterea Hellas sides, respectively, whereas its eastern end facing the Saronic Gulf, located in the area of ancient Schinous (today's Kalamaki) has not been found yet. Several phases of reconstruction followed during the 5th and 4th centuries BC. It remained in use until the AD 9th century (Ministry of Culture and Sports, 2012).

Strabo (1.3.11) reports that Dimitrios Poliorkitis (307 BC) planned to cut a passage through the Isthmus of Corinth, but he was prevented by his engineers, and also Julius Caesar (AD 44) and Caligula (AD 37) had probably the same intention. The most important works were carried out by Nero in AD 67, who, using slaves (at least 6,000 Jewish prisoners), began excavations on both sides of the Isthmus with notable progress, remains of which are either still visible (e.g. Nero's relief) or recorded (e.g. trenches, pits) during the construction of the modern canal (Gerster, 1884). The project was eventually interrupted due to either logistic difficulties or political instability (CorinthCanal). This was certainly the commencement of an ambitious project. The Venetians attempted to resume it in 1687 but were unsuccessful.

In 1830, Ioannis Kapodistrias, the first Governor of the new Greek State, assigned the project to the French engineer Virle d'Uct, who estimated that an enormous amount of 40 million gold francs would be needed for its completion. In 1869, the inauguration of the Suez Canal revived interest in constructing the Corinth Canal, and the government of Thrasyvoulos Zaimis passed a law "on the Isthmus canalization", under the provisions of which in 1870 a contract was signed with French entrepreneurs, but it was not implemented due to lack of funds (Papafotiou, 2010). In 1882, the French company 'Société Internationale du Canal Maritime de Corinthe' was formed with the purpose of completing and operating the Corinth Canal. The 99-year canal's concession, granted by a royal decree in 1881 to Hungarian General, canal architect, and engineer Istvan Türr, was transferred to the French company (Société Internationale). The project commenced on April 23, 1882, based on Nero's plans and the final design by the Hungarian engineer Bella Gerster. In 1890, the company was dissolved and put into liquidation, and the project halted. However, efforts to secure additional funding succeeded, and constructions was resumed by the Greek construction company 'Geniki Etaireia Ergolipsion', founded in 1889 (Pepelasis, 2010). With a generous contribution from Greek benefactor Andreas Syggros, the canal opened with great ceremony on July 25, 1893 (CorinthCanal).

Isthmus Infrastructure: The bridges

The 19th-century railway bridge was blown by the German occupying troops during their withdrawal from Greece in 1944, to be later rebuilt in the late 1940's. Two submersible road bridges operate at both ends of the canal (Posidonia and Istmia), which continuously facilitate the communication between central Greece and the Peloponnese.

In the late 1990s, as part of the construction projects of the new P.A.TH.E. motorway and the high-speed railway line Athens-

Thessaloniki funded by the European Union, the design of the new canal bridges was decided. The initial design was based on the geometric characteristics of the new alignments, while ensuring the stability of the bridges with the least possible excavations in the canal's slopes so that its shape would not be altered. The span of the bridges was determined after the idea of widening the canal was rejected. However, the geotectonic setting of the Isthmus area finally played a decisive role in the final position and foundation of the new bridges. The secondary tectonic activation of the faults crossing the Corinth Isthmus, as it was evidenced by their quantitative and qualitative tectonic analysis, and the thorough study of the stratigraphic, lithological and neotectonic features of the canal's slopes, demonstrated that the abutments and the piers of the new bridges had been positioned in different tectonic blocks on both sides of the canal (Peloponnese and Attica). This led to the redesign of the new bridges and the implementation of specific construction techniques using seismic isolation bearings. The new motorway and railway bridges were opened to traffic in 1997 and 2003, respectively.

The geological and geotectonic context of the Corinth Isthmus

The Corinth Isthmus is crossed by at least 46 large-scale normal faults, traverse to its direction, which have caused successive displacements on the Plio-Pleistocene and Quaternary strata, and on the recent artificial deposits from the Isthmus excavation, affecting the morphology on both sides of the canal. The faults have a NE-SW direction, with the fault mirrors dipping toward S, SE, and WNW at 60°-85°, and strike-slip lineation plunging S and SW. They have been repeatedly activated within a NNE-SNE extensional regime and are still considered to be active (Fig. 1A, 1B). With a total visible displacement of 7.50-21 m during the Quaternary, they have caused the gradual rotation of the tectonic blocks they delimit by about 10° toward the SE. The Corinth Isthmus is affected by two vectors of tectonic displacement: uplift and extensional fault-induced subsidence, which may be accompanied by block rotations. Neogene and Quaternary sediments are cut by numerous, nearly E-W striking, sub-vertical normal faults, which can be observed all along the canal. As these faults belong to two different groups dipping toward N and S, respectively, the isthmus has been interpreted as a horst (Fig. 1C). The oldest sediments are at the base of the central horst block, dominated on the NW by white and grey calcareous silts (Fig. 1B). There is an upwards transition within the central horst block from freshwater or brackish facies to sediments of a marine environment (Papanikolaou *et al.*, 2015; Mourtzas and Kolaiti, 2017 and references therein).

The crossing area of the new bridges consists of three distinct tectonic blocks, each of an average width of 60 m, bounded by four main normal faults striking NW-SE to NNE-NNW and dipping toward SE to SSW at angles 70°-90°, with a visible displacement of 4-5 m (Fig. 1D, 1E). The faults have been activated during various neotectonic deformation phases, causing a gradual displacement toward the SE and a counter-clockwise rotation of about 10°. The main faults and the accompanied parallel small-scale structures were surveyed, not only on both slopes, but also in deep trenches that were excavated parallel to the canal axis, while their geometric and kinematic features were measured (Fig. 1E). The stratigraphy of the Neogene and Quaternary units on both the canal's slopes was mapped and the relative position of the layers within the distinct tectonic blocks was recorded, thus ascertaining their spatial continuity (Fig. 1D, 1E). Moreover, the lithology, physical characteristics, and mechanical properties of the layers were determined by means of drilling of fifteen boreholes and wells (Fig. 1D). The identification of recent fault activations that have resulted in displacements of several centimetres, which are visible even in the debris of the canal's excavations, imposed the positioning of the abutments and piers of the bridges within the same tectonic block with their axes parallel to the direction of the fault lines, in order to avoid failures in case of differential movements (Mourtzas and Kolaiti, 2017 and references therein).

Landslides and Recent interventions

The high (>60 m), steep, marly slopes of the Corinth Canal, prone to landslides, have caused ongoing instability, rock falls, and slide of large volumes of materials since almost the inception of the canal, leading to interruptions in vessel passage and even extended closures. In addition to geological factors (e.g., rock type and structure, steep gradients, active tectonism, seismic activity, lack of vegetation, soil erosion), human-related factors (e.g., excavation, construction, undermining, sabotage) have further increased slope vulnerability to failure. Between 1923 and 1997, it is estimated that approximately 900,000 m^3 of material fell into the canal, resulting in a total closure period of eight years (CorinthCanal). The destructive 1981 Alkyonides earthquake sequence (24.2.1981 M=6.7, 25.2.1981 M=6.4, 4.3.1981 M=6.3) at the eastern end of Corinth Gulf, resulted in two major ruptures in the Isthmus horst, fault activation and displacement, and rock failure and serious landslides in the canal's slopes. The ENE-WSW trending Kalamaki-Isthmia normal fault downthrown to SSE, located at the eastern tip of the canal, was passively ruptured by up to 6 cm during the 1981 earthquake sequence (Papanikolaou *et al.*, 2015; Mourtzas and Kolaiti, 2017 and references therein). Between November 2020 and February 2021, frequent landslides occurred, culminating in a major collapse of 15,000-20,000 m^3 on February 3, 2021 (CorinthCanal), mainly near the wastewater treatment plant on the Peloponnese side. This serious instability resulted in the closure of the canal and disruption of navigation through it. Although the landslides affected the upper part of the slope over a 100 m-stretch near the wastewater bridge, they did not impact the bridge's stability.

In November 2021, the final design of the slope restoration project was approved by the Ministry of Infrastructure and Transportation

–now responsible for the design and construction of the slope restoration works at the request of the

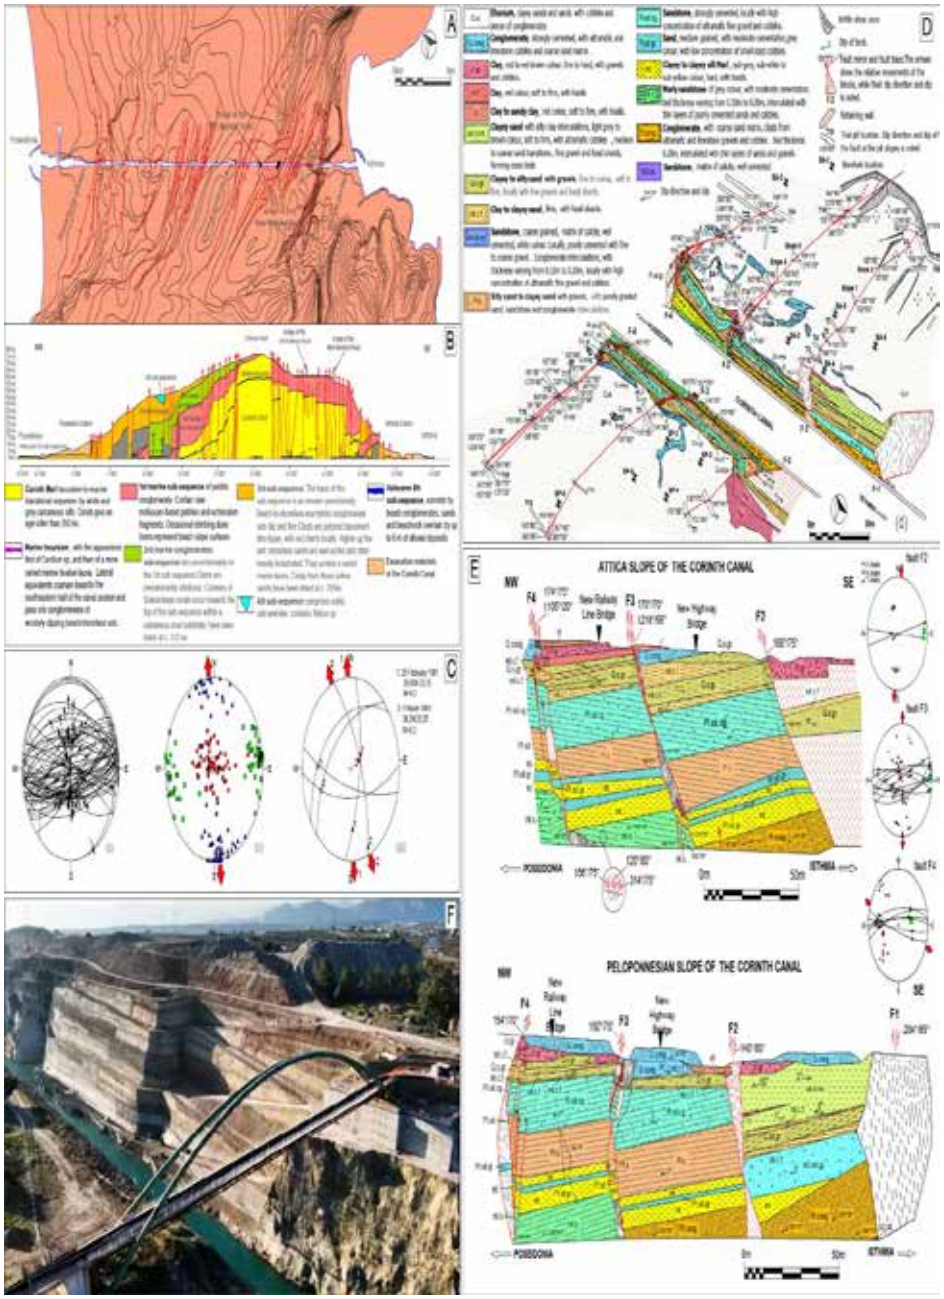

Figure 1. A: Plan view, and B: Longitudinal section of the Isthmus horst, indicating the geological structure and main faults. C: (i) Stereogram, and (ii) calculated stress axes of the Isthmus main faults, and (iii) focal mechanism solutions of the 1981 Alkyonides earthquake sequence. D: Geological plan view, and E: Front views of the two slopes of the Corinth Canal in the area of the new bridges, indicating the main faults that demarcate the tectonic blocks and their palaeostress analysis. F: Aerial view of the slope stabilisation works in 2022 at the area of the wastewater treatment plant on the Peloponnese side, showing the slope excavations and, in the foreground, the wastewater bridge [A, B, C, D, E: after Mourtzas and Kolaiti (2017) and references therein, F: modified from Papamanolakis].

Corinth Canal S.A.– especially characterized as a '*complex and special national-level project*' (Dec. 29307/ Σ6651/3.2.2021). Due to its urgent nature for civil protection ensuring public safety and restoring normal navigation, the project is exempting from environmental approval (Dec. 103435/6635/9.2.2021), with the only obligation for the operating company to submit an Environmental Impact Study for the operation and maintenance of the canal within

two years from the exemption. In December 2021, the project was assigned to the contacting company AKTOR S.A., with a budget of 30.57 million euros and a completion period of 24 months. The restoration engineering works are divided into two distinct phases: Phase A includes slope excavations for a total length of 600 m on both sides of the wastewater bridge, creation of three terraces (10 m-wide with intermediate slopes 6 m/11 m/9 m/8 m high), construction of permanent roads-ramps for heavy vehicles, strengthening with piles of the southern pier of the wastewater bridge, slope stabilisation with anchors and grouting, hydraulic works for surface water drainage management, construction and waterproofing of the western and eastern embankments. Phase B involves the construction of a toe pile wall to prevent coastal erosion and slope undermining.
The first phase of the project has been completed, leaving a significant environmental footprint (Fig. 1F). The second phase has not yet started. Furthermore, the recent approval by the Ministry of Infrastructure and Transportation to replace the seismic isolation bearings of the new motorway bridge, at the request of Olympia Odos S.A. (concessionaire of the Elefsis-Corinth-Patras-Pyrgos Motorway), and the looming plans of widening the canal (Papafotiou, 2022), will further alter this outstanding landmark, without substantial financial benefits for the Corinth Canal S.A. (A.E.DI.K), the company which exercises and exploits the rights associated with the Corinth Canal. Although outside the scope of this paper, the long-term viability of the company remains crucial. Official data (Growthfund) shows that the Corinth Canal handles over 11,000 vessels annually, mainly tourist ships. Published financial statements for the period 2019-2023 (GEMI-Publicity) reveal net profits of 1 million euros in 2019 when the canal's passage was unhindered, but losses of over 3.3 million euros in 2021 and 1.7 million euros in 2022, due to the canal's closure for restoration after the 2020-landslides.

Monumentality of the Corinth Canal or Infrastructure and Monumentality

The term '*monumentality*', introduced by several scientists with different connotations, is hard to define in a few words, although several methodological approaches and tools explore its concept, mainly for ancient civilisations (Buccellati, 2019). Despite the unfruitful attempts to find a unifying definition for the complex notion of monumentality (Levenson, 2019), it has been adopted by architectural and archaeological theory, while it has a broader approval to other disciplines and different types of structures, which reflect the cultural and socio-political context they belong to. Osborne (2014) argues that '*monumentality is something more than the shape, or size, or visibility, or permanence of the monument – though these variables absolutely carry their own significance. Monumentality lies in the meaning created by the relationship that is negotiated between object and person, and between object and the surrounding constellation of values and symbols in a culture*'. Others support that monumentality exceeds physical scale and it is '*a combination of great technical ingenuity, extraordinarily high levels of skill, the devotion of vast amounts of time to build the monument, the type and range of the resources invested and the sheer size of the task*' (Brunke *et al.*, 2016). Monumental structures can be related to four primary attributes: permanence of the structure, the place or the memory (lasting endurance: connection to the past and projection into the future), integration within a specific landscape or urban environment, statement of vision, compelling effect, strength, and social and political relations, and, projection of public values, symbols, and political authority (Brunke *et al.*, 2016; Hageneuer and van der Heyden, 2016; Horn and Proudfoot, 2016). Although there has been much discussion of monumentality, it is mainly focused on monumental architectures, in diverse archaeological and historical contexts. Infrastructures (e.g. dams, bridges, canals, roads, power stations, etc.) are often overlooked in discussions, due to the weakness of perception of their symbolic power or the profound effects they have on society. Nevertheless, large-scale technical works are undeniably significant in terms of constructional energetics and social impact. According to Levenson (2019), they possess a distinct form of monumentality rooted in their capacity to innovate, improve daily life, and create social dependencies, arguably making them even more integral to the survival of societies than palaces, temples, or other public buildings. Infrastructure and monumentality intersect in how large-scale constructions embody both functional utility and symbolic significance. Beyond serving as tools for transportation and labour, they synthesise surrounding landscape, public space, and architecture (MIT Center for Advanced Urbanism, 2016). Large-scale technical projects, while fulfilling essential societal functions, can also be monumental in design and impact, symbolizing power, progress, and cultural significance.
Under these considerations, the Corinth Canal is an infrastructure necessary for navigation, primarily designed for function, efficiency, and sustainability. The canal connected the Saronic with the Corinth Gulfs, thus making navigation faster (time), easier (risk), and more environmentally-friendly (energy). Its geographic and geopolitical position renders it to '*a communication hub between the Aegean and Ionian Seas*' (Dec. 29307/Σ6651/3.2.2021). The opening of the canal, in fact, created a man-made, geographic boundary between the Greek mainland (Sterea Hellas) and the Peloponnese, the latter now shaping the largest island of Greece. From this perspective, the canal is an outstanding landmark. The geology and faulting of the Isthmus horst adds an invaluable value to the Corinth

Canal. Crossed by at least 46 normal and oblique normal faults, all recognised and surveyed (Mourtzas and Kolaiti, 2017), the canal's slopes compose an open geo-archive, providing a great opportunity to visualise them. This unique structure shapes an '*impressive mega-trench*' (Papanikolaou *et al.*, 2015), a precious geoheritage (Velitzelos *et al.*, 2003).

Its monumentality, on the other hand, lies in its symbolic and cultural importance, emphasising permanence, vision, political power, and historical significance. First conceived 2,300 years ago, the initial design plans date back to the 1st century AD. Remains from Nero's works testify to the ambitious idea and efforts to implement the grand project. The canal's construction was organized and completed only after the emergence of the Modern Greek state. The various actors of this grand project, either known or unknown, may have had different motivations, but its completion is the result of the development policy of the Prime Minister Charilaos Trikoupis, who, through major infrastructure projects, aimed to create a modern, economically developed state and provide models for future growth. The project was also deemed necessary by the international trade and shipping conditions of the time. Though the Corinth Canal was a 2,300-year-old dream, it was the technological progress of the 19th-century Industrial Revolution that ultimately drove its realisation. Therefore, large-scale public projects, such as the Corinth Canal, serve to enhance community infrastructure and identity, reflecting the vision of their inspirers, and the cultural values and technological advancements of the society, in most cases tied to political power. It is authoritatively perceived as '*a unique landmark*' and '*a project-symbol, completely identified with the modernization of Greece*' (Hellenic Republic, 2022).

The Corinth Canal is tightly connected to the collective historical memory of the WWII period. Images of the blow up of the railway bridge by the Germans and knocking of locomotives and wagons down into the canal to block it, remain still strong to remind this period of the Greek history. Landscape transformations (e.g. earth movements) and bunkers still preserved there, reveal the strategic importance the isthmus had for the German occupiers, contributing to the historical memory.

The approaching method of '*constructional energetics*' would help to understand the canal monumentality in numbers. Records of the cost of the individual constructional processes (e.g. excavation, debris transportation, labour, etc.), aids in understanding the resources required and calculating the energy expended (Buccelatti, 2019). Beyond the quantitative approach, the study of the workforce (skills, composition, social setting) would be interesting. Therefore, the consequential correlation between cost and final result, given the limitations of data availability, adequacy, and accuracy, provides a better understanding of what the canal meant to those who produced it. Urban changes imposed by the needs of construction in the project's area can also signal its social impact, such as the creation of two settlements, Posidonia (divided in two sections, area: 139,000 m^2 and 72,000 m^2) and Isthmia (area: 144,000 m^2) (Papafotiou, 2010) to house the people occupied in the project and their families.

In addition, the huge quantities (millions of cubic metres) of excavated material from the opening of the canal and recent construction activities, have actually reshaped the landscape of the Isthmus territories (e.g., the artificial slopes on the road leading from Isthmia to Loutraki), offering insights into the design process. Recent approaches to moving grounds from the 'AlpTransit Infrastructure' project (new rail link crossing the Alps and connecting Germany to Italy through Switzerland) highlight how depots, landfills, and wastelands are shaping a collective imagination about the idea of landscape, giving rise to major political, economic, and ecological implications (Pradel, 2020).

From an engineering point of view, the Corinth Canal has no parallel in Greece and Europe. It is numbered among the three existing canals in the world, and is an excellent technological achievement of the time. Its engineering uniqueness has been authoritatively recognised: '*together with the Panama and Suez Canals, (it) constitutes the three technical canals that exist in the world today*' (Dec. 29307/Σ6651/3.2.2021). Furthermore, the implementation of the canal project opened new routes to mobilisation of scarce capital and technical know-how for the construction of public infrastructure through the collective entrepreneurial initiatives of S.A. banks (Pepelasis, 2010). Together with the construction of the 1,548 km-long national railway network, were decisive for the establishment of an integrated national economy and administrative centralization, both required for the building of the newly Greek state (Papayiannakis, 1982; Pepelasis, 2010). In particular, the mobilisation of national technical know-how was seminal to the Greek technical community. A notable example is Greek engineer-entrepreneur Antonios Z. Matsas, co-founder of 'Geniki Etaireia Ergolipsion', who replaced the foreign engineer Istvan Türr after the liquidation of the French company, ultimately leading to the canal's completion.

The long-lasting project of the canal's opening evokes the perception of a connection to a distant past, while its continuous operation for over 130 years reinforces a sense of permanence. Integrated into the unique geotectonic landscape of the Isthmus, the canal stands as a striking and timeless landmark with a dominant form, whose monumentality is constantly experienced. In terms of reception, it commemorates people, events, eras, practices, and techniques—not only from its creation, but also its lasting impact—embedded both in the structure and in collective memory (Belavilas, 2015). Numerous textual and artistic sources depict the canal, in an iconic way, further enhancing

this shared memory.

Thoughts on the future of the Corinth Canal

Nowadays navigation through the canal appears to be limited to mainly tourist vessels, as large ships prefer other easier sea routes in the open sea than a restricted canal to get from the Ionian to the Aegean Sea, thus downgrading its economic importance. The Corinth Canal is mainly a tourist attraction, thus its widening to accommodate ships larger than its current capacity seems to have no effect in conjunction with the exorbitant construction costs and the loss of its monumentality. After all, this proposal was rejected during the design of the new bridges in the 1990s. Although it seems that the Greek state is moving in this direction ['*the Canal should not only be a project that facilitates navigation, but also in itself be a visitable destination in order to highlight the overall tourism product of the region*' (Hellenic Republic, 2022)], at the same time the Ministry of Infrastructure and Transportation approves large-scale interventions for slope stabilisation on the Peloponnese side, without any environmental restrictions under the guise of urgent user safety, sadly causing significant alterations in the physiognomy of this unique monument. Immediate restoration of the canal's slope to its original form by a reinforced earth wall is required, while any future interventions of this scale will invalidate its monumentality.

Unfortunately, political decisions appear to be driven by development policies, yet they lack a clear strategy for ensuring the long-term viability of the canal. However, it seems that only an alternative management of the Corinth Canal, while maintaining its existing function, creates a development perspective. The production and promotion of a new tourism product is suggested, which will offer an immersive experience and tour of the canal through its historic path. Though it be focused on the Corinth Canal highlighting its monumental qualities and geological features, will also include accompanying monuments (e.g. ancient diolkos, bunkers, new bridges, submersible bridges, etc.). This tourism product would be flexible, catering to different types of tourism (both conventional and alternative), visitor demand, and available time, while ensuring accessibility and safety to visitors of all ages.

The Corinth Canal, a prominent engineering project of the time with an outstanding universal value, is a monumental infrastructure, highlighting how certain structures, while fulfilling necessary functions, transcend their utility and become symbols of cultural identity, history, and human achievement. It should have long since been classified as a recent monument of Greek cultural heritage, fully protected and subject to sustainable interventions under the provisions of Law No. 3028/2002, as in force. In addition, coordinated efforts ought to make the competent bodies so that the area of the Corinth Canal could be designated UNESCO World Heritage Site, recognizing its global significance both historically and culturally, as well as for its geological features. Thinking that *'monuments have shaped and are still shaping contemporary views on the past*' (Bußmann, 2019), we marvel at how this monumental, man-made '*mega-trench*' shapes perceptions of the geotectonic processes reflected on its slopes. It is our duty to preserve engineering achievements and historical memory for present and future generations, thereby substantially enhancing our social and cultural identity.

BULLETIN OF THE GEOLOGICAL SOCIETY OF GREECE, SP. PUBL.

EXTENDED ABSTRACT 155

Synergies for geo- education: materials and initiatives from Psiloritis UNESCO Global Geopark and the Center for Environmental Education and Sustainability of Anogia, (Crete) Greece.

Kolendrianou M .[1], Kefalogianni Z.[2], Kalomoiri A. [2], Fassoulas C. [1,3]

(1) Psiloritis UNESCO Global Geopark, Anogia, Greece, info@psiloritisgeopark.gr (2) Center for Environmental Education and Sustainability of Anogia, Anogia, Greece, (3) Natural History Museum of Crete- University of Crete, Heraklion, Greece

Research Highlights

The present work includes a summary of the main materials used and initiatives undertaken by Psiloritis UNESCO Global Geopark and the Center for Environmental Education and Sustainability of Anogia for the education of children and adults on Geology and Geology- related topics in the area of Psiloritis UNESCO Global Geopark, (Crete) Greece.

Introduction / Background

UNESCO Global Geoparks (UGGps) are single, unified geographical areas with exceptional geological features of international significance. They are managed with a holistic approach towards the protection, education and sustainable development of their territories, adopting a bottom-up approach through the active involvement of their local communities in their efforts (UNESCO, 2024). For any UGGp, education at all levels is one of the main focus areas of its operation (UNESCO, 2015). It is essential for a UGGp to develop and perform educational activities to disseminate knowledge and raise awareness on geodiversity and its connections to biodiversity and other traits of the tangible and intangible cultural heritage, with the purpose to educate and inspire on the significance of the territory and to increase local involvement and engage the audiences into more effective conservation.

Many UGGps form synergies with specialized educational institutions, at the national or local level, to achieve better pedagogical and more widespread results in their initiatives for education. One such example is the cooperation between Psiloritis UGGp and the Center for Environmental Education and Sustainability (CEES) of Anogia. CEESs are an institution of multiple different centers throughout Greece, established by the Greek Ministry of Education, Religious Affairs and Sports as a bridge between the school and society. In the CEESs' philosophy of operation, emphasis is put on the need to raise interest in all forms of life towards the development of an environmental ethic and by linking the education for the environment and sustainability with the need to also instill a system of values.

Objectives

Presently, there are 213 UGGps in 48 countries and, even though they produce numerous and innovative educational materials, the amount of published works on UGGp- education still remains limited in comparison to research on other topics concerning UGGps and with an availability of resources not much broader than that of local implementation and dissemination through conference participation (Martínez-Martín *et al.*, 2023). The present work aims to present the materials, programs and digital tools developed and used for education by Psiloritis UGGp and its education partner, the CEES of Anogia, as they are currently being implemented in the area.

Area

Psiloritis Geopark was established in 2001 and since 2015 it has been recognized as a UGGp. It is located in the central part of the island of Crete (Greece) with the mountain of Psiloritis, or ancient Idi (2456m), being the main point of reference for the territory, thus, also providing the name for the Geopark. It has a total area of 1272 km^2, including villages and settlements from 8 different Municipalities and a population of approximately 38.000 residents. The complex topography of the area and the variety of rocks combined with the isolation of the entire island of Crete, make the mountainous mass of the geopark a hotspot for biodiversity and endemism, leading to the inclusion of ~56% of the territory in the European NATURA 2000 Network. The connection of the area with the people has been strong and persistent since the times of antiquity, as can be demonstrated by the numerous findings and monuments spanning from the Minoan era to the Roman times and the many religious and cultural monuments of our days. The intangible cultural heritage of Psiloritis is also worldwide famous with the traditional handicrafts, cuisine, and music being only some of the examples.

Concerning the geodiversity of Psiloritis UGGp, it spans over a period of about 360 million years, with a variety of rocks attributed in 7 different tectonic nappes and ranging from the most common limestones and dolomites to the

more rare stromatolites and ophiolites. The fossils of Psiloritis UGGp also bear witness to its history and evolution of life, including findings such as the rare Fodele fossils (corals, brachiopods and bivalves of about 360-300 million years ago) or the most recent fossils from terrestrial vertebrates (dwarf elephants and deer, giant mice from the Pleistocene) as evidence of a special adaptation mechanism to island life.
The geodiversity of the Geopark bears witness to the geological history of the area that has been (and is still being) dominated by tectonism, uplift of the mountains and karstic erosion. Large- and small-scale folds and faults and all kinds of karstic features (surface and subterranean) appear throughout the area of Psiloritis, providing the opportunity for the visitor to find all the evidence that explain the formation of the high mountains and their continuous transformation through the creation of impressive gorges, mystical caves and fertile plateaus, as well as fascinating landscapes.

Results and Discussion

Psiloritis UGGp and Anogia CEES are both institutions with a long history of operation in the area (Psiloritis Geopark was established in 2001 and Anogia CEES in 2006), offering formal and non- formal educational activities in the wider area of Psiloritis. Both organizations have so far informed and trained thousands of students, teachers and also local professionals, residents and visitors. It is characteristically mentioned that for the year 2024, Psiloritis UGGp and Anogia CEES received a total of approximately 1035 children aged 5-18 (students, scouts), with whom educational activities were implemented either indoors or in the field. Most of the developed materials and tools used within this context, could be broadly categorized in the following general thematic categories: Geodiversity, Biodiversity, Human History/ Traditions and Arts, Sustainable way of life. These are briefly presented in the table below (Table) according to the typology of each material that is currently being implemented, its title and a brief description, the thematic category it falls into, whether it's being implemented by the staff of Psiloritis UGGp, Anogia CEES or by the two in cooperation and finally, the age of the audiences each material is addressed to.

Table. Summary of main materials for education implemented by Psiloritis UGGp and Anogia CEES, at the area of Psiloritis UGGp.

#	Typology of material	Title	Brief description	Thematic Category	Partner that implements the activity	Age of targeted audience
1	Multiple	Visit to the Psiloritis UGGp Information Center.	Includes informative and educational materials and small experimental displays, dioramas (cave, mountain ecosystem and traditional house), an exhibition of local products, while there is also a small collection of rocks and fossils from the geopark area as well as digital educational tools and references to the SDGs.	Geodiversity, Biodiversity, Human History and Traditions, Sustainable way of life	Psiloritis UGGp	NS
2	Educational program, field visit, simple experiments, hands- on activities	Meet Psiloritis UNESCO Global Geopark!	Includes a presentation on what is a UGGp and what are its purposes, Geopark networks, examples of geosites from Psiloritis UGGp, interpretation of the main geological processes (complementarily with simple experiments or displays) characteristic of the geodiversity and geological history of Psiloritis UGGp (and Crete), holistic approach of UGGps and links between geodiversity, biodiversity and human history and traditions. The presentation is usually followed by a field visit and/ or worksheets, hands- on activities.	Geodiversity	Psiloritis UGGp & Anogia CEES	NS

3a	Educational program	Where is the water?	Aims to explore the processes of karst erosion that have formed the relief of Psiloritis and the relationship between underground water and water availability/ management issues in the area. It may be followed by a field visit (#3c) in one of the caves of Psiloritis UGGp that are open for visitors.	Geodiversity	Anogia CEES	Kindergarten - mid-Elementary School students
3b	Educational program	When water hugged the stone…				Mid-Elementary-High School students and adult students
3c	Field visit	Discovering the secret world of caves!	This field visit incudes a visit in one of the three open for visitors caves of Psiloritis UGGp, where the students experience the geology of caves and their unique biodiversity and local legends.	Geodiversity, Biodiversity, Human History and Traditions		Elementary-High School students and adult students
4a	Hands-on activity	What makes the most common rock of Psiloritis UGGp special?	This aims to highlight the diversity of karst formations, including posters of caves, gorges, plateaus and karst springs and complementary smaller cards depicting characteristic plants, animals or human activities linked to them, that the students need to "match". This activity is used independently (during public outreach events) or follows the implementation of #2 or #5a (when there isn't an option for a field visit).	Geodiversity, Biodiversity	Psiloritis UGGp	Elementary-High School students and adults (during public outreach events)
4b		Threats for mountain ecosystems!	Includes 12 cards with different threats for mountain ecosystems (soil erosion, pollution, habitat fragmentation etc.) with pictures from the territory and different Greek mountains. This activity is used independently (during public outreach events) or follows the implementation of #2 or #5a. It can also be implemented in the field, where the students try to identify in- situ a bad practice from the cards (if present) and discuss if other threats could apply in the territory.	Geodiversity, Biodiversity, Sustainable way of life		
5a	Educational program, field visit, worksheets, hands- on activities	Biodiversity and Psiloritis UGGp.	Includes a presentation on what is a UGGp and what are its purposes, interpretation of geodiversity and biodiversity and how they are linked, introduction to endemic plants and animals of Psiloritis UGGp- mainly focusing on the species' history and threats. The presentation is usually followed by a field visit and/ or worksheets, hands- on activities in the Information Center or in the field.	Geodiversity, Biodiversity	Psiloritis UGGp	mid-Elementary -High School students
5b		In the land of Amalthea: earth, scent, life!	Includes a presentation on the typical ecosystems of Psiloritis, examples of local biodiversity and endemism, the concepts of diversity in nature and society and familiarization with the scientific approach of studying the natural world. The presentation is usually followed by a field visit and/ or worksheets, hands- on activities in the Information Center or in the field.	Geodiversity, Biodiversity	Anogia CEES	Elementary-High School students and adult students
6	Educational program, hands- on activities	A tale from Psiloritis UGGp!	Includes a presentation on what is geology and what is a UGGp, what could be a geosite and what could not (with visual examples from the territory), who are the people of the Geopark (who studies rocks? what are the main professions of the people in our geopark?), interactive narration of a local myth and activities exploring the characters/ natural setting of the story.	Geodiversity, Human History/ Traditions and Arts	Psiloritis UGGp	Kindergarten - mid-Elementary School students

7	Educational program, worksheets, activity book	How does the natural environment give birth to civilization?	This is a program that aims to highlight the connections between the natural environment of Psiloritis and the cultural heritage of its people, focusing on the local economy and the traditional arts (especially loom weaving).	Geodiversity, Human History/ Traditions and Arts	Anogia CEES	Kindergarten -High School students and adult students
8	Educational program, field visit	Visiting the shepherd's shelter!	This program aims to present the shepherd's way of life in Psiloritis, highlighting the role of the natural environment, through a field visit in a mountain plateau to experientially explore concepts of ecosystem services and visit a mitato (traditional shepherd's refuge built with the dry- stone walling practice).	Geodiversity, Biodiversity, Human History/ Traditions and Arts	Anogia CEES	Kindergarten -High School students and adult students
9	Educational kit	The underground journey of water.	Explores the relationship between limestone and water, the underground journey of water through the rocks, the formation of karst structures and the ecosystems and biodiversity found in them. The kit includes theoretical background for the teacher, instructions and materials for different activities e.g. crosswords, board games.	Geodiversity, Biodiversity	Psiloritis UGGp	Elementary -High School students
10	Educational kit	Climate Change and Island Geoparks.	Explores themes such as climate change, the "footprint" of the modern lifestyle and the natural phenomena associated with the effects of these factors. The kit includes theoretical background for the teacher, instructions and materials for different activities e.g., card- games, board game.	Sustainable way of life	Psiloritis UGGp	Mid Elementary -High School students
11	Digital tool	e-Geodiscover app (available for two different geo-trails)	This is an app for mobile devices (smartphones, tablets) that aims to provide knowledge about the geology, culture and environment of the geopark, as well as map reading, orientation and navigation skills, in the form of a pop-up "hidden treasure" quiz, which the child follows along an easy and smooth short route in the area of the Stefana plateau (Mygia's geo- trail) and/or in Gonies geo- trail.	Geodiversity, Biodiversity, Human History/ Traditions and Arts	Psiloritis UGGp	NS
12	Network for collaboration on education	National Thematic Network entitled "Feeling the memory of the Earth through geodiversity, Geoparks and anthropogenic activities"	Anogia CEES has established this Thematic Network with the aim to connect teachers and educators all over Greece, interested in topics related to geodiversity and UGGps and keep them engaged through a series of actions and initiatives (trainings, production of textbooks and education material etc.).	Geodiversity, Biodiversity, Human History/ Traditions and Arts	Anogia CEES	Teachers of all levels, Educators
13	Training seminars, field visits	Multiple themes	Both partners design, organize and implement training seminars (many times jointly) addressed to adult professionals of the area (e.g., teacher trainings, seminars for local producers). These seminars usually include a series of theoretical presentations from experts, followed by field visits to experience the examples and good practices, regarding each topic.	Geodiversity, Biodiversity, Human History and Traditions, Sustainable way of life	Psiloritis UGGp & Anogia CEES	Adults

14	Public events	Multiple themes	Both partners design, organize and implement public events (many times jointly), addressed to issues that concern the local communities with the purpose to responsibly inform and sensitize them. These events may concern public talks on Natural heritage & Conservation, Natural Hazards, debates on Clean Energy etc. and on many occasions they are organized within the context of International Days.	Geodiversity, Biodiversity, Human History and Traditions, Sustainable way of life	Psiloritis UGGp & Anogia CEES	NS
15	Partnerships-synergies	Multiple partnerships	Both partners have a close cooperation between each other, but they have also developed numerous synergies with other Educational/ Research Institutions over the years to further support their initiatives concerning education.	Geodiversity, Biodiversity, Human History and Traditions, Sustainable way of life	Psiloritis UGGp & Anogia CEES	NS

NS: Not- Specified (for "Age of targeted audience"), when there is no limit to the age of the targeted audiences to whom the material/ activity is addressed to, but is modified for different ages and situation of implementation (educational activity, public outreach event etc.).

Figure 1. Picture from a school visit in the geosite Petradolakia after an educational program at CEES of Anogia (left) and at the geosite Vossakos Folds during a three-day teacher- training seminar in 2019, within the context of the National Thematic Network of CEES of Anogia "Feeling the memory of the Earth through geodiversity, Geoparks and anthropogenic activities" with the cooperation of Psiloritis UGGp (right).

Based on the quantity and multidisciplinarity of the materials provided for geo- education and geology- related topics in Psiloritis UGGp (Table), it becomes once again evident that these territories are important loci for the interpretation and education on themes and phenomena related to the formation and conservation of the natural world. In Psiloritis UGGp, educational activities are implemented by the staff of the organization as well as by the Anogia CEES, one of the geopark' s partners for education within the territory. Interestingly, even though the educators in the CEES of Anogia are not trained geologists, they have exhibited a consistent passion for geo- education since the early years of their operation, recognizing the importance of the local geodiversity and promoting it through the numerous education programs and initiatives they implement (Table). The excellent cooperation between Anogia CEES and Psiloritis UGGp has provided high- quality (scientifically and pedagogically) education materials and initiatives, educating an overall of approximately 10.000 students and 5.000 teachers on relevant topics (Fig. 1) in the territory so far (data from Anogia CEES).

Both organizations have developed and are implementing activities in the form of complete and structured educational programs or individual materials (activity books, short experiments etc.) for students of different levels, but also adults that may be university students, teachers or professionals of the area, receiving training on Geopark- related subjects in the form of workshops. Other forms of education initiatives may include field trips, textbooks and other activities performed during special occasions (i.e., celebration of International Days, special visits etc.) (Catana & Brilha, 2020; Rossi et al., 2022) also potentially aiming at locals or visitors, within the context of communication/ public outreach- that share some goals and principles with education- on what concerns the interpretation of the natural world of a territory (Crofts et al., 2020).

A wide range of pedagogical techniques is embedded in these educational activities: step-based education, familiarization and empowerment games, field studies, observation and orientation games, experiments that visualize

natural processes, inquiry-based learning and many more, while at the same time they enhance critical thinking, cooperation between students/ student groups, and empirical knowledge. The multidisciplinary approach and the promotion of links between themes is obvious in most materials while the successful communication between the organizations itself can be seen in the complementarity of some of the materials/ initiatives e.g., the CEES of Anogia has a greater experience in organizing training seminars for teachers and educators and Psiloritis UGGp has a larger set of options of digital tools (Tab. #11; Fig.2; Fassoulas *et al.*, 2022). All the above observations (quantitatively, qualitatively) generally agree with findings and conclusions from Catana & Brilha (2020) and Rossi *et al.*, (2022) on the mode of how educational tools and activities are designed and executed in most geopark territories.
Furthermore, with reference to the seventeen United Nations Sustainable Development Goals (SDGs), the potential of the tools presented here can easily be grasped within the context of SDG 4 "Quality Education" and SDG 17 "Partnership for the Goals". Additional SDGs can also be observed in, for example, materials #4b- 5b (Table) that are clearly linked to SDG 15 "Life on Land" and material #10 (Table) that is linked to SDG 13 "Climate Action". Furthermore, other stand- alone activities and individual actions from initiatives #13, 14, 15 (Table)- that are not mentioned here in detail for reasons of space availability and overall relevance- are directly related to SDGs focusing on the triplet People- Prosperity- Planet. This further underlines the role of UGGps as areas for the promotion of the natural sciences but, also, sustainability (Catana & Brilha, 2020; da Silva, 2020).

Figure 2. Picture from a school visit where the e-Geodiscover app was used by students following Mygia's geo-trail.

Conclusions

Geology is all around us through the rocks and minerals that we use, the processes that shape our surroundings and the very substrate we walk on! However, as a scientific field, it unfortunately still remains rather unpopular and non-understandable by most of the public. UGGps as organizations and as territories are, indeed, playing a significant role addressing this issue, since they have the background and experience to "translate" this often-inaccessible knowledge for the local communities (students and adults) in a way that is scientifically and pedagogically appropriate. Thus, educational tools developed and implemented in UGGp territories, especially in cooperation with local educational partners, are numerous, innovative and extremely useful if one considers the overall limited and very much needed interpretive and teaching resources on geology for the more effective protection of this aspect of the natural heritage of our territories. Extending the conversation to other relevant issues of sustainability such as the climate crisis, natural hazards, water availability and many more, we could find ourselves in the position to also inform, sensitize, engage, and prepare members of local communities on matters that are extremely pressing nowadays. The impact of this effort increases significantly if we, as organizations, share all these tools and practices within our networks and more broadly into the scientific community and other conservation organizations and protected areas, with whom we share the same goals.

EXTENDED ABSTRACT 156

The Role of Fairy Tales in Fostering Geoscience Understanding in Early Childhood

Kolyva P. [1], Koumoutsakou O.[1], Antonarakou A.[1]
(1) Department of Geology and Geoenvironment, Kapodistrian University, Athens, Greece, pavlinak03@yahoo.com

Introduction

Storytelling through oral traditions has long been a powerful way to pass down cultural values and beliefs while nurturing imagination and creativity in children. Similarly, children's literature plays a pivotal role in education by effectively blending learning with entertainment (Pulimeno et al., 2020). This research is a small case study in which the use of fairy tales and storytelling, in general, is examined to understand geoscience and its subsections, such as earthquakes. Regarding the utilization of fairy tales as instructional resources, an extensive examination of a wide range of fairy tales was undertaken, focusing on their various attributes and potential educational significance. A fairy tale about earthquakes was created and evaluated with primary school children.

The Evolution and Impact of Fairy Tales: From Cultural Narratives to Educational and Scientific Insights

Fairy tales stimulate creativity and emotional development by embodying deep themes, offering comfort and security even when exploring conflict or danger. They nurture emotional intelligence, impart moral lessons, and inspire critical thinking. These stories are vital tools for fostering creativity, moral maturity, and thoughtful engagement with the world. (Bakaraki et al., 2018).

Fairy tales have transitioned from oral traditions to a significant presence in mass media, with geomythology—a field studying myths tied to geological phenomena—revealing how narratives about earthquakes, tsunamis, and volcanic eruptions reflect cultural efforts to explain natural events (Rahman, 2017; Dewi, 2024; Piccardi & Masse, 2007; Vitaliano, 2007). These myths, often holding sacred and cultural significance, provide valuable insights into geological science and resilience-building, especially for children living in areas prone to natural disasters (Dewi, 2024). Local myths have also contributed to addressing geological challenges, with geological terminology itself drawing inspiration from mythological figures (Vitaliano, 2007). Prominent authors like Jules Verne, Arthur Conan Doyle, and H.P. Lovecraft have integrated geological concepts into their adventure and fantasy literature, illustrating how literature can blend science and storytelling (Gargallo, 2023).

Research Methodology:

The research was conducted as a small-scale case study involving a class of 20 second-grade students from a primary school in Vasiliko Evoias, Greece. The prototype fairy tale was introduced during the school's annual earthquake drill. Data collection methods included direct observation, semi-structured interviews with the teachers, and a post-activity reflection task using visual prompts tailored for children. The research aimed to evaluate student engagement, their conceptual understanding of earthquakes, and their emotional response to the narrative.

Developing a Prototype Fairy Tale to Educate Children About Earthquakes

The initial phase of this research involved an exploration of effective strategies for the implementation of fairy tale-based instruction within the context of elementary science classrooms (Kwon & Lee, 2010). To investigate the pedagogical effectiveness of fairy tales in geoscience education, a prototype fairy tale was developed specifically for preschool and elementary school-aged children. This narrative addresses the phenomenon of earthquakes, emphasizing the importance of preparedness and mitigation strategies to minimize potential damage, destruction, and human loss. The protagonist of this tale is a small rock named Rhea, who embarks on a journey to the Earth's surface to convey an urgent message about an impending earthquake.

The prototype fairy tale was introduced to elementary school students during their annual earthquake drill. Teachers observed that the students were highly engaged throughout the process. The classroom was soon filled with exciting questions and discussions about earthquakes, sparked by the captivating story. The fairy tale not only ignited children's imaginations but also stimulated their critical thinking skills, helping them understand the appropriate actions to take during an earthquake. Importantly, these results demonstrate that incorporating fairy tales into children's education can effectively cultivate valuable character traits.

Mitigating the Risk of Misconceptions

To prevent the development of misconceptions, the fairy tale content was co-reviewed by a geoscience expert and an

early childhood education specialist. Scientific elements, such as the causes of earthquakes and safety measures, were presented clearly and accurately within the fictional framework. Educators facilitated follow-up discussions to reinforce key concepts and clarify any confusion that might arise between fiction and scientific fact.

Discussion of Results

Teachers reported increased attentiveness and participation from students, indicating the effectiveness of the narrative-driven approach. Many students could accurately recall appropriate earthquake safety measures, such as "Drop, Cover, and Hold On," and showed greater confidence in discussing natural disasters. Some students even shared how they planned to inform family members about what they had learned. These findings suggest that the integration of storytelling not only supported cognitive learning but also fostered emotional readiness and resilience. The use of relatable characters like Rhea helped students better internalize abstract scientific ideas, which is consistent with previous research emphasizing the benefits of narrative pedagogy (Dewi, 2024; Fleer, 2013).

Enhancing Scientific Learning and Motivation Through Fairy Tale-Based Pedagogy

This research revealed that students effectively connected fairy tales to their personal experiences and actively engaged in classroom activities incorporating them. Many expressed increased interest in science classes, attributing this to the engaging nature of the fairy tale-based approach. This method not only motivated students to study diligently but also facilitated a deeper understanding of scientific concepts in context.

The study concluded that instruction using fairy tales is an effective pedagogical approach that enhances learning motivation, fosters scientific inquiry, provides opportunities to apply scientific concepts, and cultivates a positive attitude toward science.

Conclusion

Recognizing the crucial role of imagination in early childhood science education is vital (Fleer, 2013). Children's literature and storytelling could help promote "*students' global development and well-being when included in school curricular activities*" (Pulimeno, et al., 2020). This study offers promising evidence that integrating scientifically accurate storytelling into early education can not only reduce fear and confusion about natural disasters but also lay the groundwork for informed and resilient future citizens. Further research with larger samples and longitudinal follow-ups is recommended to explore the long-term impact of this approach.

Acknowledgments

I would like to express my sincere gratitude to the teachers and elementary school children who have given their time to be respondents in this research, to my professor for her invaluable guidance, and to my sister for her significant contributions throughout the project.

EXTENDED ABSTRACT 157

Application of the educational proposal for geoscience: geology in secondary education through educational geopaths in the urban environment

Kontokostas G.E.[1], Antonarakou A.[1]

(1) National and Kapodistrian University of Athens, Faculty of Geology and Geoenvironment, Panepistimiopolis, Zografos, Greece, geokon@geol.uoa.gr

Introduction / Background

The research project, entitled: An educational walk in the historical centre of Athens, is an innovative educational proposal that approaches different scientific fields in an interdisciplinary way. Conducted as part of the research work (project) by 14 school girls and 13 school boys of secondary education of the high school, during the second semester of the 2019-2020 school year. In addition to the historical, social and literary approach to the selected sites, this educational process uses the area around the square in Monastiraki in the light of urban geology and can increase children's knowledge and improve their attitude towards geosciences.

1. Background and Objectives

A route guide was prepared by the students, in which each site, along with its historical and cultural characteristics, describes the geological and hydrological potential of the area.

In the course of the educational process, using techniques entailed in the scientific/educational methodology by inquiry, suggesting educational walking paths through the historical center of Athens, (Dermott, L.,1996), Selected places of the walk trail served our educational aims: Ag, Asomaton-Monastiraki-Eridanos-Stoa of Attalos-Roman Agora –Hadrian's Library-Kapnikarea.

The locations chosen for the route served our educational purposes. I am referring, for example, to the optimal understanding of the formation of rocks, the recognition of the type of rocks, information on the geological and hydrographic potential, in pupils of the Secondary Education of Attica.

2. Research Methodology

The research sample consist of 14 school girls and 13 school boys of secondary education of the high school. In this research the educational aims for the students were: a) to recognize rocks b) to be informed about geological and hydrological potential, and finally, c) to understand the geological notions in time and in space, that means to recognize the geological time and to comprehend the rock cycle (Kaliet al.,2003). The educational goals of our proposal were: a) to inform students about the urban environment of Attica, b) to show that geology is an attractive and important science, c) to study geological phenomena with an interdependence procedure with geosciences and d) to view physical phenomena with a holistic approach, improving students' ecological consciousness.

In this work, we attempted to follow research steps, (Kalkanis, 2010) set forth by inquiry-based learning (Dermott, 1996) : a) trigger for interest, b) reminder of basic knowledge/formulation of hypotheses, c) experimentation/trials, d)formulation of conclusions, e) applications/generalization according to learning.

Trigger of interest (step 1) : Initially, the students visited the exterior and interior of the Temple of Kapnikarea, where they noted with interest the diversification of the rocks and the geological relief of the area.

Reminder of basic knowledge/formulation of hypotheses: Then the necessary knowledge was presented in the way presented by the relevant school lesson of the analytical program (orogenesis, types of rocks) and by the most widely used international reference books (Kali, 2003, Tillery, 1996), - ways of rock formation and the cycle of rocks, so that the pupils could formulate hypotheses. Then, the male and female students completed an appropriately coded questionnaire (pre-test), (Bakopoulou, 2016). The pre-test examined if the students are informed of the geological and hydrological potential of the area , if they could recognize rocks (marbles, granites, limestone and fossils) and if they know the rock cycle.

Experimentation/trials: After studying the relevant literature (Bouras, 2017), the students researched the area and the sites through the internet, collecting historical, cultural and geological information, and visited the places around the area of the square in Monastiraki. They revisited the sites, observed and studied the stones with the aid of a magnifying glass in different buildings. Then they selected sites of hydrological interest (rivers, wells) and of geological interest, combining building materials (limestone, marble and granite).

Formulation of conclusions: Then, we asked the students to summarize their conclusions and to write down

observations and comments. Finally, they designed a suitable route with the selected locations and entered it in a mobile application with all the relevant information.
Applications/generalization according to learning: The successful completion of the students' survey prompted them to suggest additional routes in the surrounding area. Finally, we asked them (increasing the difficulty further) to generalize their conclusions by interpreting the creation of other sedimentary, siliceous and metamorphic rocks. They also completed a post-test questionnaire.

3. Results

The control group was also the experimental group. After the questionnaires were deleted (pre-tests are different from post-tests), the answers and observations were compared, and the following was recorded as regards the main research questions and objectives: In general, the pre-tests showed difficulties in identifying the different rocks, in understanding the geological processes and the cyclicity of the rocks. On the contrary, their responses to the post-test after the completion of the project and following the methodological steps, showed that all the students had understood the geological processes and the cycle of rocks in geological time, had the ability to recognize rocks and learned about the geological and hydrological potential of the area (Figure 1).

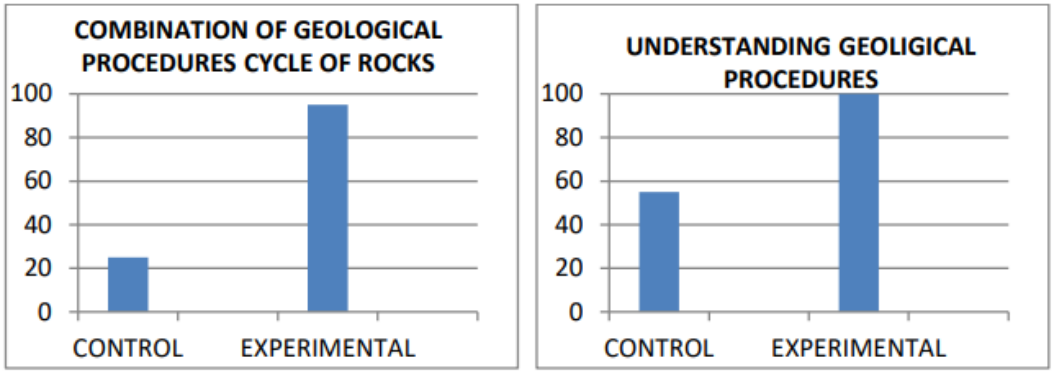

Figure 1 a. We observed an improvement in a) the understanding of geological processes by the pupils (%) and (b) the combination of geological processes in the rock cyclicity by the pupils (%), before and after the teaching intervention, respectively.

4. Conclusions

The results of the post-test show that all the pupils in the class understood the geological processes (Figure 1a) and the rock cycle (Figure 1b). The children's own design of the georoutes proved to be functional and highly useful in terms of understanding and interpreting the phenomena involved. After the educational intervention the pupils improved their geological knowledge, developed their critical thinking, their creativity and found the science of geology interesting.

Spoil heterogeneity poses geotechnical challenges during mine reclamation. CPTu data-driven slope stability analyses are crucial for safe and effective restoration.

Introduction

During the last decades, coal (also in the form of lignite) has been the main raw material for electricity production. The leading European producing countries include Germany, Czech Republic, Poland and Greece (BGR, 2014, Euracoal, 2017, EY, 2014). Due to the climate crisis, lignite mines have now entered a final phase in Europe and worldwide, heading towards decarbonization. As the transition to the post-lignite era is underway, the choice of land use after mine closure is a crucial decision, and must obviously be in line with the expectations of local communities and with the principles of sustainable development (Pavloudakis *et al*., 2009).

One of the most common practices of restoring a mine is the formation of a lake within its excavation. The creation of lakes can be done either artificially or naturally through hydrological processes, such as rainfall or groundwater infiltration. Lakes offer local communities social, recreational, ecological and economic benefits by landscaping and revegetation, creating aquatic life and maintaining water quality. However, the creation of lakes in lignite mines may cause instabilities and landslide phenomena, with social and economic consequences (Zevgolis *et al*., 2019). The elevation of the aquifer during flooding affects the stability of the slopes by increasing the water pressures of the submerged soil pores. However, increasing the water body within open excavation also acts as a supporting force, and lake creation has been reported to improve slope stability as lake height increases (Kontopidis *et al*., 2022).

The surface exploitation of lignite requires the extraction, transport and deposition of the overlying intermediate soil layers called spoil materials (spoils). According to estimates, spoil heaps reach 1.45 Gt annually worldwide (Bian *et al*., 2012). The disposal spoil takes place mainly in areas where the mining phase has been completed, so that there is the possibility of restoring the paid areas with the aim of minimal environmental impact during the transition to the post-lignite era. The variability of their characteristics and the absence of good deposition practices result in geotechnical problems, including slope stability issues, which need to be investigated both during the deposition phase and during the restoration phase of the area.

This work deals with the assessment of stability issues in the area of the artificial lake Most in the Czech Republic, which was formed in a former surface lignite mine with an average excavation depth of 100 m. At the current boundaries of the lake, spoil materials were deposited during the operation of the mine, forming artificial slopes. Due to the uncertainty about the properties of spoil, 24 cone penetration tests were performed around the lake by measuring pore pressure (CPTu) at depths up to 50 m, mainly within spoils. Raw test data were used to evaluate them and estimate undrained shear strength (c_u) based on empirical correlations. The stability analysis was performed using the commercial software Slide2 applying the limit equilibrium method.

CPTu raw data interpretation

In 2020, 5 years after the final elevation of the lake Most, 24 CPTu were performed with measurement of pore pressures, at depths up to 50 m. The purpose of the tests was to investigate and identify adverse soil conditions in terms of lake's banks stability. Figure 1 shows a sketch of Lake Most (floor plan) with the relative locations of the CPTu tests. A star symbol indicates test P20 whose primary results are shown in Figure 2. CPTu raw data consist of cone tip resistance (q_c), sleeve friction (f_s), friction ratio (R_F) and pore water pressure (u_2). Cone tip resistance (q_c) is observed to increase with depth smoothly from 2 MPa at the surface to 5 MPa at the depth of 40 m and then increase relatively sharply up to 15 MPa. Local peaks, such as those occurring at depths of 22 m, 33 m and 45 m, may be due to the presence of isolated conglomerates which momentarily hinder the advance of the cone. Sleeve friction (f_s) shows a similar increase from 0.1 MPa on the surface to 0.2 MPa at a depth of 40 m and in the last 10 m increases sharply to 0.6 with 0.8 MPa. The friction ratio (R_F) varies from 2% to 6%, while two peaks of 10% are observed at 15 m and 25 m. In the first 20 m the average R_F value is about 3.5%, while from 20 m to 45 m the average value increases to 5%. Pore water pressure (u_2) shows a small rate of increase up to 120 kPa at a depth of 40 m with no local peaks.

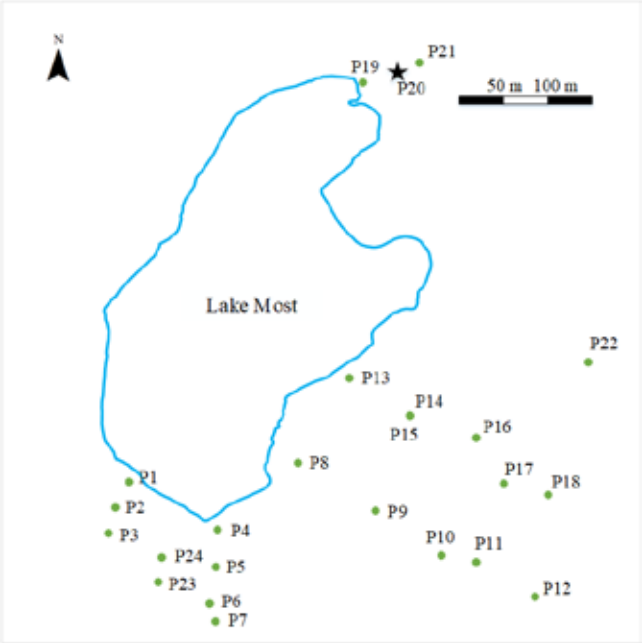

Figure 1. Overview of the lake Most with the locations of the CPTu tests.

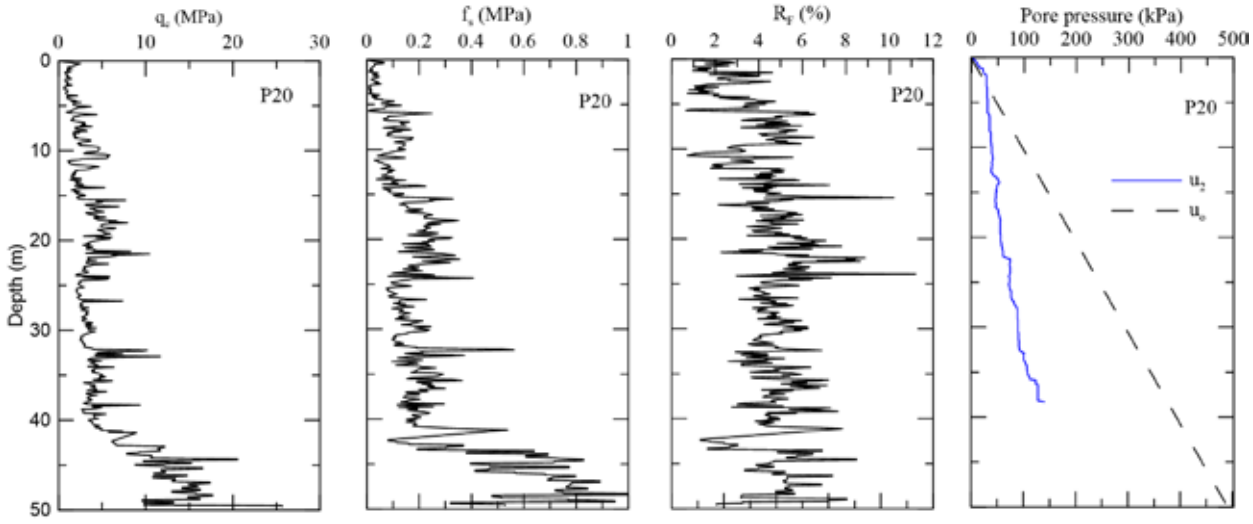

Figure 2. Measurements of q_c, f_s, R_F, and u_2 with depth for test P20.

The measurement of pore pressure allows for improved interpretation of soil conditions. In particular, several diagrams have been proposed for the determination of soil types by CPTu using the combined overburden stress (σ_v)-corrected total tip resistance (Q_t), overburden stress-corrected sleeve friction (F_r), and pore pressure, u_2. In this paper the following I_c index is used (Robertson, 2009, Mayne, 2014):

$$I_c = ((3.47 - \log Q_t)^2 + (\log F_r + 1.22)^2)^{0.5} I_c = ((3.47 - \log Q_t)^2 + (\log F_r + 1.22)^2)^{0.5} \quad (1)$$

Figure 3 presents the soil classification as a function of depth for the P20 test according to the I_c index. The values on the horizontal axis correspond to specific values of I_c associated with specific soil types. Up to 5 m sandy silty and silty sand are the main soil type and then up to 10 m sandy silt/silty sand. At a depth of 10 m to 42 m, clay prevails with sporadic silty layers. In the last 8 m, until the end of the test, silty clay is returned. Generally based on the 24 CPTu, the soil type mainly in fine-grained soils, i.e. silt, silty clays and clays.

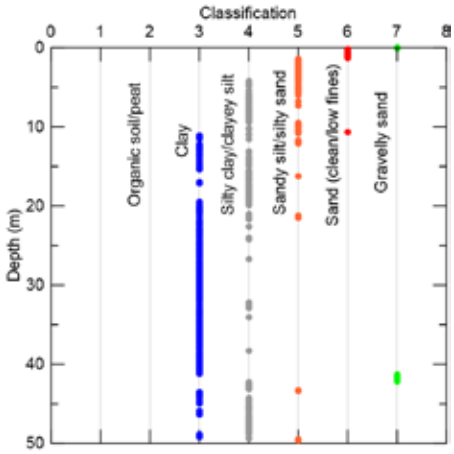

Figure 3. Soil classification using I_c index for test P20.

The undrained shear strength (c_u) is calculated based on the values of pore-pressure-corrected cone resistance (q_t):

$$c_u = \frac{q_t - \sigma_{vo}}{N_{kt}} c_u = \frac{q_t - \sigma_{vo}}{N_{kt}} \quad (2)$$

where N_{kt} is a factor taking values 10 to 18. In the context of this analysis, the mean value N_{kt}=14 was used (Robertson, 2009). Initially, a regression analysis of the q_t population was performed where a trendline equation was derived:

$$q_t = 0.12D + 1.27\ (\text{MPa}) q_t = 0.12D + 1.27\ (\text{MPa}) \quad (3)$$

where D is the depth.
The equation (2) was used for the function of undrained shear strength (c_u). For the calculation of total stress σ_{vo} a constant value of unit weight γ=18.2 kN/m^3 was considered as the population mean. Figure 4 illustrates the change of c_u with depth. Therefore, the mean function (c_u) is obtained:

$$c_u = 7.27D + 90.7 c_u = 7.27D + 90.7\ (c_u \text{ in kPa, D in m}) \quad (4)$$

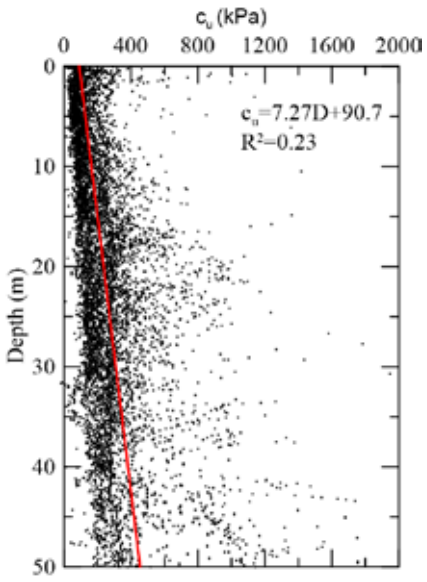

Figure 4. Variation of c_u as a function of depth.

Slope stability analysis

Slope stability analyses were performed with Slide2 software (Rocscience, 2019). The strength of spoils is determined by the function c_u=7.27D+90.7 (Eq. 4). Figure 5 illustrates a typical slope model considered for stability analysis. Specifically, the analyses are performed on two-layer slopes of (H) 100 m and inclination (β) 11°, where a clayey layer with φ´=9.5° and c´=57 kPa underling spoils. An unfavorable condition in lignite mines, usually, is the presence of weak zones at the marl-lignite or between the layers of lignite. In this work, an inclined (β_z=3°) weak zone is located at the base of spoils with low strength (φ´= 6°, c´= 6 kPa) is considered (Mikroutsikos *et al*., 2021). This weak zone was simulated with a weak layer interface condition (proposed in limit equilibrium analysis to simulate narrow layers or interfaces with low strength) through software tools (Rocscience, 2023). Table 1 shows the strength values for the layers considered in the slope model.

Table 1. Input strength values.

Layer	Strength
Spoils	c_u=7.27D+90.7
Weak zone	φ´= 6°, c´= 6 kPa
Clay	φ´= 9.5°, c´= 57 kPa

The analyses used the advanced method “cuckoo” search for non-circular surfaces, which does not require the surface to be determined from the outset, but determines it through linear sections and optimization of solutions. To calculate the safety factor, the Spencer method was used, which satisfies the equations of equilibrium of both forces and moments. The Mohr-Coulomb failure criterion was used to determine the shear strength of the clayey layer and the weak zone. The lake was considered to have been filled by about 1/3 (so the ratio of the level of the lake (H_w) to the height of the slope is H_w/H = 0.3) as the most critical condition for the stability where the safety factor (FS) becomes minimal (Zevgolis *et al*., 2021). Finally, steady-state flow conditions were considered with the water table defined by H'_w = 0.1H at the left limit of the slope and the height of the lake on the right.
Figure 6 illustrates the non-circular/bi-linear failure surface which travels along the weak zone and daylights at the toe of slope. The safety factor (FS) is equal to 1.19, which is deemed tolerable for temporary mining slopes. However, this value is insufficient for civil engineering slopes, especially when considered in the context of reclamation projects, where a minimum FS of 1.4 is required. This higher standard is crucial to ensure the stability and safety of the slopes in the long term, as reclamation projects often involve the restoration of disturbed land and the safeguarding of the surrounding environment.

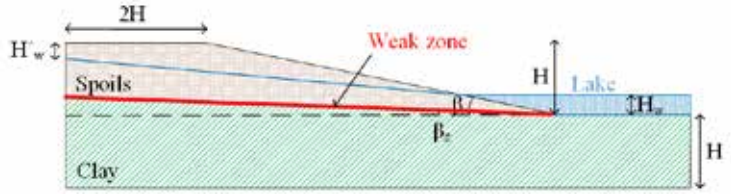

Figure 5. Two-layered slope model with inclined weak zone.

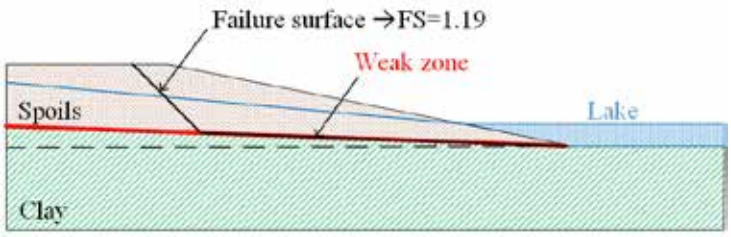

Figure 6. Bi-linear failure surface with FS=1.19.

Conclusions

This paper deals with slope stability in the area of the artificial lake Most in the Czech Republic, which was formed in a former surface lignite mine with an average excavation depth of 100 m. A key element of the slopes and their stability is the existence of spoi materials from the excavations of lignite mines. To investigate the characteristics of spoil materials around the lake, 24 cone penetration tests were performed by measuring pore pressure (CPTu) at

depths up to 50 m. Each test produced different deep primary results, confirming uncertainty and spatial variability as the main characteristics of the nature of spoil materials. Through the empirical soil index I_c spoils are mainly characterized as fine-grained materials, silts, silty clays and clays. Due to the presence of several types of soils in random spatial arrangement, it was not possible to locate a distinct stratigraphy. Consequently, a single soil material with significant heterogeneity was assumed. Evaluation of CPTu results showed that undrained shear strength c_u increases as a function of depth. The strength c_u was calculated through empirical correlations from the total cone peak resistance (q_t). A regression analysis of q_t resulted in the change function with the depth D q_t=0.12D+1.27 (in MPa). The change function of q_t derived the function of change of c_u=7.27D+90.7 (in kPa).

The use of CPTu data, although displaying some data dispersion, proved valuable for characterizing the soil properties and informing the stability analysis. The stability analysis revealed a safety factor (FS) of 1.19, deemed acceptable for temporary mining slopes but inadequate for long-term stability in civil engineering applications, especially reclamation projects. A minimum FS of 1.4 is recommended for such projects to ensure stability and safety. The analysis employed a two-layer slope model incorporating an inclined weak zone, a common feature in lignite mines, further emphasizing the need for a higher FS. The lower FS obtained highlights the potential for slope instability and underlines the risks associated with insufficient consideration of long-term stability requirements during reclamation.

EXTENDED ABSTRACT 159

A semi-quantitative multi-hazard approach for Tailings Storage Facilities

Kontopidis O.N.[1], Theocharis A.I.[2], Zevgolis I.E.[1]
(1) School of Mining and Metallurgical Engineering, National Technical University of Athens, Greece izevgolis@metal.ntua.gr (2) Department of Civil Engineering, University of Patras, Greece

A semi-quantitative approach presents a new way to assess multiple natural hazards' interactions affecting the stability of tailings storage facilities, leading to a semi-quantitative hazard index.

Introduction

The extraction and exploitation of raw materials are necessary activities for the sustainable development of society and the evolution of technology. The mining sector consists of successive stages initiating from the extraction of raw material to the storage and management of waste. Mine wastes include overlying soils that are removed to reveal the mineral, spoil materials with a content of raw material below the cut of grade and tailings. Tailings are defined as the waste of ore processing during the removal of economically important components (Vick, 1990). These can be in solid or liquid form (slurry) depending on the drying and deposition techniques chosen by the enrichment plants. The tailings, in the form of slurry, are transported by pipelines from the enrichment plant to the Tailings Storage Facilities (TSFs). TSFs are high-risk infrastructures as tailings contain a high pollutant load mainly due to the chemicals used to extract minerals. Also, the volume of tailings stored is in the order of millions of cubic meters. In general, tailings storage is often recognized as the most important source of environmental impact for many mining activities (Vick, 1990). A large number of TSFs are located in countries with a severe mining sector such as the USA, Canada, Brazil, Chile, South Africa and Australia (Piciullo *et al*., 2022).

TSFs, like any infrastructure, interact with and are affected by the environmental conditions of the surrounding area. These conditions are related to the particular geological, hydrogeological, geotechnical, climatic and topographical characteristics of the area, which potentially constitute sources of natural hazards. Infrastructures with components that perform various functions (storage, transportation, drainage), such as TSFs, tend to show vulnerability to multiple natural hazards. Indicative components are pipelines, dams, geomembranes, spillways and impoundments. In the recent past, attempts are made to review significant failures over the last 100 years by statistically recording the natural hazards and more generally the conditions under which TSFs have failed (Azam & Li, 2010; Piciullo *et al*., 2022; Rico *et al*., 2008). In this direction, on line bases are also moving, indicatively mentioning the CSP2-Tailings Dam Failures. The difference between single and multi-hazard is important, as. In a multi-hazard framework, the consequences of interrelated hazards in the components are often more significant than those deriving from individual hazard summation. These failure mechanisms, most frequently mentioned as "failure modes", are defines as the ways, or modes, in which something (in this case the various components of the TSF) might fail.

This paper presents a new way to assess the interaction of natural hazards among them, and natural hazards with failure modes of TSFs. A semi-quantitative multi-hazard method developed by Liu *et al*., 2021, hereinafter Liu's method, is adapted for TSFs. This method evaluates each hazard individually, builds triggering interactions between hazards and failure modes using adjusted factors, and aims to quantify the multi-hazard intensity of different scenarios, which trigger specific failure modes. This method has been applied once in the wider mining sector and specifically in post-mining lignite regions (Nalmpant-Sarikaki *et al*., 2023).

Methodology

Three categories of methodologies are typically encountered to explore the interaction of hazards and calculate the multi-hazard intensity: qualitative and semi-quantitative quantitative. Focusing on semi-quantitative methods, they either use correlation coefficients or calibrate hazard occurrence characteristics to capture the interaction of hazards. The current work is based on a semi-quantitative method, which is described in four main steps. The initial step involves the identification of the main hazards in the study area as typically conducted in risk assessment. In the case of TSFs, the hazard categories are related to the specific conditions of the surrounding area as described above (geological, hydrogeological, geotechnical, climatic and topographical characteristics of the area). Anthropogenic (technological hazards) also affect TSFs and are often combined with natural ones to trigger a failure mode. However, in this work, only natural hazards are employed and the scenarios that will be developed consider only natural hazards. It focuses on the methodological framework and does not extend to a large number of natural hazards that could potentially threaten the area. Thus, four natural hazards are considered for this analysis, specifically earthquake, rainfall, flooding and landslide. Individual hazards are characterized based on their predisposing factors

and associated triggering factors. For example, a landslide is influenced by its predisposing factors, such as the topography of the ground and the soil conditions, and can be triggered by climate conditions, e.g., heavy rainfall (Zevgolis, Deliveris *et al*., 2019). Moreover, in a multi-hazard scenario, a landslide can be triggered by other hazards, such as flooding and earthquakes.

The second step deals with typical failure modes identification. The most critical components of TSFs are the tailings dam as they are earthen confining structures whose failure results in the release of tailings. As geotechnical works similar to earthen water dams and levees, they mainly present geotechnical failure modes. The failure modes that will be considered in this work are the overtopping, the slope instability, the liquefaction, the foundation failure, the internal erosion and the external erosion (Clarkson & Williams, 2021).

- Overtopping can occur from excessive inflows (flooding), malfunctioning spillway or outlet structures, insufficient spillway capacity, dam settlement, external landslide into reservoir, or by waves driven by wind running up and overtopping the dam (Clarkson & Williams, 2021).
- Slope instability refers to the failure of the upstream and downstream slopes of the dam either due to static or dynamic loading.
- Liquefaction is the instant loss of saturated soil's strength in response to strong ground shaking. A particular type, which the upstream constructed dams face, is the static liquefaction, namely the brittle loss of strength in loose, saturated, nonplastic or low plasticity soil under monotonic loading (i.e., static rather than dynamic).
- Foundation failure has three components, the overcoming of the bearing capacity, the development of excessive settlements and its permeability, which will result in the seepage of water and tailings under the dam body.
- Internal erosion (called "piping" by dam engineers) of a tailings dam takes place when water that seeps through the dam carries soil particles away from the embankment, filters, drains, foundation or abutments of the dam. If the seepage that discharges at the downstream side of the dam carries particles of soil, an elongated cavity or "pipe" may be eroded backward (working upstream) toward the reservoir through the embankment, foundation or abutment. When a backward-eroding pipe reaches the reservoir, a catastrophic breaching of the dam can occur (ASDSO).
- Surface erosion is a physical process that occurs when tailings flow removes soil particles from the surface of the dam so that its cross section to thin.
- An additional failure mode is the structural failure, which refers to any non-earth-related parts, such as corrosion of pumps and fractures in reinforced concrete. However, this failure mode is ignored in this study.

The third step deals with interactions between natural hazards and failure modes determining multi-hazard scenarios. Although the type of interactions between hazards and failure modes can be of diverse types such as trigger and coincidence (when they occur simultaneously and independently), hazards that act as triggering factors for other hazards are associated to failure modes to define multi-hazard scenarios. Scenarios in the form of "chains" will therefore be built, with cause-and-effect relationships.

The final (fourth) step focuses on identifying the level of interactions among hazards and failure modes. This assessment is based on the intensity of individual hazards and the level interaction of a hazard that causes a failure mode. The multi-hazard analysis demonstrates that interacting hazards can be more destructive as the principles of Liu's method demonstrate. Thus, it is challenging to consider multiple hazards and not only assess single ones because the overall risk is underestimated in the latter case.

Application

The application of Liu's method requires the selection of a study area to assign intensity values to natural hazards according to characteristics such as seismicity, precipitation and topography as well as the history of hazard occurrence in the area surrounding the TSF. It does not require knowledge of the technical specifications of a specific TSF. The identification of failure modes and their interaction with hazards is generally applicable, regardless of the specific study area. The indicative area employed in this work refers to the area of Halkidiki in the central Macedonia in northern Greece. In Halkidiki, due to intense mining operations, various TSFs with dry tailings have been constructed. Table 1 presents the identified natural hazards that potentially affect the study area and their initial intensities considering its location, topography and the historical data. There are six intensity classes ranging from 0 to 5; the higher the number, the greater the hazard intensity, and zero means that the hazard has no impact.

The earthquake's initial intensity is related to the classification of Greek seismic hazard. According to the latest Greek seismic code, the country was divided into three seismic hazard zones. Regarding the horizontal peak ground acceleration, the study area falls into zone II. In addition, according to National Observatory of Athens two strong earthquakes have occurred in the past in the wider area, 1932 Ierissos earthquake and 1978 Thessaloniki earthquake with M=7 and 6 respectively. Therefore, the initial intensity was selected as three. Precipitation data reserved from the Hellenic National

Meteorological Service. The annual precipitation of the Halkidiki area has a moderate value, 400-450 mm, with a low to moderate duration regarding the recordings; thus, the initial intensity was selected as two. Flooding is expected, locally, on both sides of the riverbeds and streams and considering the value given to rainfall the initial intensity selected equally as 2. Finally, initial intensity for landslides is selected as 4 due to mine wastes heaps prone to instabilities. Regarding bedrock formations, there are amphibolites – amphibolitic gneisses and biotic gneisses. These rock types exhibit high strength, whenever their rock mass characteristics indicate gravitational-movement type landslides governed by their discontinuities.

Table 1. Initial intensities of hazards (scale 0-5).

Natural hazards	Initial intensity
Earthquake (EQ)	3
Rainfall (RF)	2
Flooding (FL)	2
Landslide (LA)	4

The triggering relationships among hazards and between hazards and failure modes are summarized by hazard matrices, as shown in Figure 1 and Figure 2, respectively. The interactions among them are categorized into two levels: dark blue indicates high probability of interaction; light blue indicates low probability of interaction. In Figure 1 the diagonal cells are filled with dashes and represent the interaction of each hazard with itself, which is meaningful because the current study is focused on interactions between different hazards. Indicatively, earthquake has a high probability of triggering landslide, the flood has a low probability to trigger landslide, and the earthquake is unlikely to trigger rain and vice versa. Regarding the interaction between hazards and failure modes, flooding has a high probability to trigger overtopping, the landslide has a low probability to trigger external erosion and finally the earthquake is not associated with internal and external erosion as these phenomena are inextricably related to the action of water.

	RF						
	FL						
	LA						

Figure 2. Interaction matrix between natural hazards and failure modes. OT= overtopping, SI=slope instabilities, LIQ= liquefaction, FOUN= foundation failure, IE= internal erosion, EE= external erosion.

The above qualitative characterization of the interactions is converted into semi-quantitative by introducing some sub-coefficients of approximation of the initial intensities of hazards. In the context of multi-hazard analysis, the intensities of hazards are greater when they occur in combination compared to the simple hazards analysis approach. Liu's method proposes multiplying the initial intensities by coefficients from 1.1 to 1.5 depending on the initial intensity value and the type of correlation (low or high) among hazards. Coefficient 1.1 is applied when the initial intensity value equals to 1-2 and there is a low interaction while on the other side 1.5 with initial intensity value 5 and high interaction. Liu's method presents a detailed table for coefficients. The same principle applies to this work and in addition the coefficients are similarly applied to the correlation between hazards and failure modes.

The combination of Figure 1 and Figure 2 results in scenarios development. The scenarios consist of 2 hazards and a

failure mode. In particular, a primary hazard causes a second hazard which in turn causes a failure mode. The scenarios are therefore in the form of a chain, for example, rainfall trigger flooding and the latter trigger overtopping. Thus, the building of scenarios involves pairing elements (hazards or failure modes) according to the degree of interaction observed between them. Earthquake and rainfall cannot be triggered by the other hazards (as shown in Figure 1) so, they cannot be placed as second hazards in the multi-hazards scenarios. The final multi-hazard intensity (MH) is calculated by summing up the trigger and the triggered hazard's adjusted intensity.

Table 2 presents all scenarios sorted by failure modes. Each scenario receives an MH, so for each failure mode a total MH summing up the individual MH corresponding to each failure mode is obtained. In addition, It is determined a higher (each hazard has an initial intensity of 5 and high probability to trigger other hazards or failure mode) and a lower (each hazard has an initial intensity of 1 and low probability to trigger other hazards or failure mode) limit. The range is normalized (0-1), and the MH is scaled accordingly through Norm. MH to improve visualization of scenario intensities. Table 2 presents scenarios shorted by failure mode to assess their criticality according to MH. Similarly, we could short them by hazards to find their criticality. Overtopping appears to be the most critical failure mode as 0.438 is the highest norm. MH. This is because FL and LA has high interaction with it as well as LA, which is involved in 4 out of 6 scenarios has an initial intensity of 4. SI, LIQ and FOUN have equal MH as 3 scenarios lead to them and FL acts as triggering hazards for each failure mode. They present low MH as FL and RF receive the lowest initial intensity of 2. IE shows slightly higher MH than SI, LIQ and FOUN because although equally similarly in 3 scenarios, FL has low interaction with IE. In final, EE appears to be the second most critical after OT, as LA has low interaction with EE while LA has high interaction with OT. Therefore, the criticality of FM depends on the number of scenarios involved, on the initial intensities of hazards and on the type of interaction between hazards and between hazards and between hazards and failure modes.

Table 2. Multi-hazards scenarios shorted by failure modes (FM). OT= overtopping, SI=slope instabilities, LIQ= liquefaction, FOUN= foundation failure, IE= internal erosion, EE= external erosion

FM	Scenario	Total MH	Min total MH	Max total MH	Norm. MH
OT	EQ → FL → OT	46.8	13.2	90	0.438
	RF → FL → OT				
	LA → FL → OT				
	EQ → LA → OT

	RF → FL → EE				
	LA → FL → EE				
	EQ → LA → EE				
	RF → LA → EE				
	FL → LA → EE				

Conclusions

The present work adjusted an existing multi-hazard methodology, originally designed to analyze the interaction of natural and technological hazards, adapting it to fit a framework of interactions between hazards and failure modes in the context of TSFs. Multi-hazard analysis constitutes a critical component of modern risk assessment; this assessment must also include a detailed analysis of the consequences of TSF failures in the downstream region. The initial steps involved identifying the most significant natural hazards and possible failure modes of TSFs. The region of Halkidiki, operating intense mining, was selected as an indicative area. Then, the hazards' initial intensities and levels of interaction determined using appropriate interaction matrixes. The initial intensities were modified and increased, and the resulting values were appropriately summed up to create various multi-hazard scenario intensities (MH). The ultimate objective was to identify the most critical failure by comparing various scenarios via the total multi-hazard (MH) intensities. The study showed that the criticality of failure mode for this methodology is a function of the number of scenarios involved, the initial intensities of hazards and the type of interaction among hazards and between hazards and failure modes. Based on the analysis overtopping is the most critical, with external erosion following. Finally, some limitations of the modified method and the general assumptions considered in this work should be mentioned. The scenarios were built under the premise of developing a cause-and-effect relationship among their components. However, in nature this assumption does not always apply. For example, earthquakes and rainfall, although independent, can occur simultaneously without having a causal relationship. Rainfall and earthquakes are not triggered by other hazards. Subsequently, they were not placed as second components in scenarios, consequently, they were not included as direct triggering factors of failure modes. In future work, these interactions will be better studied, and anthropogenic-technological hazards will be included in the analysis.

Introduction

Museum curators and museum staff working in the field of education face the challenges of enrolling museums in the geoscience education. The knowledge gained from the scientific work on museums' collections is transferred and communicated to public using various tools. That way public is acquainted with the current and ongoing research in the museums, has the opportunity to be part of it, and it is educated on various topics.

In this paper we show ways of communicating with the audience based on the examples from the Museum of Paleontology and Geology of the National and Kapodistrian University of Athens, Greece and the Croatian Natural History Museum, Zagreb, Croatia.

Objectives

The goal of this work is to highlight the role of museums in Geosciences and education, acting as a mediator between scientific research and public understanding. By combining traditional and digital tools, museums potentially offer learning opportunities to diverse audiences, from the general public to university students and educators. This work demonstrates how museums can communicate the complex concepts of Natural History, containing geological and paleontological terms, by fostering curiosity and providing accessible educational experiences that enamor people to science. By showcasing innovative methodologies and case studies, we underscore the importance of museums as dynamic hubs of learning and science communication.

Methods

Museum education encompass various tools that can be used in the science communication, e.g., exhibitions, catalogues related to the exhibitions and collections, workshops, lectures, conferences, flyers, etc. Examples here presented are based on the incorporation of virtual tools in the museum work, which are in recent time becoming more and more popular and applied.

First example is a new virtual online tour at the Museum of Paleontology and Geology of Athens, titled: Advanced Tour and Education Services in the virtual Paleontology and Geology Museum/v-PalM.

Second example is a virtual exhibition "Oysters of the ancient seas" available on the website of the Croatian Natural History Museum.

Results

Museum of Geology and Paleontology

- The Museum of Geology and Paleontology at the National and Kapodistrian University of Athens has long been a beacon for scientific research and public education in the fields of Paleontology and Earth Sciences in Greece. Founded in the 19th century, the institute's roots go back to the founding of the Hellenic Society of Naturalists in 1835, which began collecting specimens of animals, plants, fossils, rocks and minerals. These early collections laid the foundations for one of the most important paleontological and geological museums in Greece. Throughout its history, the Museum has grown through continuous acquisitions, research and collaborations, so that today it can preserve a rich selection of more than one million specimens documenting more than 550 million years of the Earths' geological history.

A significant enhancement to the Museum's educational output has recently been the "v-PalM" project (fig. 1), which has developed a dynamic virtual experience to increase the museum's reach and educational effectiveness. Through the collaboration with the National Technical University of Athens and the technology company OMEGA, the project has successfully integrated 3D models, multimedia content, games and interactive educational programs, offering a digital extension of the museum's physical exhibits (Konstantakis *et al*., 2023; Thanou *et al*., 2023). In this virtual museum, visitors can explore thematic educational material such as the organisms and evolution of life during the Paleozoic, Mesozoic and Cenozoic Eras, the famous Pikermian Fauna, examples of island dwarfism in Greece and the evolution of marine organisms through time. Each program is carefully coordinated

with the exhibits that are on display in the actual Museum exhibition. For the first time, these educational programs have been specifically designed to engage the public with the Museum's unique collection and enhance the learning experience through the use of detailed illustrations of specimens, 3D models and in-depth information.

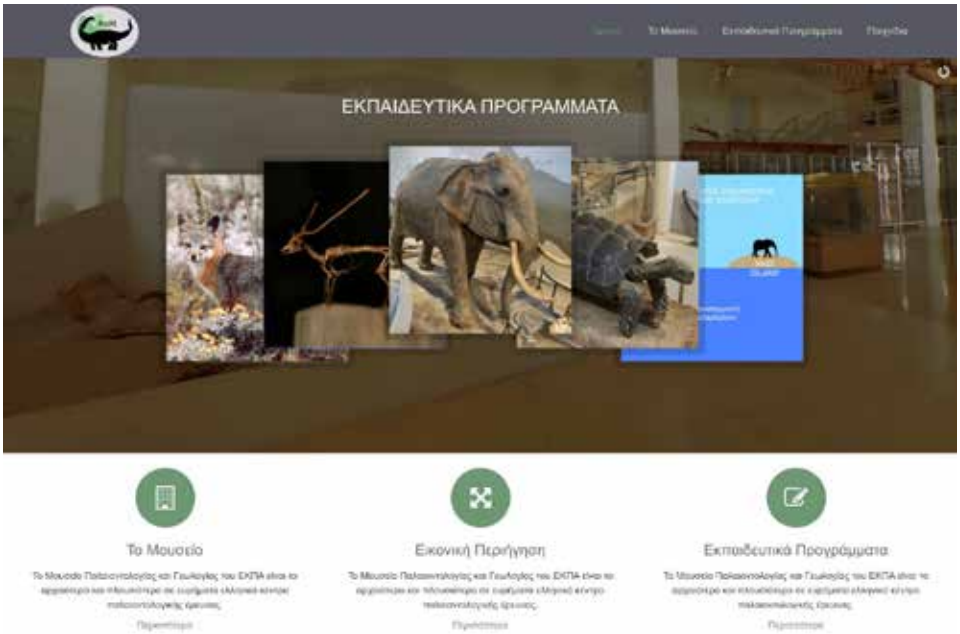

Figure 1. V-Palm Web application.

Furthermore, the Museum's impact on the educational landscape goes beyond its exhibits and digital initiatives. It has long been a center for educating students in fields such as Geology, Paleontology and Museology, providing hands-on learning opportunities through its extensive collections and research programs. The Museum hosts a variety of educational initiatives, including fieldwork, workshops and guided tours, providing opportunities for both school groups, university students and the general public to engage with the sciences of Geology and Paleontology. The Museum, through the expansion of educational offers, particularly through digital platforms such as the "v-PalM" project, makes science learning more accessible, especially for those who cannot visit the Museum in person, and promotes a deeper understanding of the natural world.

The completion of the "v-PalM" project is a milestone in the museum's mission to make science education more accessible and interesting for several target groups. By integrating advanced technology with curated educational content, the Museum has not only enriched its physical exhibitions through illustrations and paleoenvironmental reconstructions but has also made a lasting impact on the way Earth Science education is delivered in Greece. Visitors –whether in person or virtually– can now experience an interactive and enriching learning environment that emphasizes on the importance of scientific knowledge and understanding our planet's past, present and future.

Croatian Natural History Museum

- Due to the earthquake, renovation of the museum building and work on the new permanent exhibition, Croatian Natural History Museum was closed for public from 2020 until 2024. In order to continue presenting the museum collections, virtual exhibition "Oysters of the ancient seas" was prepared. That was the first virtual exhibition of the CNHM completely prepared from the scratch in the virtual environment. For the purposes of the exhibition, virtual exhibits of the Middle Miocene oysters were presented not only as photographs, but also as 3D scanned objects, that could be moved in various directions, as the visitors decided. The exhibition involved a guide in each section, who would briefly describe what can be seen in this part of the exhibition. Storytelling was a great part of the preparation of this exhibition, since the texts for the exhibition' guide were prepared based on the work with a communicator.

  Currently, the exhibition is presented in its classical form in the renovated CNHM museum building. Together with original specimens of the fossil and recent oysters, 3D prints of fossil oysters are available for touching. That way,

visitors having disabilities can feel the morphology of the fossil oysters and imagine how they looked like. Additionally, one original specimen of partial fossil oyster-reef can be studied by the magnifier and visitors can look for various inhabitants preserved as fossils, e.g., oysters, coralline algae, corals, bryozoans, etc. We noticed the positive feedback of visitors on these types of exhibits, enabling them to discover for themselves something that is not so familiar to them on everyday basis, and encouraging them to find out more.

Methods used in geoscience education include also workshops and seminars. As museum curators, we can be involved in the education of the pupils and students, as well as the schoolteachers.

One of the examples of geoscience education is the action called “Meet the Earth - Peek under the microscope” organized by the Croatian Geological Society since 2013 (e.g., Galović & Bošnjak, 2014). Geologists from various institutions are involved in this promotion of geoscience, as well as students. In the agreement with schools, geoscientists show various exhibits of macro samples of minerals, rocks, fossils, and petroleum, and thin sections of different fossils and crystals using the microscopes. Geological maps, posters from conferences, and geological models can also be shown. This type of exhibition can be followed by a presentation. Exhibiting specimens from different geological field, the students and teachers can learn more about geoscience, and specifics of each discipline.

Other example of educating teachers is the Spring seminar, organized by the Education and Teacher Training Agency, Croatia and the Croatian Geological Summer School. Each year, under one topic researchers hold lectures to the teachers of geography, taking in account the curriculum of the geographic class for the current year. Topics include various geoscience themes, e.g., vulcanism, climatic changes, catastrophic events, etc.

Conclusions

Museums are crucial in promoting and educating people about geosciences by serving as accessible platforms that combine science, culture, and education. The two examples presented here in the two museums illustrate how museums are modernized to meet the needs of modern educational practices. By adopting tools like 3D modeling, virtual exhibitions, and interactive workshops, museums are extending their reach to visitors but also enhancing their experience. These initiatives display the importance of museums not just as repositories of knowledge but as active participants in its acquisition and promotion. Finally, continued collaboration between museums, researchers, and educators is necessary for the further enhancement and impact of geoscience education worldwide.

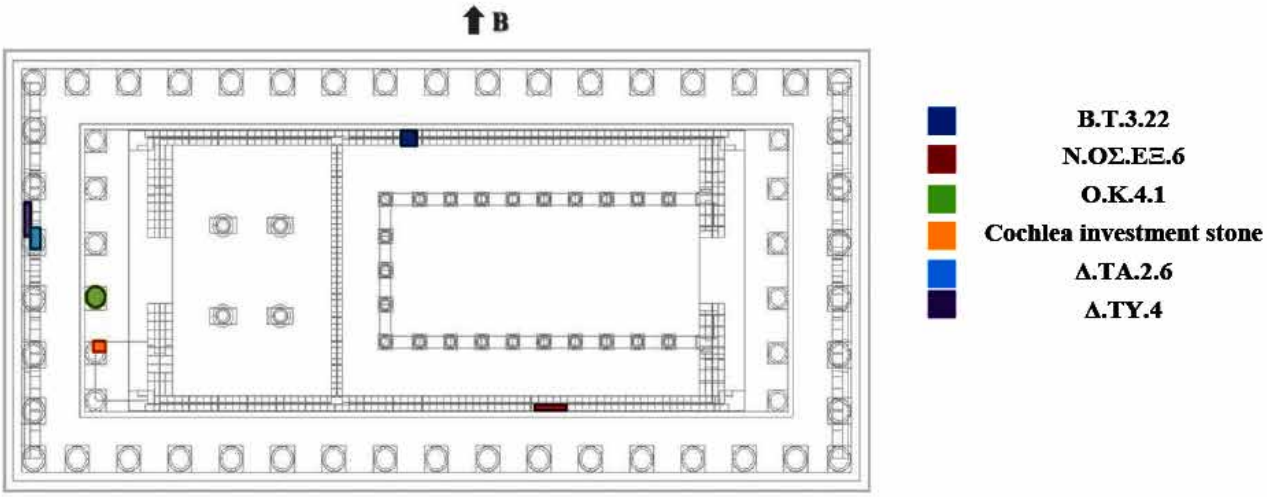
EXTENDED ABSTRACT 161

Ultrasonic analysis of the structural stones of the Parthenon at the Acropolis of Athens - Investigation of the physical / mechanical properties and integrity control of the grouted Joints

Kosmas P.[1], Loupasakis C.[1], Eleftheriou V.[2], Christodoulopoulou R.[2], Vrouva A.[2]
(1) Laboratory of Engineering Geology and Hydrogeology, School of Mining and Metallurgical Engineering, National Technical University of Athens, Athens, Greece, kosmas.panagiotis9@gmail.com
(2) Acropolis Restoration Service, Ministry of Culture and Sports, Athens, Greece

In this research, a non-destructive ultrasonic method was used to evaluate both the physicomechanical properties of the Parthenon's stones and the integrity of the grouted joints in the restoration works. Over 600 measurements of ultrasound velocity were conducted: 320 measurements for estimating the physicomechanical characteristics and 280 for assessing the integrity of the joints (Fig 1).



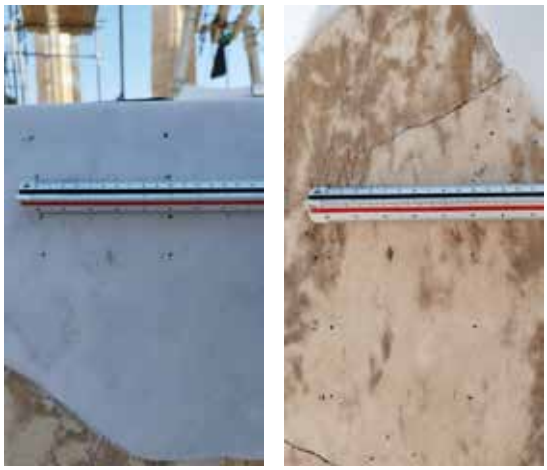


Figure1.Parthenon's layout. The physical location of the measured structural stones.

The measurements were made with the PUNDIT ultrasonic pulse propagation measurement device using P-wave piezoelectric transducers at 54 kHz, 150 kHz, and 250 kHz. After several measurements, it was concluded that, due to the roughness of the surfaces, plasticine was best suited as a contact material. Additionally, the transducers that provided the most consistent readings were those at 54 kHz, especially when used for the evaluation of the integrity of the joints.
The physicomechanical properties of the marbles were determined by taking measurements perpendicular and parallel to the unconformities (bedding or schistosity). The distance between the transducers was 10 cm, and distance between two successive rows 3 cm. A canvas was designed over the surfaces to ensure an accurate distance was maintained between the transducers (Fig 2). Physical pressure was applied to the transducers to ensure proper contact.
The properties of the Dionysos marble, after applying the above-described procedure, are presented in Table 1, and those of the Pentelikon marble are presented in Table 2. It should be noted that, according to Skoulikidis (2000) and Korres & Mpouras (1983) the density of Dionysos and Pentelic marble is 2720 kg/m^3 and 2720 to 2710 kg/m^3, respectively.

ΔΤΑ2.6 2ο	Pentelikon	27.1-27.2	7.47~13.47	3.02 – 5.45
Transducers parallel to the unconformities				
BT322	Pentelikon	27.1-27.2	15.76~19.44	6.38~7.85
ΝΟΣΕΞ6	Pentelikon	27.1-27.2	14.17~26.49	5.74~10.72
ΝΟΣΕΞ6	Pentelikon	27.1-27.2	27.61~29.76	11.17~12.04
ΔΤΑ2.6 1ο	Pentelikon	27.1-27.2	11.43~22.47	4.63~9.10

The measurements conducted for assessing the integrity of the joints are based on a two-step procedure. An initial measurement is taken with the transducers placed 2 cm from both sides of the joint, followed by a second measurement at a distance of 4 cm. After the completion of the measurements, the PUNDIT provides a clear reading of the depth of the open joint. The process is repeated until a sufficient number of readings, indicating a clear value of the depth of the open joint, is provided. Note that an open joint is considered to be the part of the joint not filled with grout, or the part where grout has detached due to shrinkage from the walls of the joint.

(a) (b)

Figure 3. (a) Joint between ancient and ancient marble pieces and (b) joint between ancient and new marble. The canvas designed for measuring the integrity of the joints is clearly illustrated.

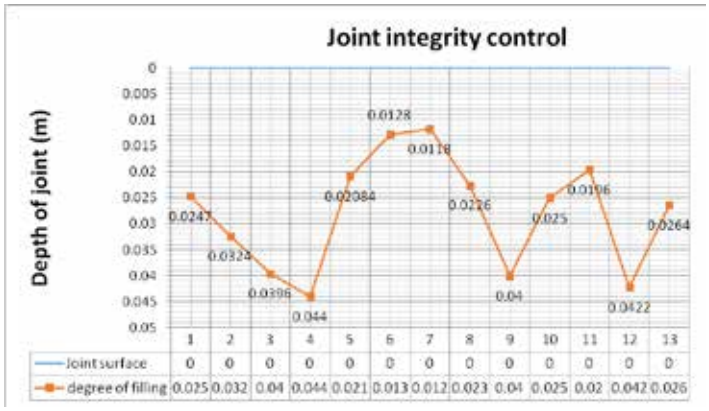

Figure 4. Graph presenting the depth of the open joint; the part of the joint that failed to get properly filed with grout. The graph presents the readings obtained at the joint depicted in Figure3.a.

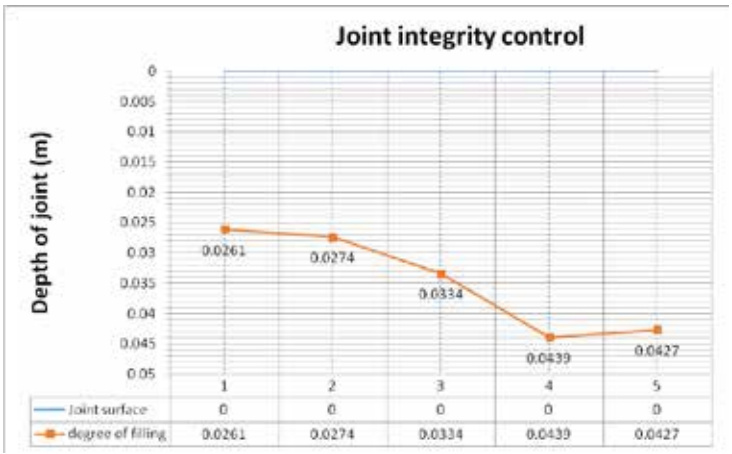

Figure 5. Graph presenting the depth of the open joint; the part of the joint that failed to get properly filed with grout. The graph presents the readings obtained at the joint depicted in Figure3.b.

Measurements of ultrasound velocity was used to examine Dionysos “new” and Pentelic “old” marble, which have been used to construct and reconstruct the Parthenon from antiquity to the present.
According to the ultrasonic measurements, both marbles’ properties appear to be compatible to each other.

Furthermore, higher values of the dynamic characteristics (shear modulus and dynamic modulus of elasticity) are noted in the measurements made parallel to the marbles' unconformities (bedding or schistosity) than those perpendicular.

Additionally, the superficial deterioration—such as cellular corrosion or gypsum formation—ultimately affects only the marbles' surface and not their interior structure and characteristics. This indicates that even though there is significant surface damage, which obviously and irrevocably alters the stone's external relief, it does not damage their mechanical properties.

When evaluating the integrity of the joints, it can be safely stated that the joints are shielded, as the mean depth of the open cracks is less than 2 cm, with only a few identified as reaching the maximum depth of 5 cm. As the ultrasound machine does not allow for the determination of the cracks' width, capillary cracks can only be observed along the joints.

EXTENDED ABSTRACT 162

The Koziakas Mélange Unit: New perspectives on Its Mesozoic paleogeographic and geotectonic evolution (Central Greece)

Kostaki G.[1], Gawlick H.-J.[2], Kilias A.[1], Missoni S., Ghon G.[2], Katrivanos E.[1]
(1) Aristotle University Thessaloniki, Thessaloniki, Greece, gkostaki@geo.auth.gr (2) Montanuniversität Leoben, Leoben, Austria

The Koziakas ophiolites in central Greece, along with their underlying mélanges, represent a part of the obducted Neo-Tethys ophiolites. During the Middle to early Late Jurassic, west-directed ophiolite obduction led to the formation of various mélanges, incorporating blocks from the Triassic Neo-Tethys Ocean floor (radiolarites) and the outer open-marine shelf (Hallstatt Facies). The Middle to Late Triassic Hallstatt Limestones, in particular, are crucial in defining the migration path of the obducting ophiolites. During Oxfordian, obduction stopped, and a shallow-water carbonate platform devolved on top of the ophiolites, shedding material into the remaining underfilled foreland basin in front of the obducted ophiolites. In the latest Jurassic to early Early Cretaceous, mountain uplift and erosion began, and the erosional products of this evolving continent were transported into this foreland basin. During the Tertiary (Eocene-Oligocene), the Koziakas ophiolite and mélange system thrust westward as a whole, together with Pindos unit, over the Gavrovo carbonate platform.

Background/Objectives

The Koziakas mélange unit, traditionally referred to as the Koziakas massif, is located in central Greece and is geologically characterized by an ophiolite nappe and associated underlying Jurassic mélanges. The unit was thrust southwestward as a whole during the Early Cretaceous over the Early Cretaceous Boeotian 'flysch', and during subsequent Paleocene-Eocene tectonics, it was displaced together with the Boeotian 'flysch' over the Late Cretaceous Thymiama succession or directly onto the Paleocene-Eocene Pindos orogenic sediments (Bortolotti *et al*., 2004, Chiari *et al.,* 2012; Fig. 1a). To the east of the Koziakas mélange unit, a Neogene basin developed, primarily receiving erosional products from the ophiolites to the west. The Koziakas ophiolites crop out between the well-known Pindos and Vourinos ophiolites to the north and the Othrys and Argolis ophiolites to the south, forming part of an ophiolite belt whose derivation remains a subject of ongoing debate. Several geodynamic models have been proposed to interpret the origin of these ophiolites, with the most prevalent divided on whether they originated: a) from a parautochthonous Triassic-Jurassic oceanic basin (Pindos Ocean) or b) represent remnants of a far-traveled ophiolite nappe stack derived from the Triassic-Jurassic Neo-Tethys Ocean floor located east of the Pelagonian units (see Robertson, 2012, for an extended review). To unravel the origin of these ophiolites is essential to understanding the Mesozoic paleogeography and mountain-building processes. A key aspect of this understanding is the study of the sedimentary and facies evolution of the passive continental margin(s) that existed prior to plate convergence and ophiolite obduction. Comprehending their evolution would assist in determining the number of the oceanic realms involved, as a multi-ocean reconstruction requires the presence of multiple passive continental margins. An important contribution to this is the study of mélanges formed in front of the advancing ophiolites, as they contain material that provide critical insights into the route taken by the ophiolites during their emplacement. A typical Triassic-Jurassic passive continental margin adjacent to an oceanic realm, from which the ophiolites originate, is characterized by shallow-water carbonates on the central shelf and open-marine carbonates dominating the outer shelf. During the obduction processes, the arrangement of the passive continental margin is disrupted, leading to the formation of a nappe stack and associated trench-like deep water basins in the lower plate position (Frisch & Gawlick, 2003). These trench-like deep-water basins receive synorogenic sediments derived from formations of the passive margin and the ophiolites, while experiencing thrusting into the foreland following the ophiolite emplacement (Gawlick & Missoni, 2019). As a result, the synorogenic sediments within these basins can undergo deformation, with most of their primary sedimentological characteristics being destructed by subsequent tectonics. However, in some cases, distinctive primary sedimentary features can still be observed in such sedimentary mélanges (in sense of Festa *et al*., 2016**)**. During the overthrust of the higher nappe (i.e., obducting ophiolites), material from the lower plate (former passive continental margin sedimentary rocks) can also be scraped off and incorporated into such mélanges (Schmid *et al*., 2008). These mélanges are characterized by a fine-grain matrix incorporating diverse exotic blocks and mass-transport deposits (Gawlick & Missoni, 2019). In this paper, we present new stratigraphic and paleontological data from the Koziakas mélange unit, integrated with structural observations to provide new insights toward a comprehensive understanding. Our analysis focuses on the carbonate exotic blocks incorporated within the mélange associated with the obduction of Koziakas ophiolites. These exotic blocks serve as a valuable tool for reconstructing the original configuration of the overridden passive continental margin. Moreover, we conducted microfacies analyses on a sedimentary sequence composed of carbonate resediments intercalated in radiolarites. This sedimentary sequence, which overlies the Koziakas mélange with the incorporated exotic carbonate and radiolarite

blocks, offers new insights into the subsequent events after the ophiolite emplacement. By combining our diverse data, we aim to contribute to the ongoing discussion surrounding the provenance of the ophiolites and the geotectonic evolution of the Hellenides during the Middle Jurassic to Early Cretaceous. Specifically, we address whether a Triassic-Jurassic Pindos Ocean or Pindos Basin existed and investigate the timing and direction of ophiolite obduction on the Pelagonian margin(s), providing new geodynamic implications and perspectives on the Mesozoic paleogeography of the region.

Methods

In the laboratory, approximately 100 thin sections, each measuring 5 cm x 5 cm, were prepared for detailed examination. Microfacies analyses were conducted to identify microfossils and paleontological characteristics, aiming to determine the paleogeographical environment and the age of the original deposition of the various components and blocks within the studied successions. For conodont age dating, carbonate samples were subjected to 10% diluted acetic acid digestion to dissolve the rock matrix, with the resulting residues examined under a binocular microscope.

Results

Microfacies analysis and conodont age dating were conducted on samples from various outcrops of the Koziakas mélange unit, situated on the eastern slopes of the Koziakas massif, west of the Koziakas ophiolites. This mélange comprises a lower section dominated by an argillaceous-radiolaritic matrix of Middle to early Late Jurassic age, containing, beside Triassic radiolarite pebbles, exotic open-marine Late Triassic carbonate blocks and slides of varying sizes and colors, resembling typical Hallstatt Limestones. Overlying this mélange follow basin-fill sediments consisting of thick, multicolored Late Jurassic radiolarites intercalated by carbonate turbidites and oolitic limestones, transitioning at higher stratigraphic levels into Late Jurassic to earliest Cretaceous shallow-water carbonate-clastic resediments (Fig. 1b, c).

- *Conodont age dating and microfacies analysis on open-marine carbonate blocks*: Samples from exotic blocks and mass-transport deposits within the Jurassic matrix of the Koziakas mélange were collected along the local road connecting Gorgogyri to Kori, as well in the vicinity of the Monastery of Vytoumas (Fig. 1d, e). Sample GR (62), obtained from a polymictic breccia, yielded conodont taxa such as *Gladigondolella*-ME, *Gladigondolella* cf. *malayensis*, *Paragondolella foliata*, and *Paragondolella* cf. *inclinata*, indicating a latest Longobardian to earliest Carnian age. Sample GR (69), collected from a filament limestone block beneath radiolarites with turbidites containing shallow-water debris, revealed taxa *Gladigondolella*-ME, *Paragondolella foliata*, *Paragondolella* cf. *inclinata*, and *Paragondolella polygnathiformis*, suggesting a lowermost Carnian (Cordevolian) age. Sample GR (70), collected from a grey micritic limestone block with red chert nodules, included taxa *Epigondolella rigoi* and *Norigondolella hallstattensis*, indicating an Early Norian age. Sample GR (71), derived from a polymictic breccia, contained the conodont *Paragondolella polygnathiformis*, corresponding to a Carnian age. Sample GR (235), obtained from mass-transport deposits with grey and red limestones, included *Metapolygnathus* cf. *commusti*, suggesting the Carnian/Norian boundary; *Epigondolella slovakensis*, indicative of Alaunian 2-3; and *Epigondolella bidentata*, corresponding to the Sevatian. Sample GR (236), collected from a reddish limestone block, yielded conodont taxa *Paragondolella polygnathiformis* and *Paragondolella nodosa*, indicating Tuvalian 3/1, as well as *Metapolygnathus* sp., suggesting the Carnian/Norian boundary. Sample GR (237), derived from a reddish limestone block, included several species of the latest Carnian (Orchard). Sample GR (238), also collected from a reddish limestone block, yielded *Paragondolella polygnathiformis* and *Paragondolella carpathica*, which are indicative of Tuvalian 2. Sample GR (240), obtained from a grey limestone block, included *Epigondolella rigoi*, indicating Lacian 2 age. Finally, sample GR (43) was collected from a medium-bedded grey siliceous limestone block and thin section analysis revealed a dark reddish-grey pelagic non-laminated wackestone with radiolarians, filaments, and a biofabric characterized by loose packing, medium sorting, and size variation of bioclasts. These facies suggest open-marine deposition on an outer shelf, with most radiolarians recrystallized into quartz.
- *Microfacies analysis of shallow-water carbonate-clastic resediments*: Shallow-water carbonate-clastic resediments are observed near Kori village, occurring at the higher stratigraphic levels of the Late Jurassic radiolarite sequence (Fig. 1f, g). Based on the examination of thin sections, the microfacies of the collected samples are identified as bioclastic packstones and grainstones, with shallow-water bioclasts being the most frequent components. In these thin sections, the bioclasts consist of bryozoans, foraminifera, crinoids, and debris from reef-building organisms. The presence of encrusting organisms is characteristic, such as the microencruster *Crescentiella morronensis* (Crescenti). Additionally, other bioclasts, such as calcareous algae *Thaumatoporella*, foraminifera *Litualinida*, and *Aptychus*, have been identified. These taxa indicate reefal facies from the Tithonian age. In specific thin sections, reworked shallow-water bioclasts are observed to be mixed with older Late Triassic clasts containing the benthic foraminifera *Aulotortus sinuosus*. The identification of radiolarian wackestone containing poorly preserved calpionellids, such as *Crassicollaria brevis* or *Calpionella elliptica*, mixed in the resediments suggests that the oldest age of redeposition can be estimated as Berriasian (Ghon *et al.*, 2018).

Discussion/Conclusions

Carbonate rocks originating from formations of the outer passive continental margin (Hallstatt Facies) are often found as exotic blocks incorporated within mélanges, a phenomenon widely observed in collisional belts (Gawlick & Missoni, 2019). These exotic blocks serve as valuable tools for reconstructing the original configuration of passive continental margins, as demonstrated in studies of the Dinarides, Albanides, and more recently, the Hellenides (Kostaki *et al.*, 2024, and references therein). Similarly, the exotic open-marine carbonate blocks within the Koziakas mélange provide critical insights into the disrupted architecture of the former passive margin preceding ophiolite obduction. Our analysis reveals that these blocks, spanning ages from the latest Ladinian–earliest Carnian, Late Carnian, and the entire Norian, correspond to a dismembered Triassic Hallstatt Limestone succession characterized by distinctive lithology, microfacies, and stratigraphy. The Hallstatt Facies were originally deposited on the outer shelf during the Middle Anisian to Rhaetian, along with the continental slope Meliata Facies, shaping the eastern Adriatic passive continental margin that faced Neo-Tethys Ocean to the east (e.g., Sudar *et al.*, 2013; Fig. 2a). However, in most instances, the Hallstatt Facies have been disrupted during Middle-Late Jurassic ophiolite obduction and preserved as components or complete successions within massive blocks and slides found in Middle to Late Jurassic far-traveled mélanges along the Alpine-Carpathian-Dinaridic collisional belt (e.g., Gawlick & Frisch, 2003). The Hallstatt Facies can be subdivided into (Gawlick *et al.*, 2018): the reef-proximal facies, characterized by light grey hemipelagic limestones intercalated with shallow-water turbidites, and the distal outer shelf facies, which consists of variously colored limestones. Within the distal outer shelf facies, two types are recognized (Krystyn, 2008): a) the famous fossil-rich facies featuring red bioclastic condensed limestone layers with local enrichment in cephalopods, and b) the facies poor in megafauna, characterized by red to whitish to grey bedded limestones with local enrichment in filaments, radiolarians and echinoderms. The biostratigraphy of the latter facies primarily relies on conodonts. In the Hellenides, the reef-proximal facies are well-

represented by Middle Triassic to Early Jurassic cherty limestones intercalated with turbidites with shallow-water material, notably observed in the Argolis Peninsula, Orthis, and Hydra (Baumgartner, 1985, Ferrière *et al.*, 2016). These limestones are interpreted as west-directed, far-traveled nappes associated with a Jurassic obduction of ophiolites originating from an oceanic realm east of the Pelagonian units (for an alternative view, see Clift & Robertson, 1990). Representing the central shelf dominated by shallow-water carbonates, the Pelagonian units served as a source for sedimentary input into the adjacent reef-proximal outer shelf environment during the Middle Triassic to Early Jurassic. A west-directed ophiolite obduction over the Pelagonian units during the late Middle to early Late Jurassic aligns with our structural observations and other published works (e.g., Kilias *et al.*, 2010, Bortollotti *et al*. 2012, and references therein). In the Avdella mélange, an equivavent mélange to the Koziakas mélange, NW-SE trending asymmetric tight to sub-isoclinal folds with a predominant top-to-the-SW sense of movement are well-preserved and associated with the emplacement of the Pindos ophiolites (Kostaki *et al.*, 2024). Additionally, ductile to semi-ductile shear zones, characterized by well-developed cinematic indicators (e.g. σ-clasts, shear bands, S-C-C` structures), clearly show a west to southwestward sense of shear, although, in some places, they are affected by the younger Tertiary brittle deformation, which typically characterizes the post-obduction phase. Furthermore, similar to the Koziakas mélange, the Avdella mélange contains open-marine Triassic blocks, from which a dismembered Hallstatt succession has been reconstructed (Kostaki *et al.*, 2024). Both mélanges, exhibiting identical characteristics, developed during the Middle to early Late Jurassic as a result of westward ophiolite obduction. Ahead of the advancing ophiolites, trench-like deep-water basins formed, receiving material from the progressing nappe stack, including Hallstatt Facies and ophiolites (Fig. 2b). These basins were subsequently sheared and incorporated into the nappe stack, resulting in the characteristic features of mélanges. Notably, the reconstructed Hallstatt succession from exotic blocks within the Avdella and Koziakas mélanges closely resemble the complete open-marine Middle Triassic to Early Jurassic succession preserved in the Western Pindos, indicating that the Western Pindos succession is the paleogeographic source of the open-marine exotic blocks (complete correlation in Kostaki *et al.*, 2024, Kostaki, 2024). This succession, attributed to the Hallstatt Facies due to its identical lithological and stratigraphic characteristics, represents the distal outer shelf facies. The original deposition of the Western Pindos succession is identified as taking place on the outer shelf from the Middle Triassic until the Early Jurassic east of the Pelagonian units, constituting the easternmost segment of the Adriatic plate (Kostaki *et al.*, 2024). During the late Middle to early Late Jurassic, the west-directed obduction of the Neo-Tethys ophiolites led to the formation of a nappe stack (Fig. 2b**)**. As a result, the Western Pindos succession also became part of this nappe stack and was subsequently bulldozed westward, providing material to trench-like deep-water basins that later evolved into mélanges. This Jurassic westward movement, reflected in both the mélanges and the ophiolites (Kilias, 2024), ultimately transported the Western Pindos succession onto the foreland, reaching the inner parts of the Pelagonian units. Consequently, in its new position during the early Late Jurassic, the Western Pindos succession underwent new sedimentation, resulting in its coverage by a subsequent Late Jurassic to Paleogene sequence. This sequence contributed to a misconception regarding its original deposition, which was perceived as parautochthonous and referred to as Pindos basin. Our biostratigraphic analysis of the exotic blocks found in the Koziakas mélange indicates that the lowermost Carnian blocks are characterized by the influence of shallow-water material, suggesting their original deposition in proximity to the central shelf. This interpretation aligns with the development of the Wetterstein Carbonate Platform, which evolved during the Late Ladinian and lasted until the Early Carnian, shedding debris into the outer shelf region.

Furthermore, our study of the Koziakas mélange unit provides additional insights into nappe stacking processes, the timing of events, and the Middle Jurassic to Early Cretaceous paleogeography. Based on our structural observations, the Koziakas mélange unit can be divided into three tectono-sedimentary sub-units: a) an ophiolitic mélange at the base, consisting exclusively of components derived from the ophiolites and their radiolarite cover, predominantly Triassic radiolarite components (see also Chiari *et al.*, 2012); b) a mélange upsection, dominated by Triassic Hallstatt limestone blocks within an argillaceous-radiolaritic matrix; c) an overlying sequence of radiolarites intercalated by carbonate turbidites and oolitic limestones, transitioning at higher stratigraphic levels into shallow-water carbonate-clastic resediments. The formation of ophiolitic mélanges occurred at the base of the advancing ophiolites, following the onset of intra-oceanic subduction and the development of metamorphic soles. Radiometric dating and geochemical analysis indicate a Middle Jurassic age (174 ± 3 Ma and 161 ± 1 Ma) for the formation of Koziakas ophiolites' metamorphic sole within a MORB-type lithosphere influenced by IAT characteristics (Pomonis *et al.*, 2002). This setting initiated a west-directed ophiolite obduction onto the passive continental margin during the Bajocian-Bathonian, imbricating the lower plate and leading to the formation of trench-like deep-water basins (Fig. 2b). These basins received material from the advancing nappe stack, which later evolved into the mélange with the Hallstatt blocks (Fig. 2c). The timing of ophiolite obduction and the formation of trench-like deep-water basins as Middle to early Late Jurassic is supported by biostratigraphic data obtained from equivalent mélanges across the Albanides and Dinarides (Gawlick *et al.*, 2017), aligning with radiolarian age dating from the Koziakas mélange, which indicate a latest Bajocian to Early Callovian age (Chiari *et al.*, 2012). This is further supported by the evolution of Kimmeridgian–Tithonian shallow-water platforms atop the obducted ophiolites, suggesting that ophiolite emplacement over the Pelagonian units predates the formation of these platforms (Kostaki *et al.*, 2013, 2024). By that time, the nappe stack had advanced into the foreland, and the progressing

basin system developed into a trench-like foreland basin in front of the obducted Koziakas ophiolites, where the radiolarite sequence of the Koziakas was deposited above the mélange with the Hallstatt blocks (Fig. 2c, d). Extending for several meters, this radiolarite sequence reflects a period of relative tectonic silence during the Oxfordian to the Kimmeridgian, as indicated by radiolarian age dating (Kostaki, 2024). The influence of a shallow-water environment from the Kimmeridgian-Tithonian platform atop of the ophiolites during the late Oxfordian to Tithonian became evident through the deposition of radiolarites intercalated with carbonate turbidites and oolitic limestones. Subsequently, from the latest Tithonian onwards, erosional products of this platform were redeposited in this remaining underfilled foreland basin, forming carbonate-clastic resediments. Microfacies analysis of these resediments reveals Kimmeridgian Saccocoma-bearing limestones and Tithonian shallow-water clasts mixed with Late Triassic carbonate clasts. This phase of erosion is attributed to the tectonic uplift of the accreted former Pelagonian margin from the Tithonian onwards, initially affecting the Late Jurassic shallow-water platform, then the ophiolites and their radiolarite cover, and later extending to the Triassic to Early Jurassic shallow-water Pelagonian carbonates. The ongoing uplift and unroofing led to further westward transport of the ophiolites and the overlying shallow-water platform, bringing them closer to the under-filled foreland basin (Fig 2d). In this setting, erosional products, including reworked Late Jurassic shallow-water platform clasts and Triassic carbonate clasts, were redeposited, forming carbonate-clastic resediments. The basin remained under-filled, allowing sedimentation to continue until the earliest Cretaceous (Ghon *et al.*, 2018). In contrast to the Koziakas setting, which partially escaped complete overthrusting by the ophiolites and allowed for prolonged sedimentation with minimal deformation of the basin fill sediments, the Avdella mélange was totally overthrust by the ophiolites, exhibiting the typical characteristics of a mélange.

Our perspective aligns with paleogeographic reconstructions of other regions within the Alpine-Carpathian-Dinaridic belt, characterized by a well-organized passive continental margin consisting of a central shelf (the Pelagonian unit) and an outer shelf dominated by Hallstatt Facies. In the Hellenides, these facies are represented by the Triassic–Early Jurassic Western Pindos succession, which we interpret as a west-directed, far-traveled nappe during Middle to early Late Jurassic. Our findings support the existence of a single Neo-Tethys Ocean located east of the broader Adria, with the Pelagonian unit forming its easternmost continuation without any interruption of an autonomous Pindos Ocean or a Triassic-Jurassic deep-water Pindos Basin.

EXTENDED ABSTRACT 163

Assessing Climate Extremes as Drivers of Geohazards in Greece

Kostopoulou E.[1], Giannakopoulos C.[2], Nefros C.[3], Loupasakis C.[3]
(1) Department of Geography, University of the Aegean, Greece, ekostopoulou@aegean.gr (2) Institute for Environmental Research and Sustainable Development, National Observatory of Athens, Greece, (3) School of Mining and Metallurgical Engineering, National Technical University of Athens, Athens 15780, Greece

Climate extremes have become more frequent and intense in recent years due to global climate change, leading to an increased risk of geohazard occurrences. Extreme events, such as heavy precipitation, can contribute directly to the occurrence of geohazards, including floods and landslides. Additionally, prolonged heatwaves can directly lead to increased soil erosion and indirectly to more frequent and intense wildfires, which, in turn, can increase landslide hazard, by reducing vegetation cover and destabilizing the soil. This study examines historical climate data and future projections, to identify potential climatic changes, which may induce geohazards in Greece.

Introduction

The Mediterranean, a climate change hotspot, is warming 20% faster than the global average (Lionello and Scarascia, 2018; MedECC, 2020; IPCC, 2021), with Greece, as part of the region, following a similar trend. The impact of climate change becomes evident with the increasing variability in temperature, precipitation, and wind patterns leading to more frequent and severe climatic extremes (Giannakopoulos et al., 2011; Lelieveld et al., 2012; Zittis et al., 2016; 2014, Politi et al., 2022, Kostopoulou and Giannakopoulos, 2023 Kostopoulou et al., 2024). Rising temperatures and shifting rainfall patterns exacerbate soil erosion, increase the frequency of floods, and destabilize slopes. This study focuses on the assessment of climate extreme indices in Greece and their direct and indirect impacts on potential future geohazards. Using climate data from the Copernicus Climate Change Service/Climate Data Store (https://cds.climate.copernicus.eu/) we analyze climate variables, indices, based on historical data and projections of future climate scenarios. The ERA5-Land is a global land-surface climate reanalysis produced by the European Centre for Medium-Range Weather Forecasts (ECMWF), providing data at various temporal resolutions from 1950 onward (Muñoz-Sabater et al., 2021). The high-resolution regional climate model data were extracted from the EURO-CORDEX database (Jacob et al., 2014). The climate projections cover the period 1971–2100 and have been used to examine future changes. The projections were estimated for two future emissions scenarios, the moderate RCP4.5 and the more extreme RCP8.5 (Moss et al., 2010). Furthermore, we study maps from the European Climate Risk Typology (https://european-crt.org/) projecting changes in representative climate indices, under the high-emissions 'RCP8.5' global warming scenario, which are related to specific hazards in Greece at regional scale. In the following sections, historical and model-projected time series of temperature and precipitation are analyzed. Subsequently, changes in climate indices and hazard indicators across Greece are presented.

Time Series Analysis of Climate Data and Projections

Reanalysis data from the ERA5-Land dataset are used to describe present climate conditions in Greece. Over the historical period 1950–2022, the mean annual temperature (TM) averaged 13.9°C. In the first half of the period, the annual TM was 13.6°C, while in the second half, it increased to 14.2°C. Anomalies from the 1991–2020 mean range from -1.5°C to 0.8°C, with nine of the ten warmest years occurring after 2010.

Increasing trends are particularly observed in daily mean, minimum, and maximum temperatures (hereafter TM, TN, and TX) on both annual and seasonal scales. Figure 1 illustrates the variations in TN and TX during winter (December to February – DJF) and summer (June to August – JJA) over the historical period. Both seasons show increasing trends, with summer temperatures exhibiting a steeper rise. Focusing on the positive anomalies, we observed deviations of 2.1°C and 1.5°C for TN, and 2.4°C and 2.3°C for TX in winter and summer, respectively, compared to the 30-year average for the period 1991–2020. However, when comparing to the average of the earlier 30-year period (1951–1980), the positive deviations reach up to 2.3°C for TN in both winter and summer, 2.9°C for winter TX, and 3.1°C for summer TX. Hence, both seasonal TN and TX are increasing in Greece, with TX exhibiting a faster rate of warming. The increasing temperatures can contribute to more frequent and severe wildfires, which, in turn, increase the risk of soil erosion (Depountis et al., 2020) and landslides (Nefros and Loupasakis, 2023), especially in mountainous areas. The rise in temperatures may also lead to increased droughts, further stressing water resources and enhancing the risk of desertification in certain regions.

Warming is projected to continue in the future, with both seasonal TN and TX expected to rise further in Greece. Figure 2 shows future projections for the near term (2021–2040), medium term (2041–2060), and long term (2081–

2100). As revealed under both RCP4.5 and RCP8.5 scenarios, not only TX and TN are projected to increase, but the number of heatwave days (TX exceeding 35° C) is expected to rise, while the number of frost days (TN below 0° C) is anticipated to decline. Moreover, according to the CORDEX-EUR-11 climate model, TX and TN are anticipated to increase, with changes ranging from 2°C to over 4°C by the end of the 21st century under the RCP4.5 and RCP8.5 scenarios, respectively.

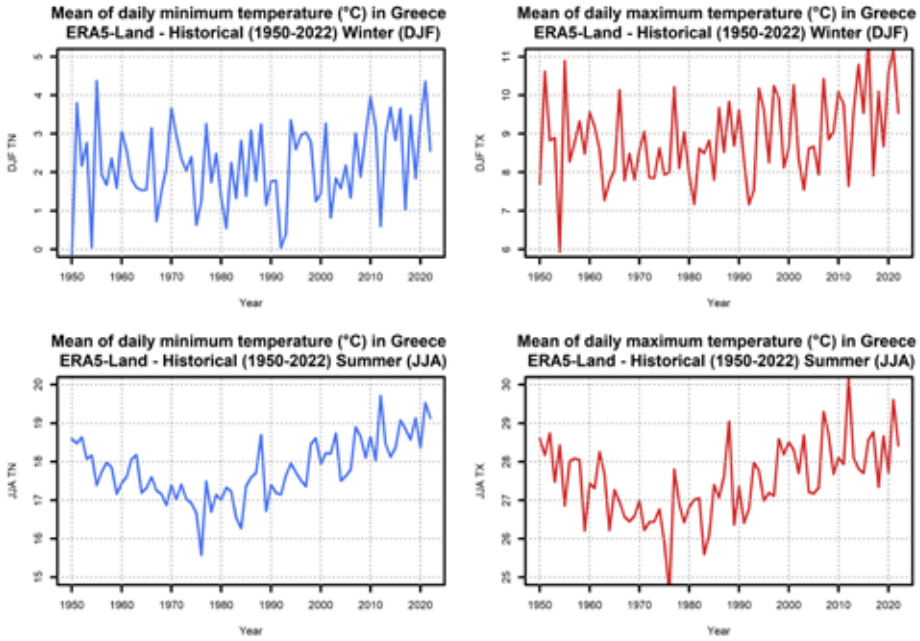

Figure 1. Variations in TN -mean daily minimum (blue) and TX -maximum (red) temperatures over the historical period 1950–2022 during winter (top) and summer (bottom) in Greece.

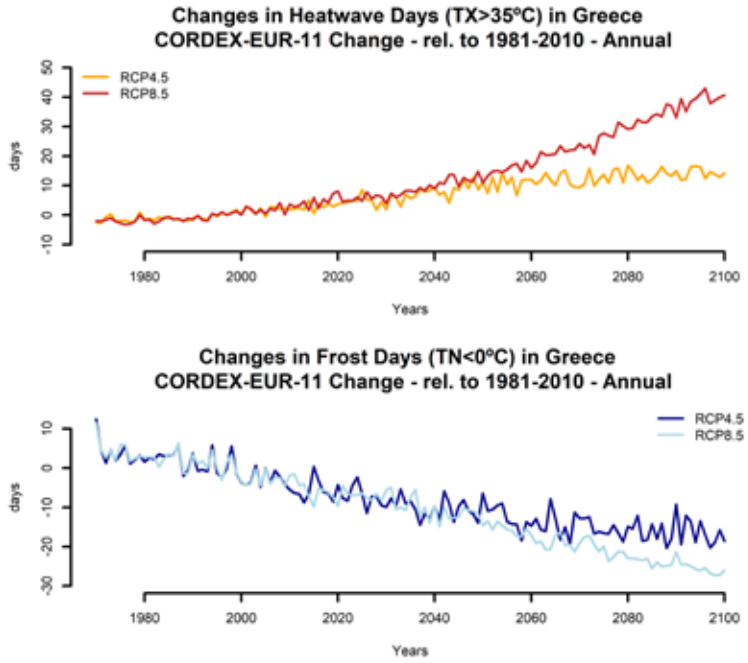

Figure 2. Simulated changes in the number of days with TX above 35°C (top) and TN below 0°C (bottom) in Greece, relative to the 30-year historical period 1981–2010.

Concerning precipitation, the mean daily accumulated precipitation fluctuates around its average over the historical period 1950-2022 (Figure 3, left column panels), with both wetter and drier years evident. An increasing trend has been observed in the annual maximum 1-day precipitation over the past decade, although this is not a long-term pattern and the trend remains uncertain. However, a more distinct trend is evident in the annual mean daily evaporation, likely driven by the rising temperatures. Regarding future changes (Figure 3, right column panels), the mean daily accumulated precipitation is projected to slightly decrease in the medium term (2041–2060) under both RCP4.5 and RCP8.5 scenarios, with a more pronounced decline under RCP8.5 in the long term (2081–2100). The annual maximum 1-day precipitation is expected to increase under both scenarios, particularly under RCP8.5, with an approximate increase of 5 mm per day. The combined effect of these changes suggests that while daily precipitation may decrease, precipitation on wet days could become more intense. The scenarios do not show a clear trend in the annual mean daily evaporation. The Standardized Precipitation Index (SPI; McKee et al., 1993) is of particular relevance, as it shows changes in precipitation relative to the average of a reference period and defines precipitation anomalies over time (i.e., dry and wet spells). The two maps shown in Figure 3, located at the far right of the figure, present the annual index values calculated over a 6-month period (SPI-6) for the medium and long term under RCP8.5. This index is typically used to identify short-term trends in precipitation. In both cases, negative values of the index are observed over Greece, indicating that the region is expected to experience drier-than-normal conditions. More specifically, the SPI-6 suggests moderate drought conditions in the medium term, which could become more severe towards the long-term period.

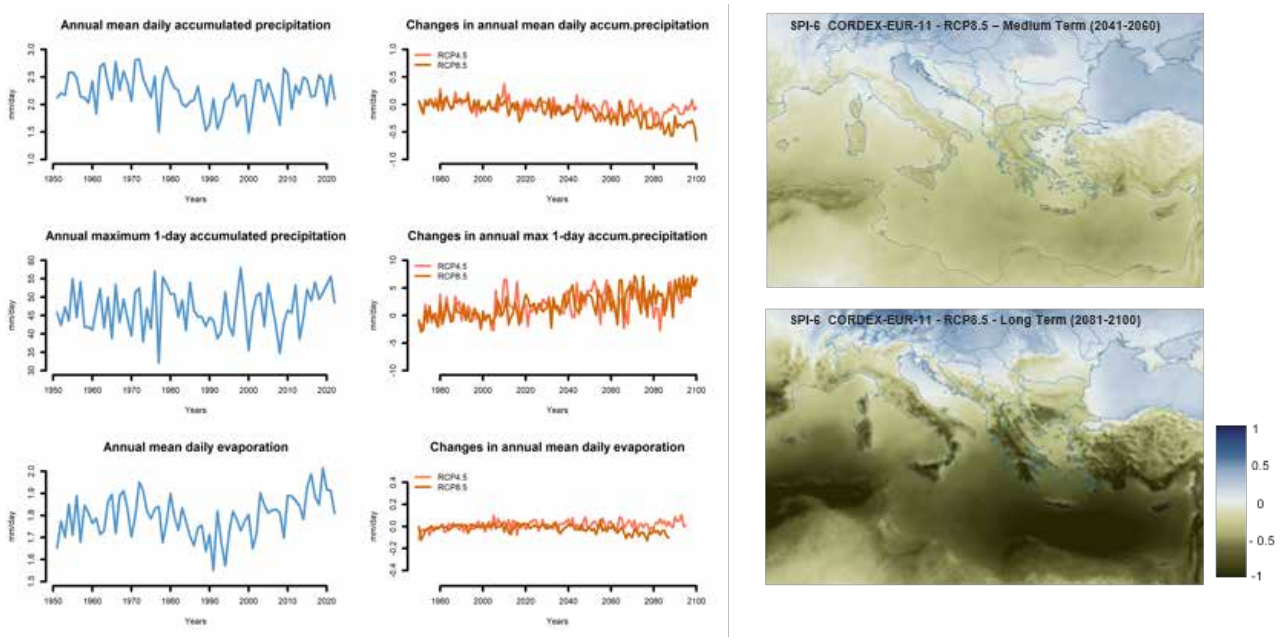

Figure 3. The diagrams show the observed values (left) and simulated changes (right) in mean daily precipitation (top), maximum 1-day precipitation (middle), and daily evaporation (bottom) in Greece. The maps, located at the far right of the figure, depict the annual SPI-6 under RCP8.5 for the medium term (2041–2060, top) and the long term (2081–2100, bottom).

Spatial Representation of Changes in Climate Indices and Hazard Indicators

Subsequently, data from the European Climate Risk Typology (European CRT, Carter et al., 2018) are utilized to examine the spatial distribution of projected climate index changes in Greece at regional unit scale (NUTS3 scale). The European CRT provides a systematic framework for assessing and classifying climate risks across Europe, facilitating a comprehensive understanding of their spatial distribution and intensity. This approach supports researchers and policymakers in developing targeted, region-specific climate adaptation strategies.

Extreme climate indices potentially related to the occurrence of specific hazards are shown and discussed. For example, the combined effect of increased temperatures and consecutive dry days creates favorable conditions for the development of drought hazards. Similarly, projections of changes in the number of consecutive wet days and extreme precipitation events provide insights into the potential for flood hazards. These maps present changes for the medium term (in this case the period 2036-2065, with respect to the reference period 1981-2010) under the RCP8.5 scenario.

The projected changes in heatwave days (TX > 35°C) are shown in Figure 4a. The Greek region is expected to experience positive changes across the entire area. Most regions are projected to see an additional 6–15 heatwave days by the mid-21st century. Notably, increases are observed in the islands of the eastern Aegean Sea. The most impacted areas, highlighted in red, are located in the central continental parts of the country. Increases are also observed in consecutive dry days (Figure 4b), with the eastern and southern parts of the country projected to experience the greatest impact. The number of consecutive dry days (precipitation < 1mm) may increase by 8 days in eastern Peloponnese and by 11 days in eastern Crete. In line with this finding, the next index refers to changes in wet spells, using the number of consecutive wet days (precipitation > 1mm). Here, we observe minimal changes, indicating a future trend toward increasing dryness in the region. The fourth index, presented in Figure 4d, shows the projected changes in heavy precipitation days. All Greek sub-regions show negative trends in heavy precipitation events. However, it is important to note that smaller-scale extreme events, such as localized heavy rainfall, may not be accurately captured by the model's long-term projections, particularly in areas with complex topography (e.g., mountains or coastal regions). As a result, extreme precipitation events may still occur despite the overall negative trend.

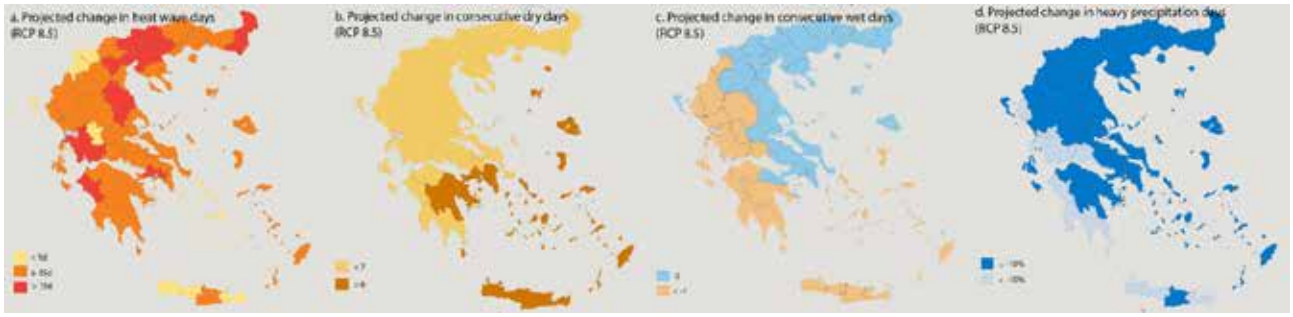

Figure 4. Projected changes under RCP8.5 in (a) heatwave days, (b) consecutive dry days, (c) consecutive wet days, and (d) heavy precipitation days (data source: european-crt.org).

Finally, maps showing several hazards over Greece were reproduced from the European CRT datasets. Figure 5 presents four types of hazards related to climate conditions. The indicator that defines 'Drought hazard' utilizes the Standardized Precipitation-Evapotranspiration Index (SPEI; Vicente-Serrano et al., 2010) at nine month timescales to provide a measure of meteorological drought. Negative values of SPEI reflect regions where precipitation over a nine-month period is reduced. Although most of the Greek region shows values below the European average, the light colors in northeastern Greece, the small islands of the Aegean, and eastern Crete indicates regions more susceptible to drought. This is of particular importance, especially for eastern Crete and the Cyclades islands in the Aegean, which are among the driest areas of the country and at high risk of desertification. The "Fluvial flooding" indicator highlights areas susceptible to flooding in the event of a 1-in-100-year fluvial flood. Parts of northeastern Greece, as well as the regions of Larissa, Voiotia, Ileia, Thesprotia, and especially Evros, are identified as areas prone to fluvial flooding. The "Landslide hazard" indicator highlights areas with moderate or higher susceptibility to landslides, considering both predisposing and triggering factors. While steep slopes are a key factor influencing landslide susceptibility, landslide hazard is determined by combining susceptibility with triggering factors, such as intense precipitation (Nadim et al., 2006). Landslides in Greece are usually triggered by heavy rainfall, seismic activity, and human activity such as deforestation, and constructions on geologically unstable or steep terrain. Changes in soil erosion can also impact landslide susceptibility (Huang et al., 2020), significantly also heighten the landslides hazard in various regions. Moreover, high temperatures and prolonged dry spells may exacerbate soil erosion, which can further increase landslides susceptibility. This indicator identifies several Greek sub-regions with values above the European average, indicating a higher susceptibility to landslides. The "Wildfire hazard" indicator uses data on past wildfire occurrences, vegetation types, climate variables, and the Canadian Forest Fire Weather Index (FWI; Van Wagner, 1987) to identify regions at risk. Most of Greece shows values above the European average, which can be attributed to the combination of rising temperatures and extended dry periods, particularly in subregions located in the eastern and southern parts of the country. Similarly, the increased wildfire hazard is expected to indirectly affect the occurrence of geohazards, such as soil erosion and landslides.

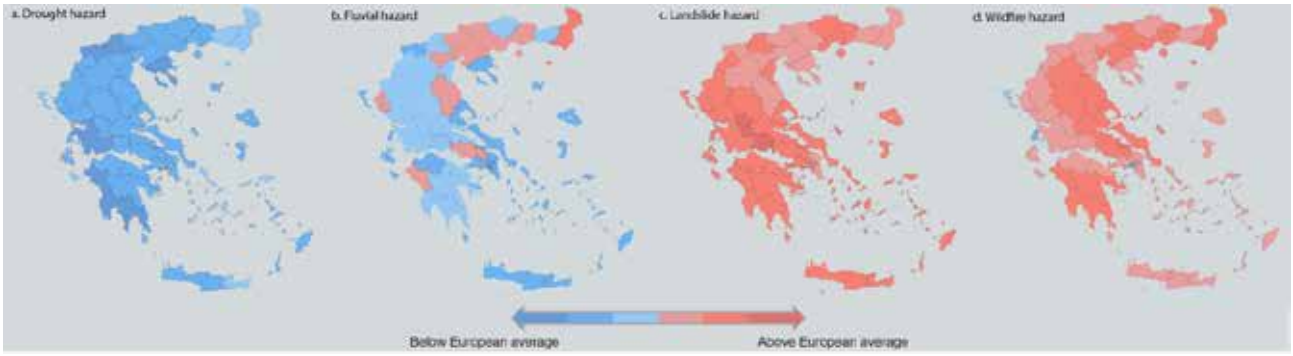

Figure 5. Estimated hazards under RCP8.5 for (a) drought, (b) fluvial flooding, (c) landslides, and (d) wildfires (data source: european-crt.org).

Conclusions

Analysis of climate data reveals a clear warming trend across Greece, with annual and seasonal temperatures rising, especially during summer. Projections suggest further warming of 2°C to beyond 4°C, by the century's end, depending on emission scenarios. Combined with prolonged dry spells, this will lead to more frequent and intense heatwaves, droughts, and wildfire risks, and in turn, to an increased occurrence of geohazards. While precipitation trends remain variable, heavy rainfall events do not show a clear increase, though models have difficulty capturing localized extremes. Future projections indicate a decline in mean daily accumulated precipitation, but an increase in the individual daily rainfall amounts, raising the risk of both droughts and floods, which can, in turn, impact accordingly soil erosion and landslides. The SPI-6 indicates drier conditions, especially under high-emission scenarios. Eastern and southern Greece is most vulnerable to drought, while coastal and mountainous areas face increased flooding, landslides, and soil erosion. Wildfire risks will also rise, especially in the east and south. These findings highlight the need for targeted adaptation strategies to mitigate extreme climate impacts on geohazards, particularly in high-risk regions.

Acknowledgements

We acknowledge the use of data from the Copernicus Climate Change Service (C3S) and the Climate Data Store (CDS), specifically the ERA5-Land dataset and the CORDEX-EUR-11 climate model data. We also thank the European Climate Risk Typology for contributing essential data on climate risk indicators.

Introduction

The underwater geomorphology of tectonically active regions is essential for understanding seismic hazards, particularly in areas with a history of destructive earthquakes. The Ionian Sea, situated at the convergence of major tectonic domains in the Mediterranean, represents a region of significant scientific interest (Fig.1). It likely features an upper crustal fault system overlying the megathrust fault system of the Hellenic Subduction Zone, trending NW-SE to NNW-SSE, which contributes to its high seismic hazard potential (Ranero et al., 2023).

Figure 1. The location of the study area in relation to continental Greece (the bathymetry is from EMODnet, while in red are shown simplified fault lines of on- and offshore Greece)

The POSEIDON Eurofleet+ cruise (10–22 June 2023) aboard Research Vessel (R/V) *Laura Bassi* focused on mapping the tectonic structure of the Ionian Sea, particularly near the western Peloponnese and Ionian Islands, including Lefkada, Cephalonia, and Zakynthos (Fig.1). This region is characterized by a complex fault network and exhibits the highest instrumentally recorded seismic activity in the Mediterranean, often associated with tsunamigenic potential, as exemplified by the 1953 Cephalonia Mw ~6.8 earthquake (Stiros et al., 1994).

Methods

During the cruise, approximately 1,940 km of high-resolution swath bathymetry data were collected using the keel-mounted EM304 (Kongsberg Maritime) system. To enhance data accuracy, adjustments were made to optimize swath

width, and sound velocity profiles (SVP) were acquired in shallow and deep waters to correct refraction errors. Data acquisition was performed using SIS and Quincy software, while processing—including sound speed corrections, line cleaning, and CUBE surface creation—was completed using Qimera software. The processed data was gridded at a 50 m resolution.

The high-resolution bathymetric data were then integrated with medium-resolution data from the EMODnet database, along with single- and multibeam datasets provided by the Hellenic Navy Hydrographic Service (HNHS) (Fig.2). These combined datasets were visualized and analyzed using the ESRI GIS software suite, producing a comprehensive morpho-bathymetric map of the region.

The bathymetric data reveal a rugged seafloor with significant variability, especially in the northern sections. Offshore Lefkada Island, a well-defined continental slope extends from 150 m to 680 m water depth, marked by amphitheater-shaped canyon heads at the continental shelf's edge. This area can be divided into two distinct zones: a relatively flat section up to 600 m depth, hosting sediment waves in the northern part, and deeper regions characterized by NE-SW trending canyons. These canyons exhibit flanks indicating multiple, coalescent and nested landslides, with their mouths reaching depths of nearly 2800 m (Fig.2).

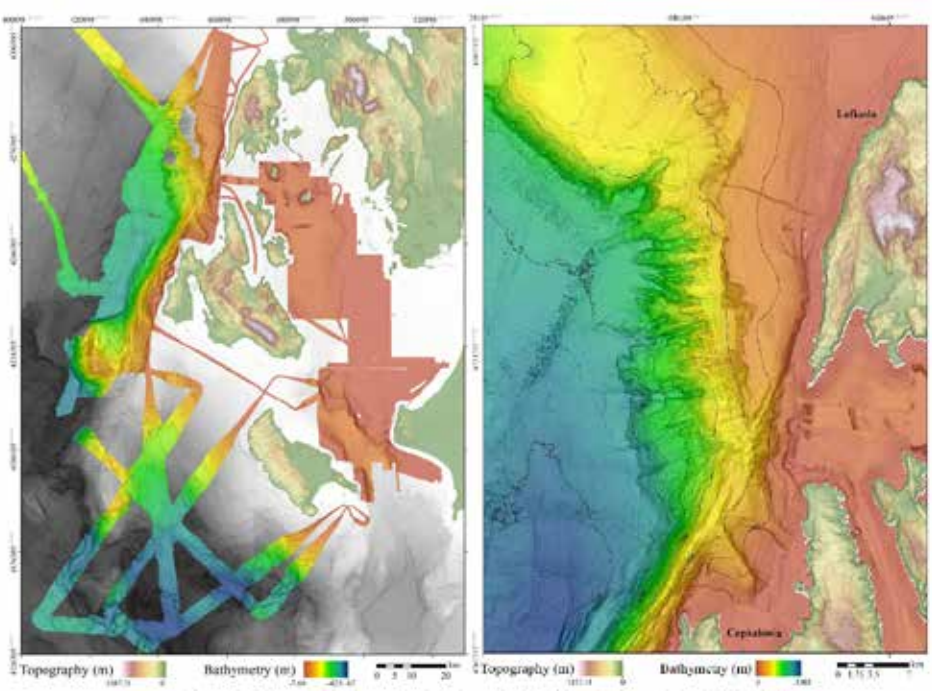

Figure 2. Integrated bathymetric data from the Poseidon Cruise and the HNHS (left) and offshore Lefkada region (right)

Results

The bathymetry of Cephalonia and Zakynthos shows stark contrasts. Northwest of Cephalonia, a steep (>40°) slope connects the abyssal plain to a narrow continental shelf or directly to the coastline. Southward, the slope becomes gentler (~21°) with NE-SW trending steps along the Cephalonia Transform Fault (CTF) system, forming a corrugated seabed (Fig. 4). The CTF trends in a NE-SW direction and extends morphologically to the northern edge of Cephalonia. To the west, the CTF system connects to the Lixouri Seamount, which transitions from a N-S to an E-W orientation. Another Unnamed Seamount further south features steep (36°), triangular, E-dipping faces (Fig.3).

The SW-facing slopes of Cephalonia and Zakynthos are even steeper, with angles up to 40° (Fig. 4), lacking features like canyons or gullies, but are marked by crescent-shaped landslide scars and large-scale landslides, such as a 51 km-long and 2 km-wide feature south of the Paliki Peninsula (Cephalonia) and Zakynthos. These areas display morphological steps indicative of landslides, with E to ENE-dipping detachment planes. The Argostoli Ridge runs NNE-SSW and is bounded by the CTF system and several crescent-shaped landslide scars. Further south, this ridge fragments and collapses. The southernmost area features two elongated abyssal basins reaching depths of 4230 m and 4220 m (Fig.3).

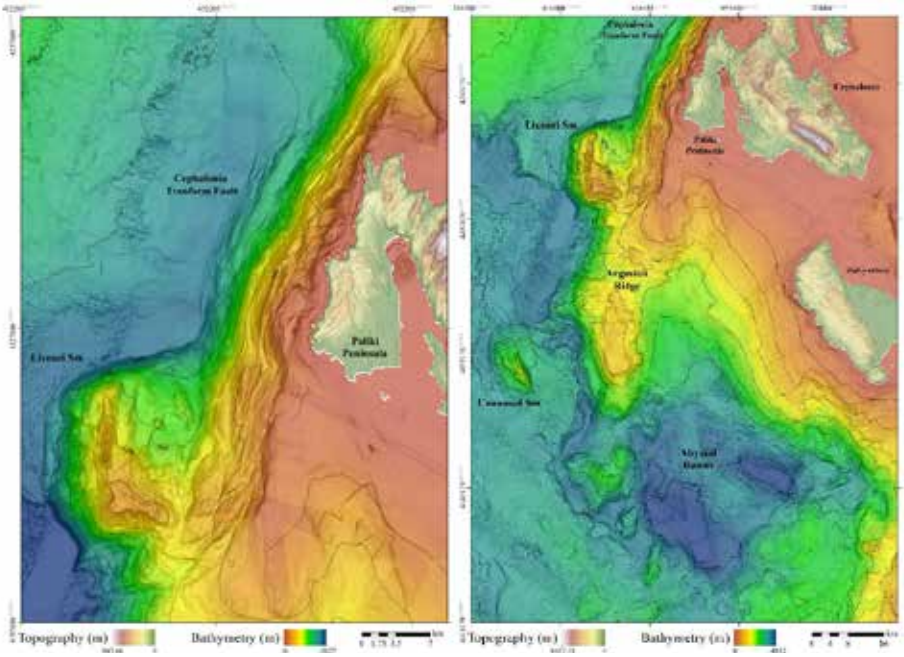

Figure 3. The Cephalonia Transform Fault and the Lixouri Seamount (left) and the SW Cephalonia and Zakynthos area (right)

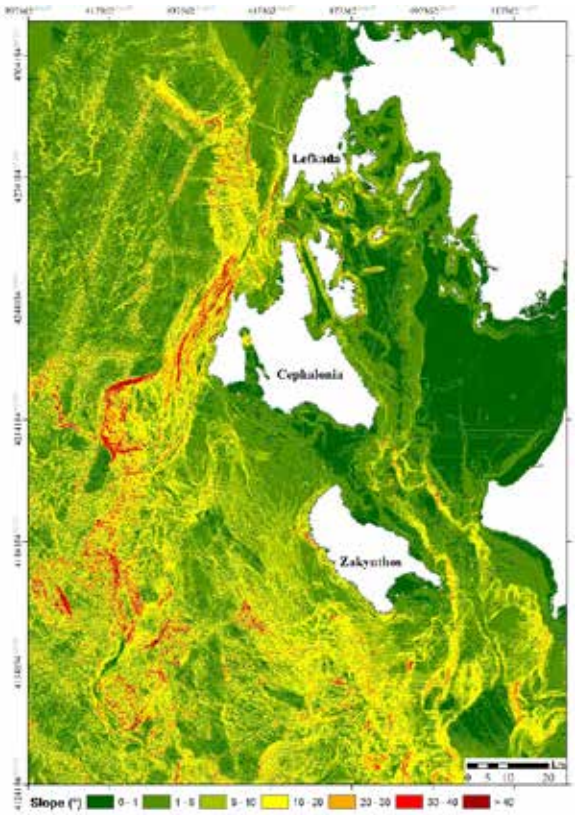

Figure 4. Morphological slope map of the Ionian Sea

Introduction

Heavy metals in indoor environments have raised growing concern due to their potential adverse health effects, especially in residential settings where individuals, including vulnerable populations such as children and the elderly, spend a significant amount of time (Cheng et al., 2018). Among various indoor substrates, house dust serves as a significant reservoir for heavy metal contamination, often reflecting the combined influence of outdoor pollution, household activities, and the use of materials containing toxic metals. These metals, including lead (Pb), cadmium (Cd), arsenic (As), and chromium (Cr), can be introduced into indoor spaces through numerous pathways, such as outdoor air deposition, contaminated building materials, household products, and the wear and tear of everyday items (Isley et al., 2021).

The presence of these toxic elements in house dust poses serious health risks, with evidence linking exposure to neurological, respiratory, and developmental disorders, particularly in children. Furthermore, long-term exposure to even low concentrations of heavy metals can contribute to chronic health conditions, including cancer, kidney damage, and cardiovascular diseases (Thomas et al., 2009). The variability in the distribution and concentration of heavy metals across different homes highlights the complex interplay between environmental factors, socio-economic status, and lifestyle choices, making the study of house dust as a vector for heavy metal exposure a crucial area of research.

This study aims to explore the concentration of heavy metals in house dust from diverse residential settings in the city of Thessaloniki, with an emphasis on understanding the indoor environmental quality and promoting healthier living spaces.

Materials and Methods

A total of 10 house dust samples were collected from residences within the city of Thessaloniki (Fig1). An effort was made to ensure that the selected residences are uniformly distributed within the city. Sampling was performed during June 2024. House dust was collected by vacuuming repeatedly hard floor surfaces of all living spaces in the house. Vacuum bags were sealed, labeled and stored. Dust samples were sieved to 150 μm using a stainless-steel sieve and analyzed for seven (7) trace metals: arsenic (As), chromium (Cr), copper (Cu), manganese (Mn), nickel (Ni), lead (Pb) and zinc (Zn) as they are known to occur in potentially toxic concentrations in residential environments and to allow comparison with other international dust studies (Isley et al., 2021). Trace metal concentrations were determined via pXRF. A Bruker S1 Titan 600 with a 4 W Rh X-ray tube, 5 mm spot size, a silicon drift detector (resolution < 145 eV), and the inbuilt Geoexploration mode, a factory calibration method for soils, was applied for pXRF analysis. The analysis was conducted in three energy ranges (15, 30 and 50 kV) for 30 s each (a total of 90 s). The elemental contents calculated with the Geoexploration mode were calibrated using certified reference materials (CRMs); calibration curves with R^2 values higher than 0.9 were obtained.

Results and Discussion

The summary statistics of heavy metals in house dusts are given in Table 1 and graphically shown in Figure 2. Heavy metals in house dusts exhibited ranges as: 4 to 11 mg kg^{-1} for As, 106 to 279 mg kg^{-1} for Cr, 62 to 614 mg kg^{-1} for Cu, 263 to 544 mg kg^{-1} for Mn, 23 to 160 mg kg^{-1} for Ni, 22 to 77 mg kg^{-1} for Pb and 339 to 885 mg kg^{-1} for Zn. The median concentration values are following a descending order as: Zn > Mn > Cr > Cu > Ni > Pb > As in line with previous studies (Kelepertzis et al., 2020). In particular, sampled house dusts exhibited higher contents in Zn (650 mg kg^{-1}) followed by Mn (384 mg kg^{-1}), Cr (179 mg kg^{-1}) and Cu (166 mg kg^{-1}), while As presented the lowest concentrations (9 mg kg^{-1}).

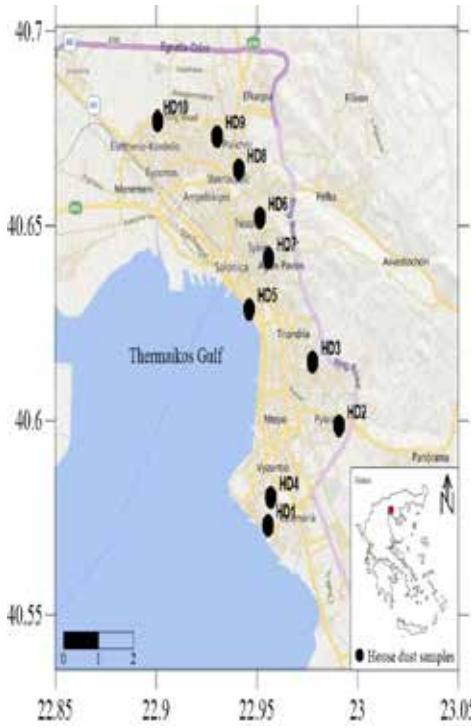

Figure 1. Map of house dust sampling sites in the city of Thessaloniki, N. Greece.

Compared to global crustal values (Isley et al., 2021), most of the elements (except Mn and Ni) are presented moderately to significantly enriched in house dust samples (Fig. 2). Specifically, enrichment ranges of 1-2.6 for As, 1.5-4.0 for Cr, 1.6-15.7 for Cu, 0.7-1.5 for Mn, 0.4-2.9 fon Ni, 1.3-4.5 for Pb and 5.1-13.2 for Zn, were estimated. On the contrary, heavy metal levels (except Cr and Mn) are relatively lower (Fig. 2) than those reported for a dataset of 2265 vacuum dust samples from 35 countries (Isley et al., 2021).

Table 1. Summary statistics of heavy metal contents (mg kg^{-1}) in house dust samples. Background crustal values and international vacuum dust values are also given.

Element	Indoor house dusts (n=10)					Upper Continental Crust [2]	Global Crustal Values[3]	International Vacuum Dust Values[4]
	Mean	SD[1]	Median	Minimum	Maximum			
As	8	3	9	4	11	4.8	4.2	25
Cr	185	49	179	106	279	92	69	128
Cu	204	158	166	62	614	28	39	264
Mn	392	92	384	263	544	1000	363	333
Ni	66	43	50	23	160	47	55	78
Pb	51	21	52	22	77	17	17	224
Zn	623	197	650	339	885	67	67	1470

1: standard deviation, 2: Rudnick & Gao, 2004, 3: Isley et al., 2021, 4: average values from 35 countries (Isley et al., 2021)

Although a direct comparison of heavy metal contents is difficult due to the different sampling protocols, analytical procedures and examined dust fractions, the obtained elemental contents were compared with reported values worldwide (Table 2). As shown, heavy metal contents were relatively higher than those reported for residences from Turkey, Croatia or Ghana; however the sampled house dusts are relatively enriched in Cr and Mn compared to other Greek cities such as Athens (Kelepertzis et al., 2019). Moreover, sampled residential environments display elevated Cr, Mn and Ni contents compared to data from an international vacuum dust analysis program including values from 35 countries worldwide (Isley et al., 2021). Specifically, median Cr levels of 179 mg kg^{-1} were recorded, in contrast to 86 mg kg^{-1} exported from a dataset of 2265 samples from 35 countries. Though Cr sources mainly reflect natural inputs from ultramafic rocks and soils, anthropogenic or industrial inputs cannot be excluded.

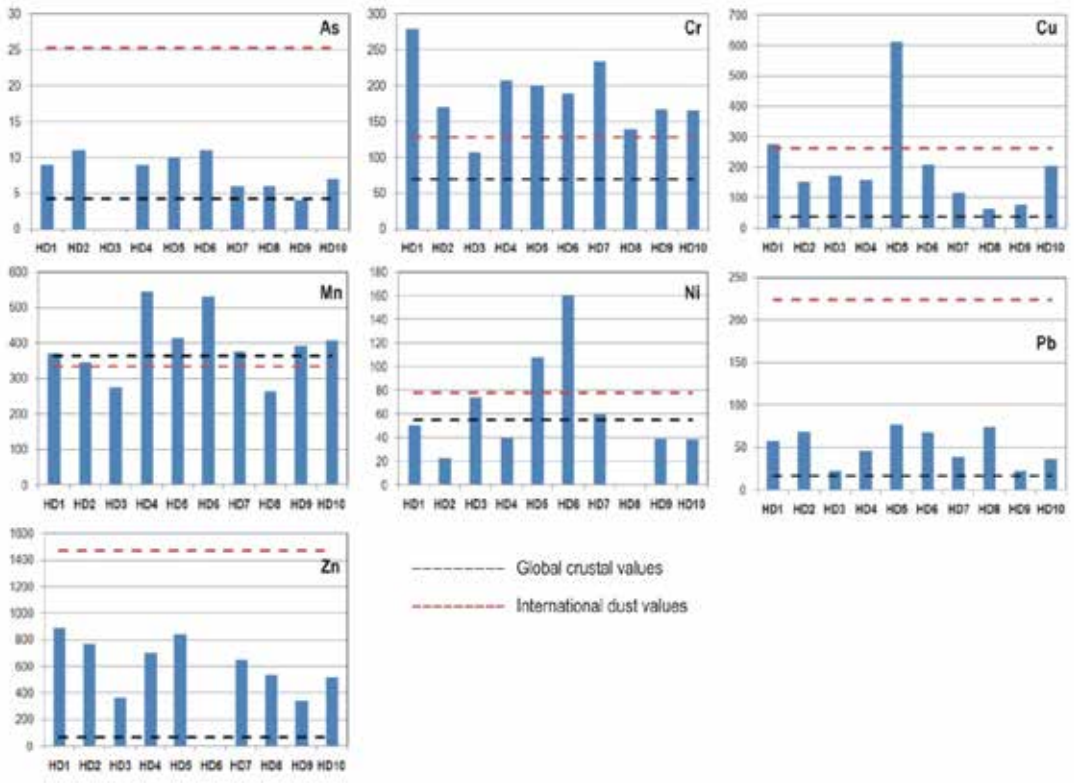

Figure 2. Heavy metal contents (mg kg^{-1}) in house dust samples. Global crustal elemental concentrations (black dashed line, data in Table 1) and international dust values (red dashed line, data in Table 1).

Table 2. Bibliographic data of median heavy metal contents in indoor dust from previous studies.

To decipher the influence of anthropogenic activities on indoor dust concentrations, Enrichment Factors (EFs) were calculated for As, Cr, Cu, Ni, Pb, and Zn by normalizing vacuum dust trace metal ratios to ratios from global crustal values selected from relevant crustal assessments in the literature and the results are illustrated in Figure 3. The EF was calculated using the following equation:

$$EF = \left(\frac{C_n}{C_{ref}}\right)_{sample} / \left(\frac{B_n}{B_{ref}}\right)_{background}$$

where $(C_n/C_{ref})_{sample}$ and $(B_n/B_{ref})_{background}$ refer to the concentration ratios of a target metal and the reference metal in the house dust samples and the background material, respectively (Yuen et al. 2012). In this study, aluminum (Al)

was taken as a normalization factor and concentrations of elements in the upper crust (Rudnick and Gao, 2004) were taken as background values.

An enrichment factor (EF) less than 2 indicates natural conditions, while EFs larger than 2 suggest anthropogenic influence (Isley et al., 2021). Overall, enrichment of Zn was the greatest, followed by Cu > Pb > Cr > As. Zinc and copper returned values EF > 2 in all sampled house dusts, while EFs for As, Cr and Pb were above 2 in more than 80% of the sampled residences. Specifically, the median EF values of Zn (13.7), Cu (8.8), Pb (4.3), Cr (3.1) and As (2.4) were higher than 2, implying that these heavy metals in house dusts are related to anthropogenic activities (Kelepertzis et al., 2020). For instance, pigments of the wall paints are an important source of heavy metals in household dust (Chattopadhyay et al., 2003). On the contrary, the median EFs for Ni (1.5) and Mn (0.6) indicate a minimal enrichment, which therefore, is linked to the lithogenic component of the house dust mainly inherited from the outdoor soil. However, Ni moderate enrichment in 40% of the sampled residences (maximum values of 4) cannot exclude an anthropogenic input. Moreover, EF values did not exhibit great variability among sampled house dusts suggesting the absence of local anthropogenic activities adjacent to the sampled residential environments. However, residences close to city center presented significantly higher EF values reflecting possible outdoor input from adjacent roadside environments as enhanced heavy metal contents in road dusts have already been reported (Bourliva et al., 2018).

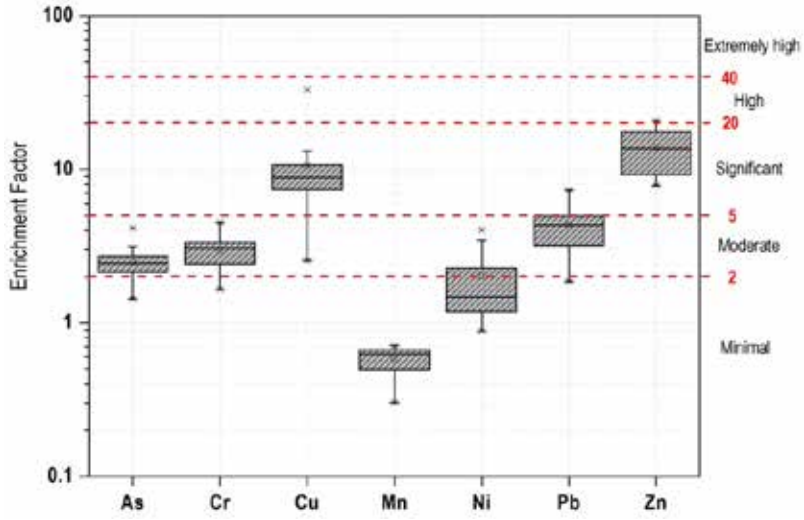

Figure 3. Box plots of enrichment factor (EF) calculations for the assessed trace metals in house dusts, normalized against the reference element Al. Red dashed lines indicate the level of enrichment.

Conclusions

People spend increasing amount of time at home, yet household environments remain understudied. The present study investigated the heavy metal contents in house dust samples from 10 residences within the city of Thessaloniki. Concentration values exhibited a descending order as: Zn > Mn > Cr > Cu > Ni > Pb > As, while concentration levels of these elements were high when compared with those from countries such as Turkey and Croatia. Moreover, the concentrations of As, Cu, Pb and Zn are lower than that of a global vacuum dust dataset. However, Cr levels were relatively higher than those reported from other countries or areas. Values of EFs larger than 2 suggested anthropogenic inputs (except of Ni and Mn), while higher EF values in residences close to city center suggest vehicular traffic as a factor contributing to the rise of heavy metal levels in household environments. Thus, distance to city center could be suggested as an important consideration for the choice of housing.

EXTENDED ABSTRACT 166

New *Clypeaster* fossils from South Crete (Rodakino, Rethymno)

Kotsomitopoulou A.[1], Tsaparas N.[1], Galazoudi E.[1]

(1) National and Kapodistrian University of Athens, Athens, Greece, artemiskots@gmail.com

Introduction

The study area is located near the village of Rodakino in the southwestern part of the Rethymno prefecture (Crete). In this region, the marine Neogene deposits overly the Phyllite-Quartzite unit, which structure the wider area.

The Neogene deposits of Crete are extensive covering a large part of the island. Many researchers have described them throughout the years, classifying them into four lithostratigraphic units ranging from Upper Tortonian to Lower Pleistocene. From oldest to youngest these units are: Tefeli Group (conglomerates and coarse-grained sands to claystone and siltstone with turbidites), Vrysses Group (white marls, calcarenites and bio-calcarenites of Tortonian-Messinian age), Foinikia Group (marls and marly silts of lower Pleistocene age) and Agia Galini Group (conglomerates and coarse-grained sands of lower-middle Pleistocene age) (van Hinsbergen & Meulenkamp, 2006; Tortorici et al., 2010).

The fossiliferous section is 20 meters thick and consists of fine marly sandstones alternating with blue marls. In detail, from the bottom of the section and for 5 meters, thick layers of marly sandstones (~ 70cm) alternate with very thin layers (~5cm), while towards the top, the marly layers are thicker (~ 20 cm). The studied sea urchins were found in the marly sandstones from the first 5m of the outcrop.

Objectives

The purpose of this paper is to present findings from a new fossiliferous site in Crete with echinoids of the genus *Clypeaster*, a taxon now extinct from the Mediterranean. Additionally, data about the age of the studied site were based on calcareous nannoplankton.

Materials and methods

Samples and data collected during the area's mapping were used to create the stratigraphical section. The *Clypeaster* species were identified according to Marcopoulou-Diakantoni (1985), by measuring length (l), width (L), height (h), ratio width-length (L/l) and ratio height-width (h/L).

The material was transported to the Laboratory of Historical Geology and Biogeosciences (Department of Geology and Geoenvironment, National and Kapodistrian University of Athens), where it was cleaned and, when necessary, reconstructed to restore its original shape in cases of fracturing.

A preliminary investigation was conducted on the age of the section based on calcareous nannofossils, but it needs further and more detailed analysis. The sample preparation for the study of calcareous nannoplankton followed standard smear slide techniques. The slides were analyzed using a polarising light microscope LEICA DMLP at 1,250×..

Results

Five different *Clypeaster* species were determined: *Clypeaster altus, C. calabrus, C. campalanatus f. portentosus, C. tauriqus, and C. altostratus*. Several of the specimens could not identified in species level as they were not well preserved. The descriptions of the species presented herein were created according to Markopoulou-Diakantoni (1985), Kroh (2005) and Tsaparas (2005).

Classification

Phylum: Echinodermata KLEIN 1734
Subphylum: Echinozoa HECKEL in ZITTEL, 1895
Class: Echinoidea LESKE, 1778
Subclass: Euechinoidea BRONN, 1860
Superorder: Gnathostomata ZITTEL, 1879
Order: Clypeasteroida A. AGASSIZ, 1873
Suborder: Clypeasterina A. AGASSIZ, 1872
Family: Clypeasteridae L. AGASSIZ, 1835
Genus: Clypeaster LAMARCK, 1801

***Clypeaster campanulatus f. portentosus* MICHELIN, 1861**

(Figure 1.a, b)

Large size species with long pentagonal shape. It has slightly curved edges and very distinct surface ridging and it's characterized by a very elevated petal area, which gives the animal the shape of a bell. The sides are very inclined and not well developed, while the petals are curved and slightly open. Its underside is particularly flat.

***Clypeaster altus* KLEIN, 1734**
(Figure 1.c)
Pentagonal symmetry, elongated, angular on the front and almost straight on the back. Its upper side is erect, the upper surface is relatively high, erect, hypoconical and thick on the sides. Sides very poorly developed and oblique like petals, with their edges rounded and thick. The lower surface is smooth and has prominent peripatetic grooves. The upper side sports a madreporite with ten pores. Ambulacral zones are protruding and petal shaped, with their sides open.

***Clypeaster calabrus* SEGUENZA, 1880**
(Figure 1.d)
Medium to large sized, elongated with pentagonal shape. Its front side is blunt and pointed and its back side is transversely truncated, with well-defined recess and a margin that gets thinner from the front to the back side. The margin of the test is rounded off.

***Clypeaster tauricus* DESOR, 1859**
(Figure 1.e)
Medium height, with its test size pentagonal, elongated and angular, with the 5 points rounded off. The ambulacral zones are petal like in shape, long, protruding, wide open and form a bulge when they come to the side. The lower surface is smooth, the peristome is not well developed while the peripectorium is small and circular.

***Clypeaster alticostatus* MICHELIN 1861**
(Figure 1.f)
Large sized species, with its upper surface very elevated and conical and the madreporite plate submerged. Its sides are underdeveloped, thick and curved, and less extended. The periphery is slightly elongated and the ambulacral zones are petal and almost lance like. The test margin is thin and slightly angular.

Table 1. Measurements of the *Clypeaster* species

Species	Length (l)	Width (L)	Height (h)	L/l	h/l
C. campanulatus f. portentonsus	228	181	96	0.79	0.42
C. altus	152	135	64	0.88	0.42
C. calabrus	158	134	72	0.86	0.45
C. tauricus	189	151	70	0.80	0.37
C. alticostatus	165	142	68	0.86	0.41

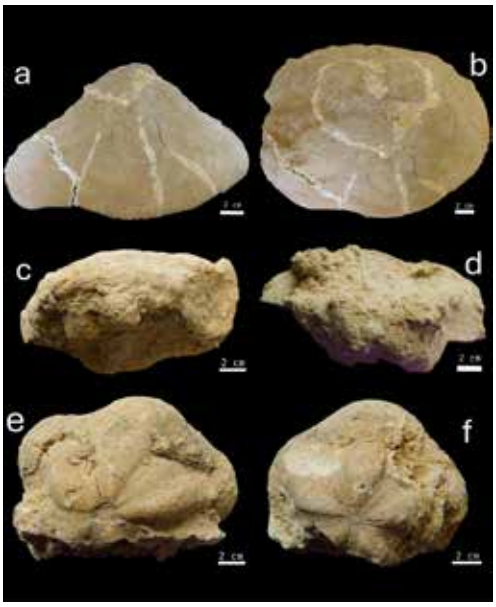

Figure 1. ***a, b. Clypeaster campanulatus* f. *portentosus*. C: Clypeaster altus d. Clypeaster calabrus. E. Clypeaster tauricus. F. Clypeaster alticostatus***

Several specimens of the large benthic foraminifera *Heterostegina* were found on the echinoids (Figure 2) and in the sediment that was collected after cleaning the specimens. This large benthic calcareous foraminifer is a circum-tropical nummulitid foraminifer with photosymbionts, which prefers forereef environments (Boudagher-Fadel, 2008; Benedetti *et al*., 2017).

The micropaleontological analysis for calcareous nannoplankton (Young *et al*., 2022) of the sediment from the interior of a sea urchin determined two species of the genus *Discoaster* : *Discoaster variabilis* MARTINI AND BRAMLETTE, 1963 and *Discoaster exilis* MARTINI AND BRAMLETTE, 1963 (Figure 3).

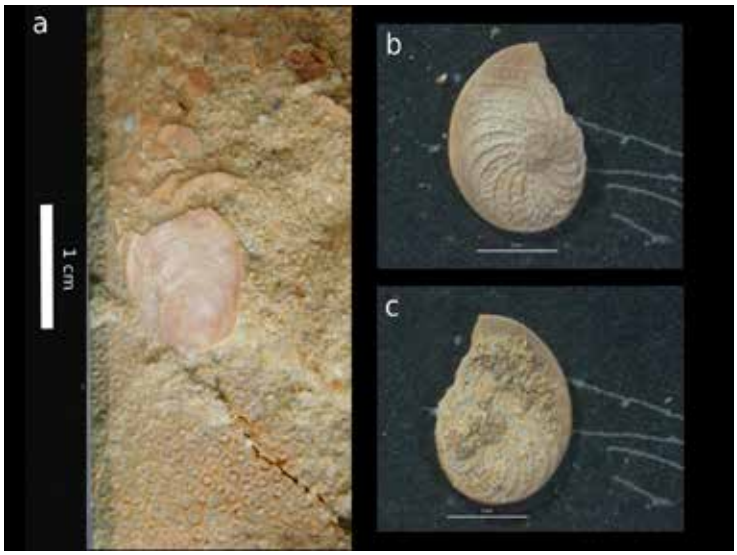

Figure 2. *Heterostegina* members found on the echinoids

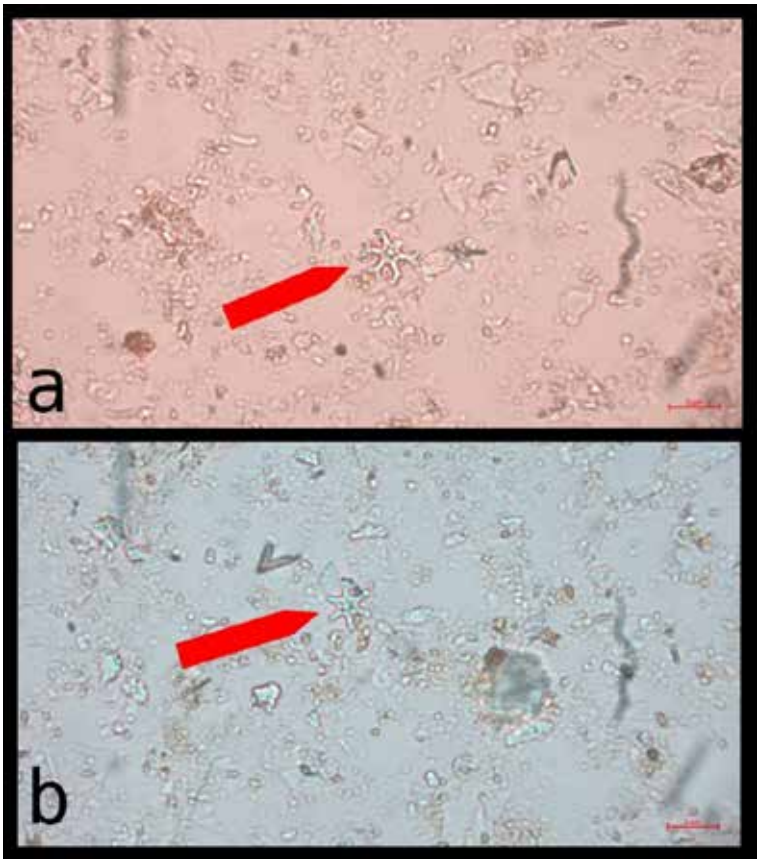

Figure 3. a. *Discoaster variabilis.* b. *Discoaster exilis*

Conclusions

After measurements were made, the following *Clypeaster* species were determined*: C. altus, C. calabrus, C. campalanatus f. portentonsus, C. tauriqus, C. alticostatus*. Based on the presence of *Discoaster variabilis* and *Discoaster exilis* individuals that were found in the sediment, their age was identified as Middle Tortonian (NN9-NN10). Further study on calcareous nannoplankton will determine the age. The environmental conditions inferred from the presence of *Heterostegina*, which coexisted with the sea urchins, suggest a shallow, warm marine environment, similar to that of Gavdos, where comparable findings had been reported.

Acknowledgements

We would like to thank Mr. Nils Sappok for his kind gesture to provide us with the large, complete specimen of *Clypeaster* for our study and for indicating the location where he found it. This enabled us to conduct extensive sampling, the results of which are presented in this paper.

EXTENDED ABSTRACT 167

Measurements of soil gas emissions (radon and thoron) in the municipality of occidental Lesbos, Stypsis – Petras, and correlation with tectonic structures (rift zone) of the subsidence coast of Petra

Koukoulis A.[1], Xenakis M.[1]
(1) H.S.G.M.E., Athens, Greece, akoukoulis@eagme.gr

Panoramic view of the measurement area.

Summary
In this work, a radiological, geological and tectonic approach is carried out, for the evaluation of radon-thorium soil, in two predetermined areas of Petra, which have been designed by PPC RENEWABLES S.M.S.A. for the needs of geothermal research conducted in the region. The objective of the HSGME service project was to identify the optimal pathways for radon increase in the soil and their possible connection to the mapped tectonic structures and the corresponding optimal geothermal fluid pathways in the research area.
The most important results of the work are that radon and thoron concentrations in the soil, which reach high levels of up to 57.448 and 10.357 Bq/cm3 respectively, are independent of the activity of local geological formations and are fed by deeper bottom horizons via fault zones. The spatial distribution of radon shows high concentrations with growths of about 200 to 400m on the ground, correlated with the corresponding tectonic structures.
From the shape and the particular characteristics of the distribution of soil gases (radon and thoron), the data so far change, and from the lines of the mapped tectonic structures, we have the identification of rift zones, with optimal circulation of soil gases and possibly also of geothermal fluids.

Methodology-Measures

In situ measurements (N=435) were performed at predetermined positions of a 400m orthocanonical cell grid, with some thickening in the center of the squares and at the 200m edge vertices, which cover the entire area of the research field with a total of 87 situations (Fig. 1).

For each location, underground air is pumped to a depth of about 50cm, and radon and thoron are measured on site using an automatic semi conductor detector (RTM-1688-2, Sarad), for an average time of about 45 minutes. At the same time, with the help of special detectors (Camberra smart probes), the variation of activity on the ground surface, three radiological parameters is recorded (Fig. 2) :

(a) total contamination of α-β-γ radiation, by the Radiagem 2000 instrument and the SABG 15 probe

b) the equivalent dose rate when detecting a gamma photon flux by the Radiagem 2000 instrument and the external 2΄X2΄ SG-2R gamma probe

c) total γ radiation, by scintillation meter SPP2 (Saphymo-Stel).

The measurements of these quantities (Table 1) give a satisfactory consistency of the arguments in favour of the activity of the radiation emitted by the ground in the field of research, and above all make it possible to assess the origin of the high concentrations of radon in the soil, since it is known that among the factors that influence it are geology, geotectonic, radiology, geothermal field, etc., with which an investigation is attempted.

Discussion of the results

In the study area, radon-thoron increases are independent of the type of volcano and the primary or secondary stages of volcanism (Fig. 3, 4), which have a high radiological background, several times higher than that of other regions of the country (Table 1, Fig. 5, 6). However, there is no direct relationship between radon-thoron and volcanism, which is essentially identical (Fig. 2, Fig. 9. 10, 11) to the upper unit of lavas of Hehct 1974, or to that of the subalkaline potassic series (shoshonites) as identified by G. Piper 1992, and which is more uranium-rich and potassic, with accessory minerals responsible for uranium concentrations, selective aggregation of thorite-titanite-allanite-zirconium-apatite (Koukoulis A. et al., IGME, 2001).

A few kilometers from the Stypsi geothermal field, there are high concentrations of radon and thoron in the ground, with small isolated developments (about 200-400m on the ground), which are located both in the research field and its extension, which requires further research (Fig. 7, 8).

On the descending side of the Avlaki and Petra faults, maximum radon values were recorded in the upper unit of lavas (53.522Bq/cm3) and in the alluvial deposits (48.015Bq/cm3), which structure individual soil extenctions (about 200-400m), at the boundaries of the research field, suggesting a possible expansion beyond these.

On these margins and approximately above the Petra ring road, private and municipal water supply and irrigation wells have been recorded, with high temperatures (25-45°C), at depths of a few tens of meters, which is considered particularly encouraging for further research.

In the field of research, the individual high concentrations of radon, with a growth of more than about 600m, have a NE-SW direction, which is affected by deep long-range faults, which form the important sunkens of the island.

This development of high radon concentrations seems to have been dismembered towards the SW, under the influence of the more frequent and later NW-SE faults. In the fragment descending echelon to SW of the NW-SE faults, the highest radon concentrations in the research field were recorded (45.175 and 55.578 Bq/cm3), with NW direction and a development greater than 400m in the upper unit of lavas.

Further research is also needed in the north-western extension of the search area, in which the high concentrations of thoron appear (maximum value 10.357 Bq/m3), with a NW-SE direction of about 200m on the ground.

International Ocean Discovery Program Expedition 398 'Hellenic-Arc-Volcanic-Field' took place in the Christiana-Santorini-Kolumbo Volcanic-Field (CSKVF) in the central Hellenic Volcanic Arc. The CSKVF is one of the most hazardous volcano-tectonic regions in the world, as the volcano has produced many and highly explosive eruptions in the past and could be of a threat for at least eastern Mediterranean (Druitt *et al.*, 1999; Nomikou *et al.*, 2013, 2019). This volcanic field produced the notorious Late Bronze age Minoan eruption that is considered to have contributed to the fall of an entire civilization (Bruins et al., 2008). The overall objectives of the expedition were to investigate the links and feedbacks between volcanism/magmatism, crustal tectonics and sea level, to groundtruth the seismic stratigraphy of the Santorini caldera, to reconstruct the subsidence history of the southern Aegean Sea and to search for deep life inside and outside of Santorini caldera (Druitt *et al.*, 2022).

IODP Expedition 398 was conducted with the R/V JOIDES Resolution, from 11 December 2022 to 10 February 2023. During the expedition despite the very challenging drilling conditions, twelve sites were drilled, for a total of 7345 meter in 28 holes, retrieving 780 cores with a total recovery of 3356 meters (Druitt *et al.*, 2024b; Figure 1). Outside of Santorini caldera, drilling penetrated the thick basin fills of the crustal rift system hosting the CSKVF, and identified more than 1000 tephra layers, some known from onland and others formerly unknown. The seismic stratigraphy was groundtruthed (Preine *et al.*, 2024), detailed age-depth constraints were provided mainly by biostratigraphy. Drilling penetrated the Alpine basement and ancient life DNA was recovered, proving that most of the volcano-tectonic history of the CSK field, as the volcano-sedimentary sequences, lies under the sea.

One of the first results, constrained by a multidisciplinary approach and highlighting the hazards of submarine explosive eruptions, includes the discovery of a giant rhyolitic pumice, the Archaeos Tuff, as the result of a shallow marine eruption of ancestral Santorini Volcano (Druitt *et al.*, 2024a). The Archaeos Tuff was emplaced during the Middle Pleistocene at water depths of 200 to 1000 m, as suggested by foraminiferal and calcareous nannoplankton biostratigraphic markers and benthic foraminiferal paleodepth indicators. It formed a 90 km^3 volcaniclastic megaturbidite up to 150m thick in the marine basins (Druitt *et al.*, 2024a), six times bigger than the pyroclastic current deposit from the Minoan eruption (~15 km^3; Karstens *et al.*, 2023).

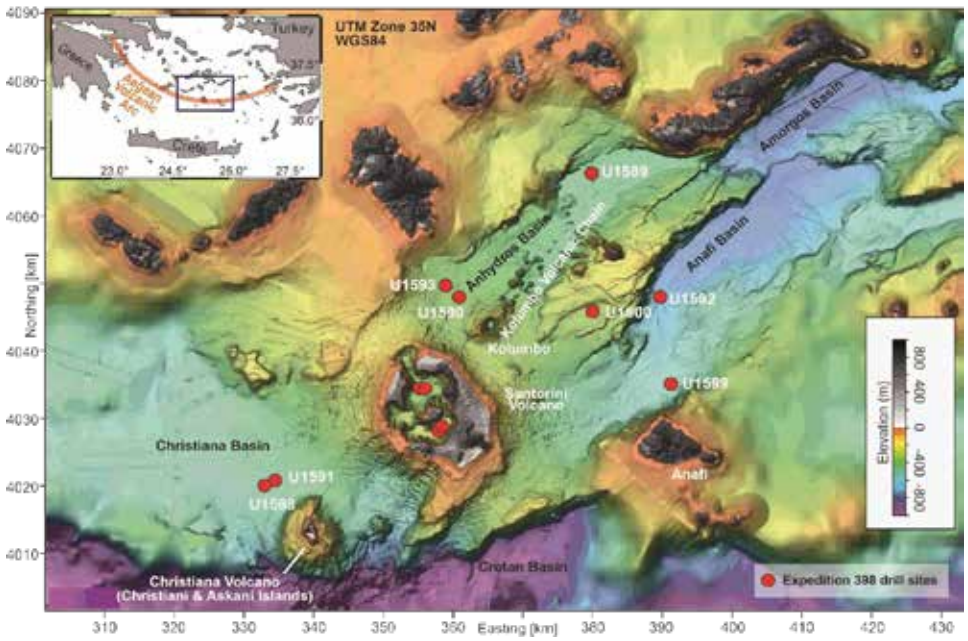

Figure 1. The IODP Expedition 398 drill sites (modified by Druitt *et al.*, 2024a).

These kind of large explosive volcanic eruptions from island arcs pour pyroclastic currents into marine basins, causing high plumes of ash, earthquakes and associated tsunamis and severely affecting coastal communities and infrastructures. Marine ecosystems are particularly vulnerable to eruptions and their consequences (ocean acidification, fertilization, debris flows, increased temperatures, ash falls) leading to diversity changes and even biodiversity loss (e.g., Finger and Lipps, 1981; Hart *et al.*, 2022). The effects in foraminiferal microfauna of such extreme events, as volcanic eruptions, were investigated in the sediments deposited prior and after the emplacement of Archaeos Tuff.

The exact intervals before, during and after this pyroclastic flow (for interval details on the Archaeos Tuff see Druitt *et al.*, 2024a) were studied in six cores along the different basins, and here we present our preliminary results on its impacts on foraminiferal community structure. During deposition of the submarine pumice, benthic foraminifera species were severely affected both in terms of density and diversity, with survivor infaunal species, shelf species and damaged specimens likely representing downslope reworking. Some samples were barren even from accompanying ostracods, molluscs and pteropods, while planktonic foraminifera were also rarely present. Following deposition of the pumice, the foraminiferal repopulation took place, with high numbers and diversity values, suggesting the recovery of the stressed environment and the restoration of the oligotrophic and well-oxygenated conditions.

Our findings highlight the foraminiferal fauna ability to tolerate major catastrophic events in their environment and to recover and recolonize, which is both admirable and extremely useful as a tool to interpret biostratigraphic correlations and paleoenvironmental conditions.

Acknowledgements

We are thankful to the International Ocean Discovery Program (IODP), the technical staff of the JOIDES Resolution, and all of the shipboard personnel for a great expedition. We also thank the member organizations of IODP for financial aid, and the Municipality of Thera for help in preparing for the expedition.

EXTENDED ABSTRACT 169

Late Quaternary dynamics of paleoenvironments and ecosystems in the Gulf of Corinth (eastern Mediterranean): IODP Expedition 381

Koukousioura O.[1,2], Panagiotopoulos K.,[1,3], Fatourou E.[4], Kafetzidou A.[4], Diz P.[5], Kouli K.[4], Grunert P.[1]

(1) University of Cologne, Cologne, Germany (2) Aristotle University of Thessaloniki, Thessaloniki, Greece, okoukous@geo.auth.gr (3) Forschungszentrum Jülich, Jülich, Germany (4) National and Kapodistrian University of Athens, Athens, Greece (5) Universidade de Vigo, Vigo, Spain

Abundance and assemblage composition of benthic foraminifera, dinoflagellate cysts and pollen grains were analysed together with sedimentological (grain size) and geochemical (organic and inorganic carbon content, XRF, benthic foraminifera oxygen and carbon isotopes) proxies to investigate paleoenvironmental changes recorded in the Gulf of Corinth during MIS 1-5, from IODP Expedition 381 core M0080. The Gulf of Corinth is a relatively young (<5 Ma) and active continental rift zone in the eastern Mediterranean Sea, with a length of about 120 km (McNeil *et al.*, 2019a and references therein; Gawthrope et al., 2022). The Gulf is currently connected to the Ionian Sea through a shallow sill (Rion sill; 60 m-deep) and to the Aegean Sea via the Corinth Canal (Isthmus; 6 km-wide). The eastern part is divided by the Perachora Peninsula into the Lecheon Gulf in the south, and the Alkyonides Gulf in the north, a shallow semi-enclosed sub-basin within the northeastern part of the Gulf of Corinth, where core M0080 is located (Fig. 1; McNeil et al., 2019b). The closed drainage system and the high sedimentation rates (approx. 0.5-3 mm/yr; McNeil et al., 2019a) make the study area a natural laboratory for the investigation of the complex interaction between sedimentary input, tectonics and climate through the basin's evolution.

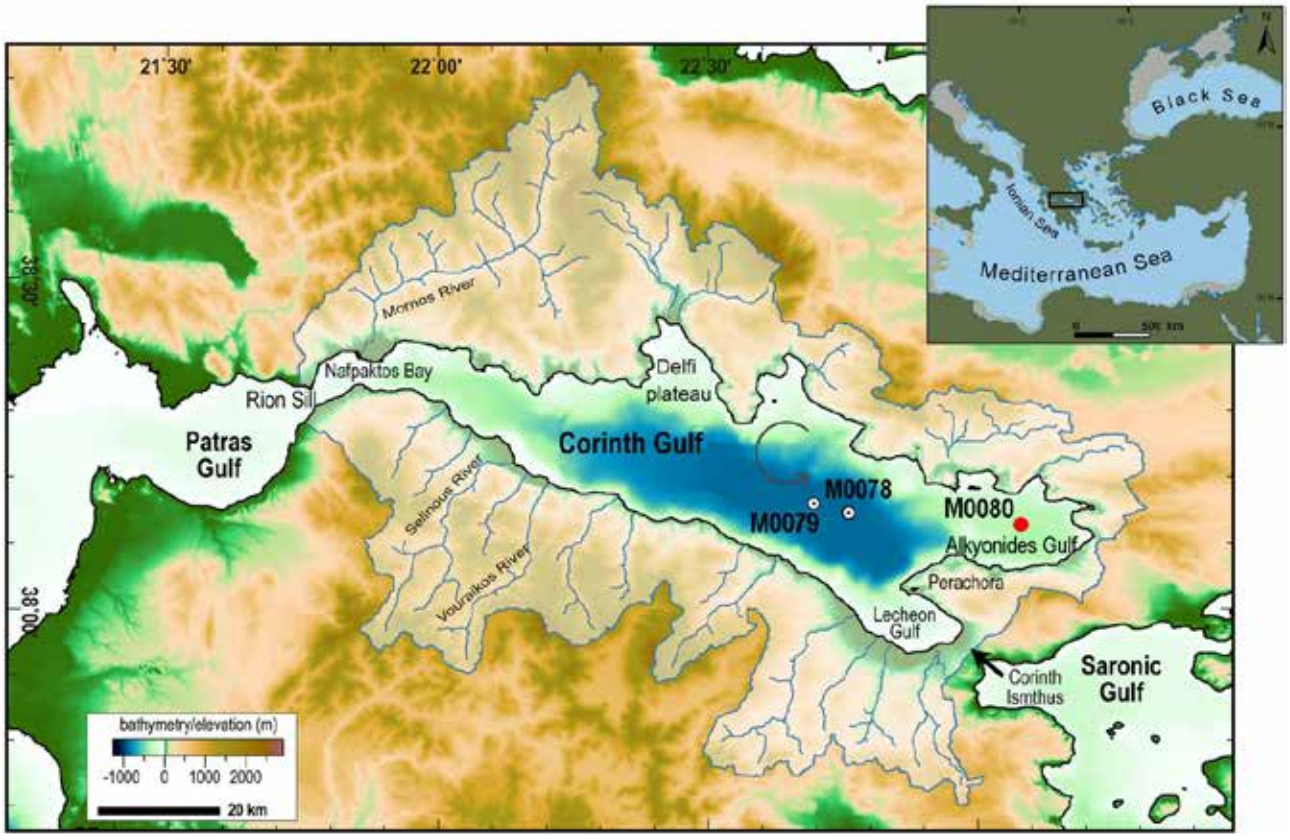

Figure 1. The IODP Expedition 381 drill sites with the location of M0080 indicated by the red dot (modified from Fatourou *et al.*, 2023 and Kafetzidou *et al.*, 2023).

The benthic foraminiferal, dinocyst and pollen records are highly variable during both the Last Interglacial complex and the Holocene. Infaunal foraminiferal species characterize these assemblages with high abundances of *Bolivina* spp.,

Melonis affinis, *Bulimina* spp. and *Cassidulina carinata*, indicating mesotrophic to eutrophic marine conditions, with marine dinocysts (*Nemaosphaeropsis labyrinthus*, *Spinifireties ramosus*) and montane trees likely to have occurred during high sea-levels. During glacial and interstadial intervals, benthic foraminifers are very low in numbers or even absent, whereas abundant brackish dinocysts (*Pyxidinopsis psilata*) suggest a sea-level drop below sill level and the subsequent (semi-)isolation of the basin. Inorganic carbon content and elemental counts varied following the inferred sea-level fluctuations, while the benthic foraminifera oxygen isotope record is discontinuous and conditioned to the presence of well-preserved benthic foraminifera. The beginning of the Holocene is marked by the re-establishment of marine conditions as the sea-level rose above the sill and the basin re-connected to the Mediterranean Sea.
Ongoing high-resolution studies and a refinement of the age model will improve our understanding of paleoenvironmental changes in the Gulf of Corinth during glacial and interglacial stages and allow us to define the factors driving changes in this unique active rift of the eastern Mediterranean.

Introduction

Carbon Capture, Utilization, and Storage (CCUS) is critical for reducing CO_2 emissions from industry and energy generation, aligning with net-zero goals under the Paris Agreement (Koukouzas *et al.,* 2021). CCUS captures CO_2 for reuse or secure storage in geological formations, including saline aquifers and depleted fields, offering flexibility through enhanced recovery and mineralization (Koukouzas *et al.,* 2018, 2021, Tyrologou *et al.,* 2023). While cost remains a challenge, technological advancements and successful projects (e.g. Sleipner, Norway) highlight its potential for supporting the low-carbon transition (Tyrologou *et al.,* 2023).

The Horizon 2020-funded PilotSTRATEGY project advances CO_2 storage research in Southern and Eastern Europe, focusing on deep saline aquifers in five basins, including the Mesohellenic Trough (M.T.) in northern Greece (e.g. Ayala *et al.,* 2023, Berrezueta *et al.,* 2023, Tyrologou *et al.,* 2023, Ordóñez *et al.,* 2024). Geological modeling in the M.T. identified the Pentalofos and Eptachori Formations (Fms) as prime storage sites, with capacities of 1 Gt and 0.85 Gt, respectively (Koukouzas *et al.,* 2021). Petrophysical studies confirm low porosity and water permeability in specific sedimentary strata, designating sedimentary layers in the Eptachori, Pentalofos, and Tsotyli Fms as effective cap rocks for secure CO_2 storage (Tyrologou *et al.,* 2023). This publication presents preliminary findings on the geological characterization of sandstone formations in the M.T. using a multidisciplinary approach. Methods include thin section analysis under optical and SEM microscopy for grain and texture evaluation, XRD and XRF for mineralogical and chemical characterization, and automated image analysis for macro-porosity assessment.

Geological Setting

The Mesohellenic Trough (M.T.) is a Tertiary sedimentary basin along the suture zone between the Apulian platform and the Pelagonian nappe, marking the Hellenide orogenic belt boundary (Vamvaka *et al.,* 2006, Fig. 1a). Extending over 200 km in length and 40 km in width, it features five siliciclastic formations – Krania, Eptachori, Pentalofos, Tsotyli, and Ondria – deposited from the Late Eocene to the Middle Miocene in environments varying from fan-deltas to turbiditic sandstones, and deltaic sediments, reflecting a transition from marine to terrestrial settings (Vamvaka *et al.,* 2006). The asymmetrical syncline, with up to 4.5 km thick sediments near Grevena, reflects orogenic and extensional tectonics. Its evolution involves Eocene-Oligocene and Miocene faults and N-S extension linked to recent seismicity, shaping fault zones and river alignments (Tyrologou *et al.,* 2023).

Methods

Three sedimentary rock samples were selected for study, originating from the Tsotyli (sample Tsot-1; marly sandstone; Burdigalian; Lower Miocene), Eptachori (sample Ept-2; fine sandstone; Rupelian; Upper Oligocene), and Pentalofos (sample Pent-3; sandstone; Chattian-Aquitanian; Upper Oligocene-Lower Miocene) Fms of the M.T. (Figs 1b-g). Three thin-polished sections were prepared at the School of Geology, AUTH, and analyzed using a ZEISS Axioskop 40 polarizing microscope to examine mineral composition. SEM-EDS analysis was conducted with a JEOL JSM-IT500 equipped with an OXFORD INCA X-ACT system at Analytical Services Unit, CPERI, CERTH, under 20 kV accelerating voltage, 0.4 mA probe current, 20 s analysis time, and ~1 μm beam diameter in BSE mode. Elemental mapping revealed mineralogical variations, and pore characteristics were evaluated with representative photomicrographs. Automated image analysis (×200 magnification, BSE mode) was performed using ImageJ software (Schneider *et al.*, 2012).

X-ray diffractometry (XRD) was performed using a Bruker D8 Advance diffractometer with a CuKα anode (λ = 0.1542 nm) operating at 40 kV and 30 mA at the School of Geology, AUTH. The counting statistics of the XRD study were, step size: 0.019° 2θ, start angle: 3.000°, end angle: 93.009° and scan speed: 0.19° 2θ/s. Rietveld refinement

were implemented by using the Profex5 (v.5.2.7, Doebelin and Kleeberg, 2015) software acquiring semi-quantitative estimates on the abundance of the mineral phases and on the chemical composition of the analyzed samples.
X-ray fluorescence (XRF) analysis was conducted using a Bruker S4-PIONEER WDXRF system at the School of Geology, AUTH, to determine the geochemical composition of the samples. Equipped with a Rh lamp, five crystals, and dual detectors, the system operated at 50–60 kV, analyzing Ka and La lines for elements. Corrections for spectral overlaps and matrix effects ensured accuracy.

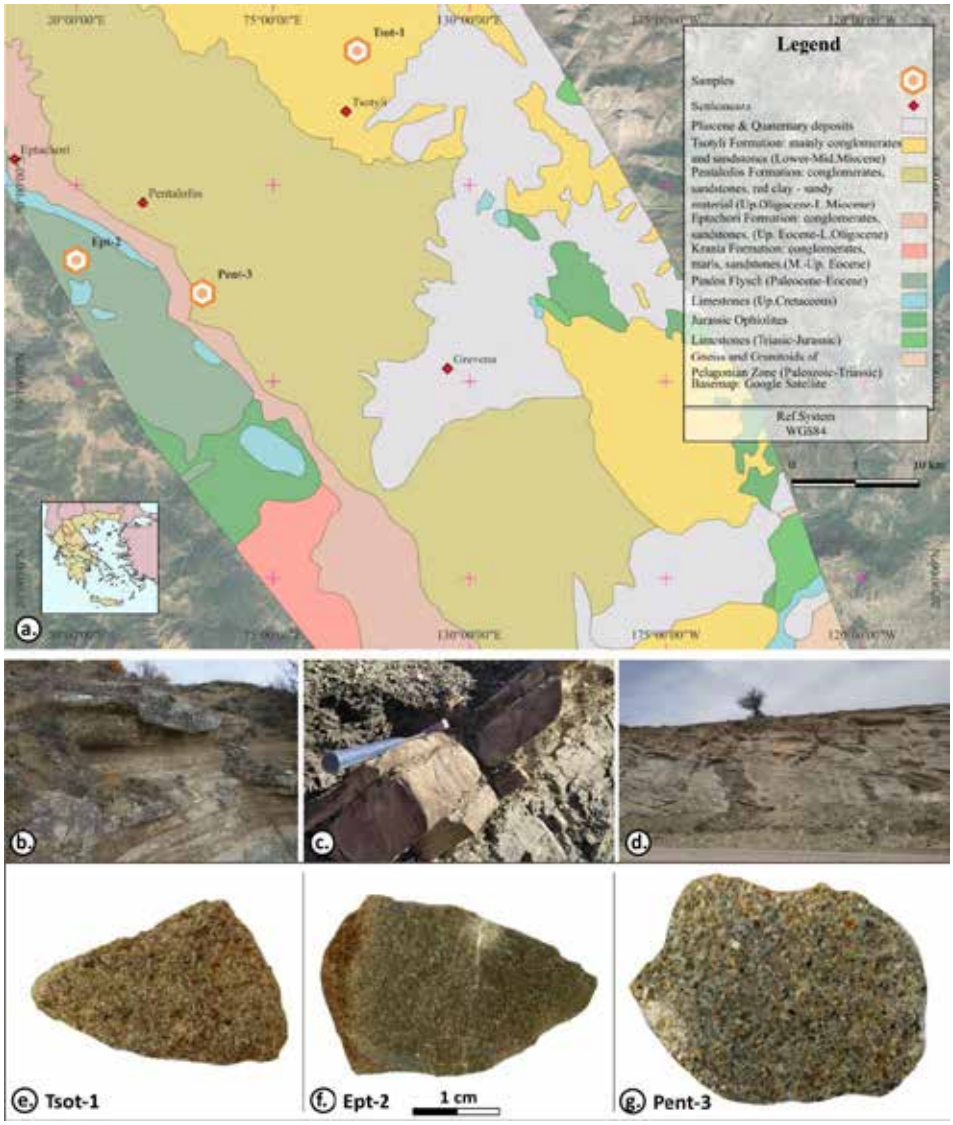

Figure 1. a. Geological map of the Mesohellenic Trough at Grevena region, showing the sampling locations of Tsot-1, Ept-2 and Pent-3 samples (modified after Savoyat & Monopolis, 1972, Bornovas & Rondogianni-Tsiambaou, 1983). b-d. Field photographs of the sampled outcrops (b: Tsot-1, c: Ept-2, Pent-3: d). d-f. Macro-photographs of the analyzed samples.

Results & Discussion

Field survey and macroscopic observations revealed that Tsot-1, Ept-2, and Pent-3 outcrops share similarities, including their light-colored sandstones, medium bedding (200 to 600 mm in thickness), and slightly weathered (Grade 1) tabular rock masses, and very strong material strength (100-250 MPa, Fig. 1b-d). However, they differ in texture, features, and bedding orientation: Tsot-1 lacks fossils, has a homogeneous marly texture, and bedding striking 322°/12°, Ept-2 exhibits burrows, plant fragments, Liesegang discoloration, and bedding striking 122°/33°, while Pent-3 shows alternating clast-rich and mudstone units with diverse compositions and bedding striking 128°/33°.

Optical microscopy and SEM-EDS analysis and petrographic examination of bulk samples and thin-polished sections from Tsot-1, Ept-2, and Pent-3 highlighted distinct mineralogical and compositional characteristics. In Tsot-1, the identified minerals include calcite (30 wt.%), quartz (29 wt.%), and albite (21 wt.%), minor muscovite, chlorite, dolomite and aragonite, as well as microcline, zircon and jacobsite in traces (Table 1, Figs 2a, 3a). The sample consists of well-cemented grains dominated in average by Si (52 wt.%) and Ca (24 wt.%), with additional Al (11 wt.%), K (11 wt.%), Fe (7.0 wt.%), Mg (4.0 wt.%), and Na (3.0 wt.%, Table 3). Macro-pores are rounded to irregular, averaging 45 μm in width, and the siliceous cement is locally crystalline, containing up to 9.9 wt.% Fe (Tables 2, 3). Sample Ept-2 includes quartz (37 wt.%), calcite (29 wt.%), albite (13 wt.%) and muscovite (13 wt.%), minor dolomite and chamosite, while as traces are found biotite, titanite, pyrite, crichtonite, actinolite and zircon (Table 1, Figs 2b, 3b). It is well-cemented, with a bulk composition dominated by Ca (<53 wt.%) and Si (≤26 wt.%), alongside Mg (<8.8 wt.%), Fe (<8.3 wt.%), and Al (3.7 wt.%, Table 3). The calcareous microcrystalline cement contains up to 41 wt.% Si and 18 wt.% Fe, with macro-pores averaging 66 μm and smaller pores at 11 μm (Tables 2, 3). In Pent-3, calcite (41 wt.%), dolomite (18 wt.%), quartz (15 wt.%), and albite (12 wt.%) are found, while minor minerals include microcline, muscovite and aragonite, with trace amounts of chlorite, titanite, chromite, pyrite, Fe-chromite, actinolite, apatite, andradite and enstatite (Table 1, Figs 2c, 3c). The sample displays the largest grains among the analyzed material, with grains occasionally exceeding 500 μm, with a dominantly calcareous composition (61 wt.%) and cement enriched in Mg and Si (Fig. 3c). Rare elongated macro-pores average 65 μm, while smaller pores within the cement average 6.0 μm.

Table 1. Sample identification numbers, localities (coordinates), main, minor and trace mineralogy. Abundances (%) of the main and minor mineral phases are given after the Rietveld refinement.

Sample	Coordinates WGS84 (Latitude/Longitude)	Main minerals	Minor minerals	Trace mineralogy	Qtz/ Fsp ratio
Tsot-1	N 40.3075°/ E 21.3354°	Cal: 30%, Qz: 29%, Ab: 21%	Ms: 7.2%, Chl: 7.1%, Dol: 4.5%, Arg: 1.4%,	Mc, Zrn, Jcb	1.4
Ept-2	N 40.1535°/ E 21.0824°	Qz: 37%, Cal: 29%, Ab: 13%, Ms: 13%,	Dol: 4.6%, Chm: 3.1%	Bt, Ttn, Py, Cic, Act, Zrn	2.9
Pent-3	N 40.1332°/ E 21.1997°	Cal: 41% , Dol: 18%, Qz: 15%, Ab: 12%	Mc: 8.0%, Ms: 4.3%, Arg: 2.6%	Chl, Ttn, Chr, Py, Fe-Chr, Act, Ap, Adr, En	0.8

Abbreviations: Ab = Albite, Act = actinolite, Adr = andradite, Ap = apatite, Arg = aragonite, Bt = biotite, Cal = calcite, Chl = chlorite, Chm = chamosite, Cic = crichtonite, Chr = chromite, Dol = dolomite, Fe-Chr = Iron-chromite, Fsp = feldspar, Mc = microcline, Ms = muscovite, Py = pyrite, Ttn = titanite, Qz = quartz, Zrn = zircon.

Relative abundances of quartz and feldspars (albite, microcline) were obtained by XRD analysis and plotted in the QFR (Quartz-Feldspar-Rock fragments) triangular classification diagram (McBride, 1963). The analyzed samples fall within the “Feldspathic litharenite” field, with Tsot-1 and Ept-2 clustering closely, while Pent-3 exhibits relative enrichment in lithic fragments (Fig. 2d). In addition, the mineralogical analysis conducted via XRD and Rietveld refinement, revealed that for sample Tsot-1 the quartz/feldspar (albite) ratio is 1.38 (Table 1), while Ca/Si ratio of 0.6 complements SEM-EDS results (Ca/Si = 0.5), indicating a consistent siliceous matrix (Table 3). Sample Ept-2 has a quartz/feldspar (albite) ratio of 2.9 (Table 1). Although SEM-EDS geochemistry highlights a Ca-enriched matrix (Ca ≤53 wt.%), the Rietveld refinement analysis revealed a siliceous chemical composition (25 wt.% Si) with a Ca/Si ratio of 0.5, underscoring the complex interplay between primary mineral inputs and diagenetic processes (Table 3). The quartz/feldspar (albite, microcline) ratio of 0.8 for sample Pent-3, reflects feldspathic contributions, while the Rietveld-derived Ca/Si ratio of 1.5 aligns with SEM-EDS findings (Ca/Si = 1.5), indicating a calcite-dominated cement matrix (Tables 1 & 3).

Bulk geochemical analysis applying XRF spectrometry reveals the compositional variability among samples Tsot-1, Ept-2, and Pent-3, with calcium and silica identified as the most enriched elements (Table 3). Sample Tsot-1 (25 wt.% SiO□) is slightly siliceous, Ept-2 (36 wt.% SiO□) is dominantly siliceous, and Pent-3 (42 wt.% CaO) is dominantly calcareous (Table 3). These findings align closely with the semi-quantitative mineralogical data derived from XRD and SEM-EDS analyses. In sample Tsot-1, the XRF results support the mineralogical profile established by XRD, where calcite (30 wt.%) and siliceous components, quartz (29 wt.%) and albite (19 wt.%), collectively constitute 50 wt.%, confirming its slightly siliceous composition. For Ept-2, XRF results indicating a dominantly siliceous composition (36 wt.% SiO□) are consistent with the XRD data, which identified quartz (37 wt.%) as the primary phase, followed by calcite (29 wt.%). Similarly, the calcareous dominance of Pent-3 (42 wt.% CaO by XRF) corroborates XRD findings, which showed calcite as the most abundant phase (41 wt.%). The XRF data also reveal insights into trace element distributions, particularly for Ept-2, which

exhibits the highest enrichment in minor elements, including Cr (1680 ppm) and V (990 ppm), alongside Co, Cu, Ni, and Zn (Table 3). These variations in trace element content are associated to minor mineral phases, such as chromite and pyrite, which were detected through the SEM-EDS analysis of the thin-polished sections (Table 1, Fig. 3c), and suggest a significant contribution of detrital material, likely derived from the erosion of ophiolitic basement rocks surrounding the Mesohellenic Trough.

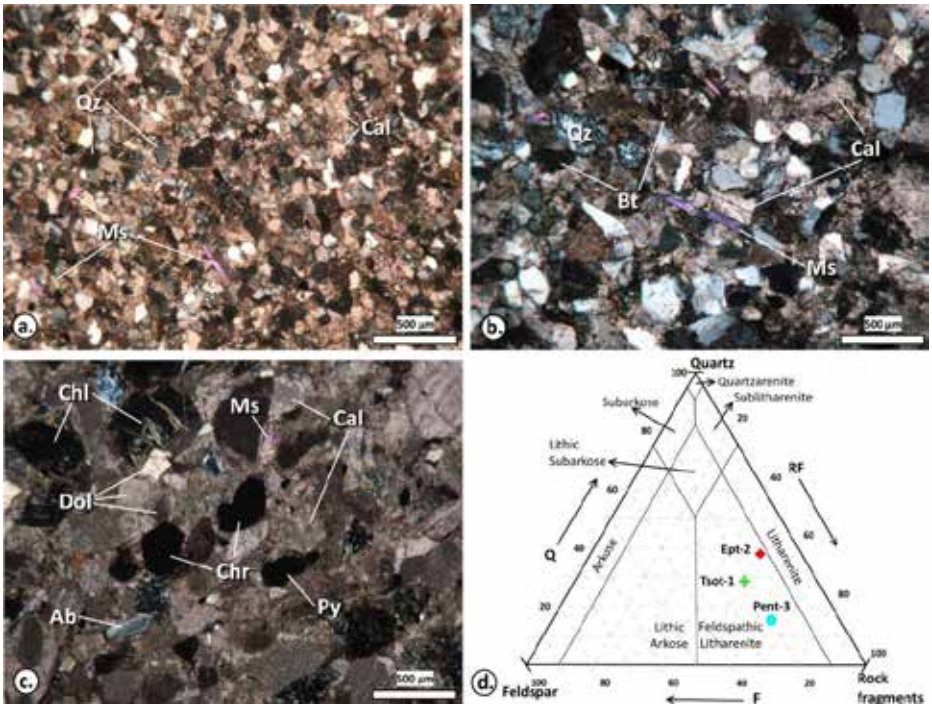

Figure 2. Photomicrographs of the studied samples: a. Well-cemented quartz (Qz), calcite (Cal) and muscovite (Ms) in sample Tsot-1. b Quartz (Qz), biotite (Bt), calcite (Cal) and muscovite (Ms) in sample Ept-2. c. Calcite (Cal) and dolomite (Dol) with chlorite (Chl) and minor albite (Ab), chromite (Chr) and pyrite (Py) in sample Pent-3. Dolomite was identified by SEM-EDS analysis. d. QFR (Quartz-Feldspar-Rock fragments) triangular plot diagram for classification of the studied samples after McBride (1963).

Table 2. Average morphometric characteristics by SEM-EDS analysis of the pores width between grains and in cement for samples Tsot-1, Ept-2, and Pent-3, along with macro-porosity data obtained through automated image analysis.

	Average morphometric characteristics				Macro-porosity data				
Sample	**Pores between grains**	**Pore shape**	**Pores in cement**	**Pore shape**	**Sample**	**MIN**	**MAX**	**STDEV**	**AVG**
Tsot-1	45 μm (n = 12)	Irregular, rounded, elongated	-	-	**Tsot-1** (n = 5)	1.4	1.9	0.2	1.7
Ept-2	66 μm (n = 8)		11 μm (n = 5)	Rounded	**Ept-2** (n = 9)	1.7	1.9	0.1	1.8
Pent-3	65 μm (n = 4)	Irregular, elongated	6.0 μm (n = 3)	Rounded	**Pent-3** (n = 12)	1.0	4.0	1.4	2.0

Abbreviation: average = AVG, maximum = MAX, minimum = MIN, standard deviation = STDEV.

The maximum porosity (4%) measured after automated image analysis is related to sample Pent-3 (Table 2). The results are in accordance with these previously published where porosity was measured at 6.0%, 7.4% and, 4.9 to 10.8% for the samples Tsot-1, Ept-2 and Pent-3, respectively (Tyrologou *et al.,* 2023). The lower porosity values from ImageJ analysis compared to petrophysical testing reflect differences in methodology, as ImageJ focuses on 2D observable pores, potentially overlooking micro-porosity (Figs 3d-f). Petrophysical testing, measuring bulk porosity provides a more comprehensive view of the porosity of the samples. Despite this, ImageJ remains a valuable and cost-effective tool for identifying porosity trends and comparing samples, particularly for macro- and meso-pores.

Table 3. Bulk geochemical composition, determined through elemental mapping via SEM-EDS, XRD and Rietveld refinement, and XRF analysis of major elements in samples Tsot-1, Ept-2, and Pent-3. Values are in weight percent (wt.%), except for the trace elements where they are reported in parts per million (ppm).

Element by SEM-EDS	**Si**	**Al**	**Fe**	**Ca**	**Mg**	**Na**	**K**	**Mn**	**Ti**	**P**	**Ca/Si**	
Tsot-1 in average (n = 6)	52	11	7.0	24	4.0	3.0	11	n.a.	n.a.	n.a.	0.5	
Ept-2 in average (n = 6)	26	3.7	8.3	53	8.8	n.a.	n.a.	n.a.	n.a.	n.a.	2.0	
Pent-3 in average (n = 6)	21	3.3	3.6	48	7.9	1.8	1.4	n.a.	n.a.	n.a.	2.3	
Element by XRD	**Si**	**Al**	**Fe**	**Ca**	**Mg**	**Na**	**K**	**Mn**	**Ti**	**P**	**Ca:Si**	
Tsot-1	23	4.3	0.8	14	1.8	1.8	0.7	n.a.	n.a.	n.a.	0.6	
Ept-2	25	4.0	1.1	13	0.8	1.1	0.8	n.a.	n.a.	n.a.	0.5	
Pent-3	14	2.8	0.1	21	2.3	1.0	1.4	n.a.	n.a.	n.a.	1.5	
Element by XRF	**SiO_2**	**Al_2O_3**	**Fe_2O_3**	**CaO**	**MgO**	**Na_2O**	**K_2O**	**MnO**	**TiO_2**	**P_2O_5**	**LOI**	**Total**
Tsot-1	35	7.0	2.7	31	4.2	1.0	2.2	0.1	0.3	0.08	17	100
Ept-2	36	6.6	3.3	26	7.2	0.7	1.4	0.1	0.4	0.1	18	100
Pent-3	16	2.9	1.2	42	6.0	0.4	0.9	0.03	0.1	0.06	30	100

Tsot-1	189	7.0	749	14	112	192	bdl	298	650	31	100	
Ept-2	149	13	1680	23	221	95	bdl	342	990	38	113	
Pent-3	66	4.0	512	7.0	78	82	bdl	242	306	15	54	

Abbreviations: LOI = Loss of ignition, n.a. = not available.

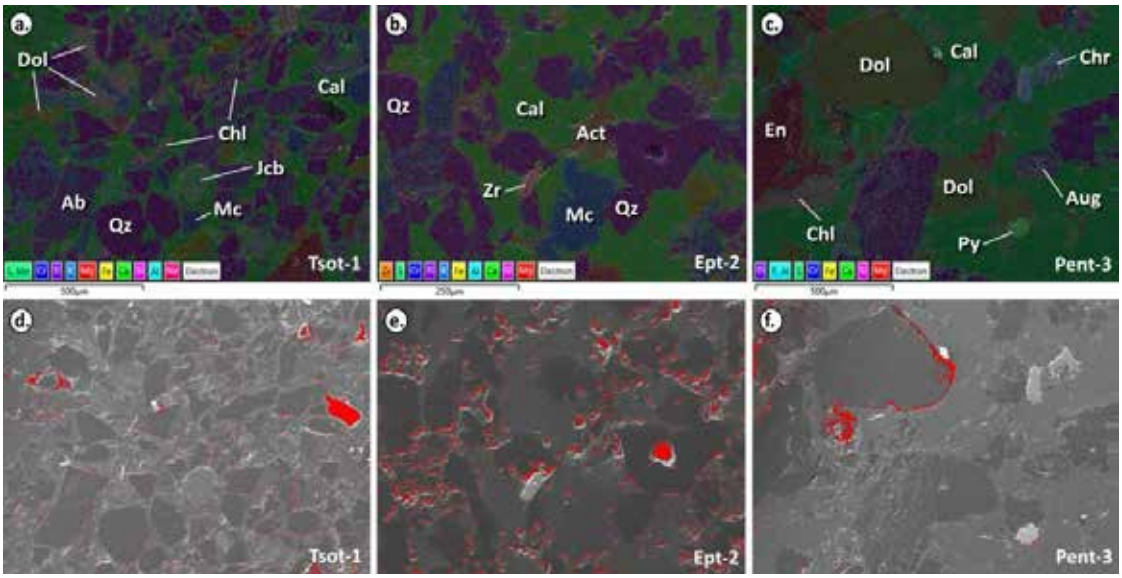

Figure 3. Representative photomicrographs illustrate elemental mapping (a–b) and porosity assessment (d–f) via automated image analysis for samples Tsot-1, Ept-2, and Pent-3. The calculated porosity values are 1.8% for Tsot-1 (d), 1.9% for Ept-2 (e), and 1.1% for Pent-3 (f).

Conclusions and Ongoing Research

The combined mineralogical, geochemical, and textural analysis of samples Tsot-1, Ept-2, and Pent-3 reveals significant variability in depositional environments and diagenetic processes. In addition, SEM-EDS analysis and automated image analysis enables fast, cost-effective macro-porosity characterization. Sample Tsot-1, with its siliceous dominance, moderate macro-porosity, and traces of microcline and zircon, suggests deposition in a high-energy environment with significant siliciclastic input, consistent with its well-bedded sandstone structure. Sample Ept-2, characterized by its carbonate-rich composition and microcrystalline cement, indicates deposition in a marine-influenced or lacustrine setting, supported by bedding features and burrow evidence. In contrast, the complex mineralogy of sample Pent-3, including high calcite content and inclusions like titanite and chromite, reflects a mixed depositional environment influenced by the erosion of the ophiolitic rocks surrounding the Mesohellenic Trough.

These findings highlight the interplay between provenance, depositional energy, and diagenetic processes in shaping the regional sedimentary formations, offering insights into the tectonic and sedimentological evolution of the basin.

Acknowledgements
This research was funded by the EU Horizon 2020 program under grant No. 101022664 (PilotSTRATEGY). The funders had no role in study design, data collection, analysis, publication decisions, or manuscript preparation. Special thanks to Agnes Vamvaka, Dina Ghikas, and Anna Mpatsi for their assistance in field sample collection. XRF analyses were conducted under a service agreement between CERTH and the Laboratory of Mineralogy and Petrology, Faculty of Geology, AUTH.

EXTENDED ABSTRACT 171

Unveiling the Potential of AI in Geoscience Education: A Student-Centered Perspective

Koumoutsakou O.[1], Antonarakou A.[1]

(1) Department of Geology and Geoenvironment, University of Athens, Ilisia, Greece, okoumout@geol.uoa.gr

Introduction / Background

According to a recent survey by the Digital Education Council, 86% of students globally incorporate artificial intelligence into their studies, with 24% using it every day and 54% using it at least once a week (Digital Education Council, 2024). This highlights the growing integration of AI into students' academic routines. Integrating Artificial Intelligence (AI) into geoscience education is rapidly transforming the learning landscape, presenting unprecedented opportunities and significant ethical challenges (Patra et al., 2024). This research explores the multifaceted impact of AI on geoscience students, focusing on their perspectives regarding the future of their field in this era of technological advancement. It draws upon a range of studies that examine the practical applications, ethical dilemmas, and prospects of AI in Earth sciences.

AI's Role in Geoscience Education

AI is becoming increasingly prevalent in geoscience, from data collection and processing to complex modeling and interpretation (Sun et al., 2024; Zhao et al., 2024). Artificial intelligence techniques, such as machine learning (ML) and deep learning (DL), allow for the analysis of large datasets, improving our insights into Earth's systems (Sun et al., 2024). "AI can help students analyze satellite imagery to detect land-use changes, monitor environmental degradation, and study natural disasters. In mineral exploration, AI algorithms can identify mineral deposits based on geophysical data patterns" (Sun et al., 2024). AI can also improve the analysis of seismic data, enhance our understanding of the Earth's interior, and aid in the prediction of earthquakes. Furthermore, AI techniques can optimize climate modeling, making the process more accurate and efficient despite its complexity and time demands (Sun et al., 2024).

Furthermore, AI tools such as ChatGPT, Gemini, etc., can help with tasks such as scientific writing, data interpretation, and hypothesis generation (Baucon et al., 2024). GeologyOracle, a specialized artificial intelligence system created by Baucon and his colleagues, can handle complex geoscientific tasks, interpret geological sites, and provide support in educational environments (Baucon et al., 2024). Such tools can accelerate scientific discovery, automate research tasks, and support educators, students, and geotourists (Baucon et al., 2024). However, this technological integration also presents considerable challenges.

Ethical Considerations and Student Perspectives

Ethical concerns are central to discussions of AI in education. Plagiarism and academic integrity present significant challenges, as students might rely on AI to produce written content, potentially hindering the development of their skills (Assapari et al., 2025; Patra et al., 2024; Weijemars et al., 2023). There is a concern that some students may use AI to complete assignments, bypassing plagiarism detectors, and there are concerns regarding the authenticity of written work. Additionally, the potential for AI to generate biased or inaccurate information raises questions about the reliability of these tools in an academic setting (Ghotbi & Ho, 2021).

Student perceptions of AI in education are varied

While many recognize the potential benefits of AI, particularly for improving learning and research activities, there are also concerns about over-reliance on technology, its impact on critical thinking, and the need for human oversight (Patra et al., 2024; Sarwari & Adnan, 2024; Kumar & Ramanm, 2022; Crawford et al., 2024). Many students find AI tools like ChatGPT valuable for everyday learning activities, as they provide access to information anytime and anywhere without limitations. "However, they also prefer traditional teaching methods and consider human teachers indispensable" (Patra et al., 2024; Sarwari & Andnan, 2024).

Research conducted among 94 geoscience students in Mumbai (Patra et al., 2024) revealed that most students disapprove of AI-generated texts bypassing plagiarism detection, emphasizing their concern for academic integrity. There is also concern that using AI may diminish critical thinking and problem-solving skills. Furthermore, some students believe AI should be excluded from specific academic processes, like admissions, exams, and placements, due to concerns about accuracy and fairness (Kumar & Raman, 2022).

The Future of Geoscience in the AI Era

Although challenges exist, AI is anticipated to become increasingly important in shaping the future of geoscience (Zhao et al., 2024, Sun et al., 2024). Many scientists envision a hybrid environment where AI and numerical models coexist, working collaboratively to solve complex environmental issues (Sun et al., 2024). Advancing explainable and physics-based AI models is crucial for improving accuracy and building trust (Sun et al., 2024). It is also important to address the ethical implications of AI in geoscience, including algorithmic bias and data privacy (Ghotbi & Ho, 2021; Sun et al., 2024; Zhao et al., 2024).

AI is also anticipated to aid in creating personalized learning experiences that are customized to meet the specific needs of each student and support educators in providing effective interventions (Burner et al., 2025; Miller, 2025). AI-powered tools can provide tailored feedback, assist with language barriers, and offer adaptive testing, which is particularly beneficial for international students (Wang et al., 2023). However, some scholars highlight gaps in understanding the long-term psychosocial effects of AI usage in education (Crawford et al., 2024).

According to Sun et al. (2024), the success of AI in geoscience will rely on collaboration between computer scientists, mathematicians, and geoscientists to develop tailored tools and training. It is critical to foster a culture of innovation and ethical AI use, educating students on the importance of critical thinking and responsible application of AI technologies (Sun et al., 2024; Baucon et al., 2024; Patra et al., 2024; Ghotbi & Ho, 2021).

Preliminary research results

The preliminary results of our survey of students and graduates of Earth Science in Greece reveal important findings about students' understanding, use, and opinions about Artificial Intelligence (AI). Although AI is embedded in their daily lives, a small percentage of students remain unaware of its presence. The majority use AI tools mainly for information access, data analysis, and task automation, with a particular focus on geoscientific data. Familiarity with these tools ranges from moderate to high, with voice assistants and recommendation systems emerging as more popular applications. However, the use of more specialized tools, such as for music production, video, navigation or translation tools, and bibliographic analysis, remains in high demand, much more frequently than the use of chatbots. Students appear divided on the reliability of AI responses, with several expressing concerns about privacy and human autonomy, while very few feel adequately informed about the ethical issues arising from its use.

Conclusion

The integration of AI in geoscience education is a complex, evolving process that requires a balanced approach. AI is expected to assist in developing tailored learning experiences that address the unique needs of each student (AI-powered personalized learning systems, adoption of artificial intelligence). (Sun et al., 2024; Zhao et al., 2024; Sarwari & Andnan, 2024; Wang et al., 2023). Students have expressed concern regarding potential over-reliance on AI, and their role as future geoscientists in a rapidly changing world (Patra et al., 2024; Kumar & Raman, 2022; Crawford et al., 2024; Ghotbi & Ho, 2021). Therefore, the future of geoscience in the AI era will depend on our capacity to integrate these technologies responsibly and ethically while prioritizing human expertise, critical thinking, and environmental responsibility.

Acknowledgments

Thank you to all the students who participated in my research questionnaire. Your valuable insights were greatly appreciated and contributed significantly to this study.

(3) Instiute of Oceanography, National Centre for Marine Research, 46,7 km Athens Sounio ave., P.C. 19013, Anavyssos, Attiki, Greece

Introduction

Among the processes that govern the formation and evolution of beach zones is the grain-size of beach material; the latter together with slope have recognized as key geomorphological elements for characterizing the beaches as they appear interrelated with each other and with the oceanographic conditions (Carter, 1988; Wright and Short, 1984).

The scope of the present study is to provide an insight to the grain size distribution of the sediments consisting of both subaerial and submarine sectors of beach zone that extends along the north coastline of the Messiniakos Gulf from Messini to Kalamata with a West – East trending shoreline, a length of 21 km and an average width of 20 m. It is exposed to southerly wind-generated waves, with average significant wave height of 1.2 m and period of 7.6 s (Koumpou et al., 2018). The subaerial beach zone gentles smoothly, having rhythmic morphological features (e.g. beach cusps, berms) at its central and western part and crescentic / longshore bars at its subaqueous part. In addition, low dunes, river mouths (central and western sector) and artificial coastal structures (eastern sector) are also present.

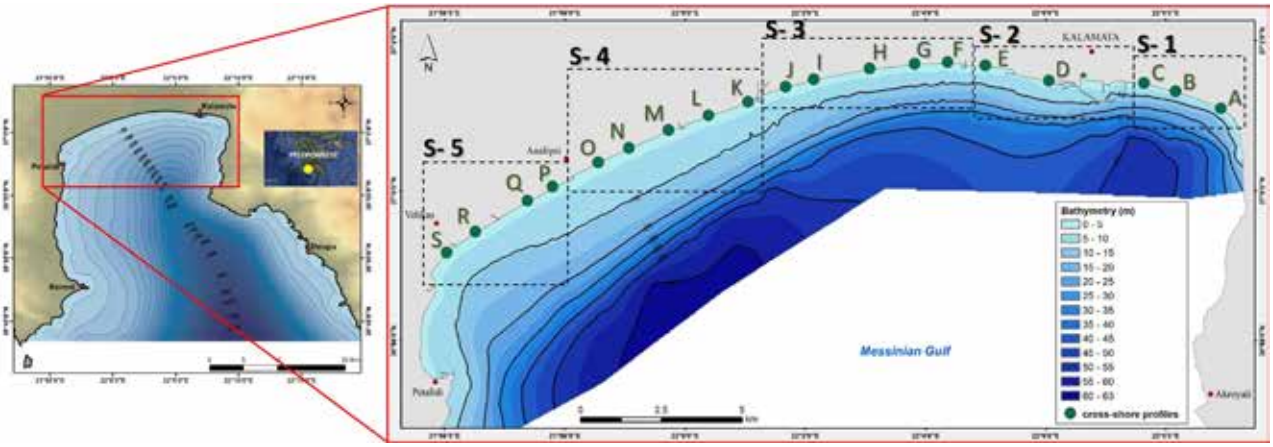

Figure 1. The study area with the positions of the shore-normal profiles (A-S) and the five beach sectors (1-5).

Methods

Nineteen (19) shore-normal profiles (A to S, from east to west) (Fig.1) were measured with the use of a Leica Distance Meter (subaerial part) and a Portable Handy Depth Sounder Hondex PS-7 (subaqueous part). For the geographical position of the profiles a Topcon GPS was used. 118 ssurficial (upper 2 cm) sediment samples were selected along these profiles, i.e., 60 subaerial, 19 from the beach face (shoreline) and 39 subaqueous samples (see Table A).

Subsequently sediment samples >625μm were subjected to dry sieving according to the Folk (1974) procedure, whilst sediment samples (<625 μm) were analyzed with a Sedigraph-Micrometrics using X-rays (type III PLUS). The statistical elaboration of the grain size identification included the determination of the graphical mean grain size (Mz; equation 1), the graphical standard deviation (σI; equation 2) and the mean diameter (D50), while the samples were classified according to their content in gravels, sand and mud following the Folk' (1974).

Results

The subaerial, beach-face and subaqueous slopes of the 19 normal to shoreline profiles (A-S) are presented in Table 1, while the types of sediment samples, according to their grain size composition, is presented in Table 2.

Table 1. Average slopes of subaerial, subaqueous and beacface of the 5 beach sectors (T1-T5)

Key. G: Gravel; S: Sand; M: Mud; sG: sandy Gravel; (g)S: slightly sandy Gravel; gS: gravelly Sand; sG: sandy Gravel; mS: muddy Sand; sM: sandy Mud

Discussion and Conclusions

The beach zone along the northern coast of the Messiniakos Gulf consists predominantly of mixed sediments, with sand-sized material being the primary component. As expected, the subaerial sediments are coarser, with gravel-sized particles being as significant as the sand-sized ones. In contrast, the subaqueous sediments are dominated by sand, particularly in water depths greater than 2 meters. Beyond 5 meters of depth, the proportion of mud increases, becoming the dominant sediment type at depths exceeding 15 meters. Along the beach face (±0.5 m), the sediment consists of a mixture of sand and gravel in varying ratios. Additionally, the results of the grain size analysis align with the classification of the 19 profiles into five main sectors, based on shoreline orientation and beach slope (Table 1).

There is a notable similarity between the eastern Sector 1 and the central Sector 3, particularly in the slopes of their beach face and shoreface. Both end sectors are characterized by relatively coarser material and exhibit similar slopes. This similarity is likely influenced by the original terrestrial material and the presence of coastal structures, such as port breakwaters, in the eastern Sector. The observed differences between the sectors may be attributed to variations in sediment input from rivers discharging along the shore, combined with the effects of longshore sediment transport in the nearshore zone and wave runup on the subaerial beach.

EXTENDED ABSTRACT 173

A systematic review of grey literature in Greek universities repositories to uncover Greek UNESCO Global Geoparks

Alexandros Aristotelis Koupatsiaris[1], Hara Drinia[1]
(1) Department of Geology and Geoenvironment, National and Kapodistrian University of Athens, 15784 Athens, Greece, alkoup@geol.uoa.gr

Research Highlights

A systematic review of grey literature from Greek university repositories reveals a growing interest in UNESCO Global Geoparks, primarily focusing on geotourism, geology, management, and education, but also identifies gaps in social sciences and community engagement. Future research should adopt a holistic approach, integrating socio-economic, cultural, and environmental aspects, while enhancing geoenvironmental education and stakeholder involvement to support the United Nations' seventeen Sustainable Development Goals.

Introduction / Background

Our world is experiencing rapid urbanization, interconnectivity, and environmental changes. The global population is projected to reach 9.7 billion by 2030 and 10.4 billion by 2050. Currently, 55% of the population lives in urban areas, a figure expected to rise to 68% by 2050. This trend impacts land use, biodiversity, and ecosystems, with significant urban land development anticipated by 2030 (Fragkias, 2013). Environmental challenges, such as pollution, erosion, desertification, deforestation, fires, intensified agriculture, overgrazing, invasive species, overfishing (Scoullos, 2008), climate change, greenhouse effects, droughts, floods, habitat loss, chemical pollution (Krasny, 2020), environmental emergencies, and anthropogenic impacts on economic systems, global warming, natural disasters, declining biodiversity, land degradation, water pollution, mineral resource exploitation, coastal vulnerability, and geodiversity alterations (Peppoloni et al., 2022) threaten our planet's natural capital (Gray, 2018). These issues necessitate proactive measures and community involvement to protect our environment for future generations.

UNESCO Global Geoparks (UGGps) play a crucial role in sustainable development by managing areas with significant geological heritage. Established in 2000 and supported by UNESCO since 2001, these UGGps promote awareness of societal issues through geoconservation, geotourism, and geoeducation, enhancing community well-being and sustainability (Zouros, 2016). There are currently 213 UGGps in 48 countries. In Greece, nine areas are designated as UGGps (Lesvos Island UGGp, Psiloritis UGGp, Chelmos-Vouraikos UGGp, Vikos-Aoos UGGp, Sitia UGGp, Grevena-Kozani UGGp, Kefalonia-Ithaca UGGp, Lavreotiki UGGp, Meteora-Pyli UGGp), with one more in the nomination process (Nisyros aspiring UGGp).

Greece's geotectonic position offers a rich geological landscape, making its UGGps invaluable. These sites serve as "natural geological laboratories," chronicling Earth's history from the Proterozoic Eon to today and providing insights into tectonics, sedimentation, volcanic activity, and landscape evolution. The geoconservation and sustainable development of these UGGps are crucial. Scientific research helps formulate effective conservation strategies. Greek UGGps also serve as effective platforms for teaching about the environment, enhancing public awareness of the connections between geology, ecology, culture, and sustainability (Koupatsiaris et al., 2023). They promote social, economic, and cultural growth through educational programs, geotourism, and geoethics (Zafeiropoulos et al., 2021). The study of UGGps supports interdisciplinary research in geosciences and geoconservation, informing global efforts in sustainability and environmental stewardship.

Objectives

The systematic review aims to evaluate the repositories of Greek universities to identify and catalog research topics related to Greek UGGps. It seeks to provide a comprehensive overview of the research landscape, highlight underexplored areas, and suggest directions for future research, offering insights to the academic community, policymakers, and stakeholders.

The research questions addressed are:

- What research topics and themes are covered in Greek university grey literature about Greek UGGps?
- What research gaps exist in this literature?
- What are the potential future research directions for Greek UGGps?
-

Methods

This study gathers research evidence on Greek UGGps to guide future research studies. Using a systematic review

approach, specific steps were followed to ensure replicability and reliability. The criteria included publications from Greek university repositories published between 2000 and 2022, using the keyword “Geopark.” The search focused on publications primarily discussing Geoparks as holistic entities, rather than specific geological or other features within Geopark boundaries. A total of 138 items were accessed, with 28 theses deemed relevant after applying selection criteria. The process followed PRISMA guidelines for a thorough review (Figure 1).

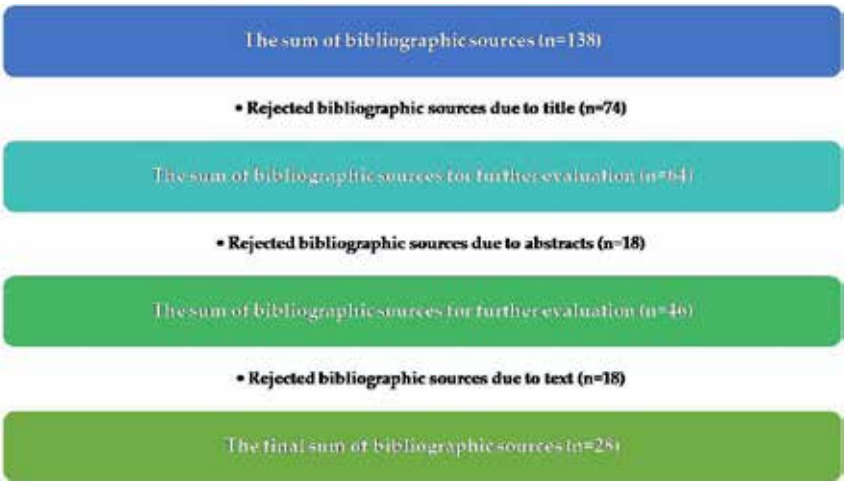

Figure 1. Flow chart for the grey literature review in Greek university repositories.

Limitations included reliance on a single keyword and variations in search capabilities across institutions, which may have resulted in omissions. External literature from global databases related to Greek UGGps was not examined.

Results

The review identified 28 theses on UGGPs: 23 master’s, 3 graduate, and 2 doctoral theses. This indicates a growing academic interest, although there was a notable dip in publications during 2021 due to the SARS-CoV-2 pandemic (Figure 2).

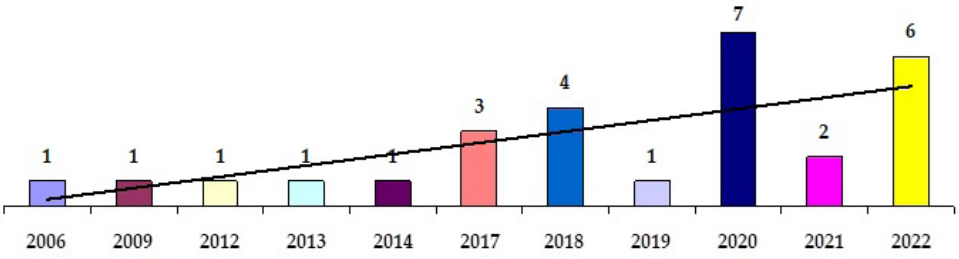

Figure 2. Distribution of the theses by the year of publication in Greek university repositories.

Most theses were found at the University of the Aegean (n=9), likely due to its collaboration with the Lesvos Island UGGp, followed by the Hellenic Open University (n=6) and the National Kapodistrian University of Athens (n=4) (Figure 3).

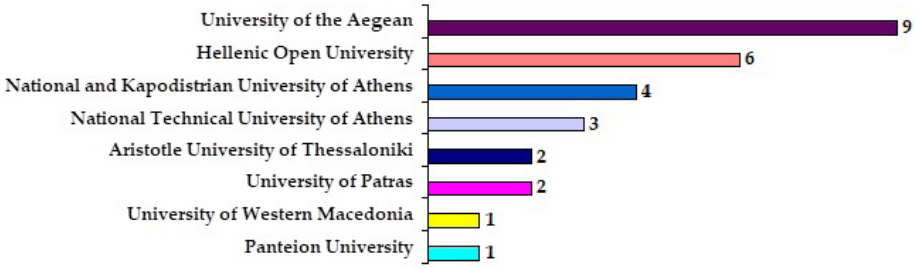

Figure 3. Distribution of the theses by Greek university repositories.

The Department of Geography had the most theses (n=7), followed by the Department of Geology and Geoenvironment at the National and Kapodistrian University of Athens (n=4) and the Tourism Business Administration at the Hellenic Open University (n=4) (Figure 4).

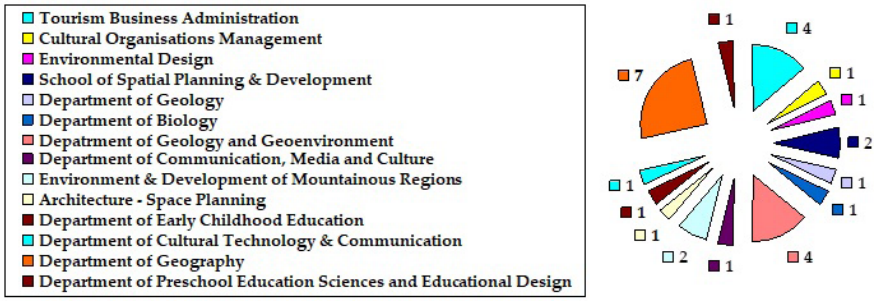

Figure 4. Distribution of the theses by Greek university department.

The 28 university theses focused on Lesvos Island (n=11) and Sitia UGGps (n=6), with newer UGGps like Grevena-Kozani, Kefalonia-Ithaca, and Lavreotiki having fewer studies due to their recent establishment (Figure 5).

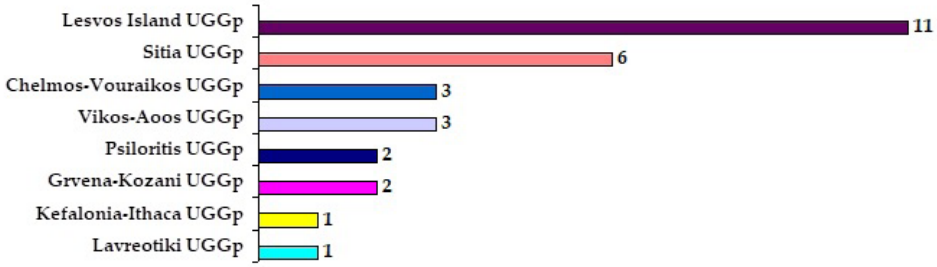

Figure 5. Distribution of the theses according to their Greek UNESCO Global Geopark focus.

Research topics included geotourism (n=7), geodiversity and geology (n=6), sustainable management (n=4), and geoeducation (n=4). Other areas were geoinformatics, biodiversity, cartography, cultural development, spatial planning, and georoute promotion, highlighting the multidisciplinary nature of UGGps studies (Figure 6).

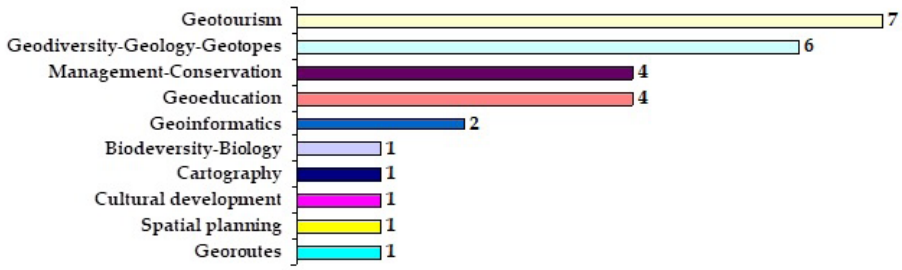

Figure 6. Content classification of the grey literature in Greek university repositories.

Conclusions

This review underscores the importance of Greek UGGps as globally recognized assets supporting scientific research and societal contributions. It addresses key global issues such as urbanization, environmental challenges, and the alienation from nature, emphasizing the need for new sustainability and resilience policies. Greece, renowned for its geological richness, hosts nine UGGps, offering opportunities for geoconservation, geodiversity and biodiversity, and cultural appreciation. The review focused on grey literature from Greek universities to identify research gaps and align domestic efforts with international trends. There is strong academic interest in Greek UGGps, particularly in geology, biology, tourism, and culture.

Recent proposals, such as Martini et al. (2022), suggest a roadmap for UGGps focusing on climate change, water

resources, sustainable tourism, and community engagement. International research emphasizes interdisciplinary studies and community involvement. Stoffelen's (2020) review focused on geomorphological aspects, while Herrera-Franco et al. (2021) noted this area's dominance in research, particularly in Asia and Europe. Ferreira et al. (2023) highlighted the need to explore UGGps' role in sustainable development and their benefits to local populations. Evaluations of the International Geoscience and Geoparks Programme showed UGGps' contributions to the United Nation's Sustainable Development Goals, including quality education (UNESCO, 2019). However, educational topics remain underrepresented in research.

Greek research aligns with international trends but often focuses on geotourism, geology, and management, with limited attention to social and humanitarian aspects. To fully harness the potential of UGGps, Greek studies should expand to include social development and stakeholder engagement, drawing from successful international models aligning with the United Nations' Sustainable Development Goals and fostering a sense of belonging and responsibility among future generations in Greece and beyond (Koupatsiaris et al., 2023). Addressing these research gaps can enhance the role of UGGps in environmental awareness, sustainability, and education, providing a roadmap for future academic research.

Future research within UGGps, highlighted in the grey literature of Greek university repositories, should focus on:

- Socio-economic and cultural aspects: Explore the socio-cultural dimensions of UGGps, integrating historical and cultural narratives with geological significance. This holistic approach can transform UGGps into cultural and economic hubs, enhancing their role in local identity and advancement.
- Collaborative management and governance: Investigate stakeholder participation in UGGps management, involving local communities, students, and special interest groups. Innovative governance structures can improve UGGps' visibility and recognition, reflecting their significance in local culture.
- Climate change and environmental challenges: UGGps can educate the public on climate change and resilience. They serve as living laboratories for studying environmental impacts and engaging communities in climate action through science initiatives, contributing to public health and well-being.
- Geoenvironmental education: Emphasize education with a focus on integrating UGGps into educational curricula to raise awareness about geoconservation, sustainability, and environmental challenges. This can enhance public understanding and foster a sense of responsibility towards preserving geological heritage.

By addressing these areas, future research can strengthen the role of Greek UGGps in promoting sustainability.

Acknowledgements

The authors extend their heartfelt thanks to the organizing committee of the 17th International Congress of the Geological Society of Greece and the anonymous reviewers for their thorough consideration of this extended abstract.

EXTENDED ABSTRACT 174

Assessing Educators' Sense of Place and Geoethical Awareness at the 4th Summer School of Sitia UNESCO Global Geopark

Alexandros Aristotelis Koupatsiaris[1], Hara Drinia[1]

(1) Department of Geology and Geoenvironment, National and Kapodistrian University of Athens, 15784 Athens, Greece, alkoup@geol.uoa.gr

Introduction / Background

The environment is shaped by a complex interplay of natural and human influences affecting ecological balance, quality of life, public health, cultural traditions, and aesthetic values. Current environmental challenges, intensified by urbanization, threaten natural resources and cultural and geological heritage. The United Nations' Sustainable Development Goals provide a strategic framework to address these issues. In the Anthropocene Era, it is crucial to adopt modern geoenvironmental strategies grounded in geoethics (Koupatsiaris et al., 2024). Pro-environmental behavior, aimed at enhancing environmental quality and sustainability, is essential for confronting these challenges.

UNESCO Global Geoparks (UGGps) play a vital role in conserving and promoting areas with notable geodiversity, biodiversity, and geotourism, while also advancing education, public understanding, sustainability, and resilience. These UGGps inspire a sense of belonging and responsibility, encouraging local communities to re-evaluate their heritage through tourism and eco-friendly activities (Fassoulas et al., 2010). At present, there are 213 UGGps across 48 countries, with Greece hosting nine, including the Sitia UGGp, established in 2015. It is located on the eastern edge of Crete, encompassing an area of 713.5 km² with internationally significant geology.

For over six decades, environmental education has aimed to develop environmentally conscious citizens capable of addressing complex environmental problems (Krasny, 2020). Geoeducation integrates natural and cultural features with geology to raise awareness and foster participation in geoconservation efforts (Gordon, 2019). Place-based education (Sobel, 2004) emphasizes the importance of local geoenvironments in a globalized world, countering the alienation from nature. The sense of place (Kudryavtsev et al., 2012), a key concept in environmental education, involves the connections people have with locations, influenced by physical, psychological, and emotional factors (Semken et al., 2009). It intersects with geoethics (Peppoloni et al., 2022), which explores the ethical dimensions of human interactions with the natural environment, promoting sustainability, environmental responsibility, and social justice.

Objectives

In response to the increasing global interest in geoenvironmental education, geoheritage, geoconservation, and geoethics, this study presents a novel approach to exploring the interrelations between sense of place and geoethical awareness within the context of UGGps. The research addresses the following questions:

- What changes occur in participants' sense of place (including place attachment and place meaning) and geoethical awareness before and after attending the summer school?
- Is there a relationship between place attachment, place meaning, and geoethical awareness among the summer school participants?
-

Methods

The study was conducted during the 4th Summer School of Environmental Education on Geotopes and Sustainability at the Sitia UNESCO Global Geopark from June 29 to July 4, 2024, involving 50 educators from Greece. A quasi-experimental design with a single experimental group and a pre-post technique was employed. Convenience sampling resulted in 41 questionnaires at the start and 36 at the end, with 33 matched pre-post questionnaires analyzed. The comprehensive survey included four sections: Section A (place attachment)—12 items, Section B (place meaning)—28 items, Section C (geoethical awareness)—32 items, and Section D (demographics)—15 items. The place attachment scale was adapted from Williams and Vaske (2003), and the place meaning scale was a modified version of Young's (1999) scale. A new geoethical awareness scale was developed based on geoethics literature. All items used a Likert scale from 1 to 5. Ethical standards were strictly followed. Data analysis was conducted using IBM SPSS Statistics version 29. Normality tests (Kolmogorov–Smirnov and Shapiro–Wilk) indicated a non-normal distribution ($p > 0.05$), so non-parametric tests (Spearman's rho, and Wilcoxon signed-rank) were used for correlation analyses and multiple linear regression.

Results

The questionnaire's internal consistency was assessed using Cronbach's Alpha. Section A had $\alpha = 0.942$ (pre) and $\alpha = 0.929$ (post) with 12 items. Section B had $\alpha = 0.917$ (pre) and $\alpha = 0.914$ (post) with 28 items. Section C had $\alpha = 0.945$ (pre) and $\alpha =$

0.955 (post) with 32 items. For all 72 items, both pre- and post-summer school consistency was α = 0.967.
Among participants, 36.4% were male and 63.6% female. Age distribution: 9.1% were 25–34, 27.3% were 35–44, 33.3% were 45–54, and 30.3% were 55 and above. Educational qualifications included 66.7% with a postgraduate degree, 24.2% with an undergraduate degree, and 9.1% with a Ph.D. Employment varied: 6.1% in kindergarten, 30.3% in primary school, 33.3% in middle school, 21.2% in high school, and 6.1% in other institutions.
In analyzing the ''Place Attachment'' section of the questionnaire, notable changes in participants' responses were observed before and after attending the summer school (Table 2).

Table 2. Distribution of mean value, standard deviation, and total score for place attachment.

Items		PRE M.V.	PRE S.D.	POST M.V.	POST S.D.	SUM PRE	SUM POST
A1	I feel Sitia Geopark is part of me.	3.58	0.204	4.06	0.168	118	134
A3	Sitia Geopark is very special for me.	3.79	0.178	4.33	0.142	125	143
A5	I identify strongly with Sitia Geopark.	3.39	0.162	3.88	0.161	112	128
A7	I am very attached to Sitia Geopark.	3.36	0.203	4.12	0.167	111	136
A9	Visiting Sitia Geopark says a lot about who I am.	3.52	0.145	4.12	0.149	116	136
A11	Sitia Geopark means a lot to me.	3.48	0.185	4.18	0.154	115	138
Total (place identity)		3.52	0.157	4.12	0.137	697	815
A2	Sitia Geopark is the best place for what I like to do.	3.39	0.157	3.79	0.167	112	125
A4	No other place can compare to Sitia Geopark.	2.58	0.123	3.24	0.163	85	107
A6	I get more satisfaction out of visiting Sitia Geopark than any other.	3.12	0.167	3.61	0.157	103	119
A8	Doing what I do at Sitia Geopark is more important to me than doing it in any other place.	3.24	0.174	3.61	0.130	107	119
A10	I wouldn't substitute any other area for doing the types of things I do at Sitia Geopark.	2.82	0.154	3.24	0.180	93	107
A12	The things I do at Sitia Geopark I would enjoy doing just as much at a similar site.	3.30	0.119	3.39	0.137	89	86
Total (place dependence)		3.08	0.115	3.48	0.113	589	663
Total (place attachment)		3.30	0.130	3.80	0.118	1286	1478

Note: Odd-numbered items measure place identity, and even-numbered items measure place dependence. The final item is reverse-scored. Responses are based on a Likert scale where 1 corresponds to ''Strongly disagree,'' 2 to ''Disagree,'' 3 to ''Neither disagree nor agree,'' 4 to ''Agree,'' a nd 5 to ''Strongly agree.''

Overall, the measure of place attachment, which includes both place identity and place dependence, showed a notable increase. The average score for place attachment rose from 3.30 (S.D. = 0.130) before the summer school to 3.80 (S.D. = 0.118) after the event. The total score for place attachment also increased from 1286 to 1478 units. Participation in the summer school positively influenced participants' place attachment, enhancing their emotional connections and deepening their bonds with Sitia UGGp in the context of geoenvironmental education.
The analysis of the ''Place Meaning'' section revealed significant shifts in participants' perceptions of Sitia UGGp both before and after their attendance at the summer school (Table 3).

Table 3. Distribution of mean value, standard deviation, and total score for place meaning.

Sitia Geopark is for me:		PRE M.V.	PRE S.D.	POST M.V.	POST S.D.	SUM PRE	SUM POST

Total (place meaning)		3.71	0.089	4.05	0.085	3639	3900

Note: Items 12, 17, 18, and 19 are reverse-scored. This instrument uses a Likert scale where 1 corresponds to ‘‘Does not fit at all,’’ 2 to ‘‘Fits to some extent,’’ 3 to ‘‘Neither fits nor does not fit,’’ 4 to ‘‘Fits sufficiently well,’’ and 5 to ‘‘Fits perfectly.’’

Overall, the comprehensive measure of place meaning increased from a mean of 3.71 (S.D. = 0.089) to 4.05 (S.D. = 0.085). This reflects a stronger alignment with the idea that Sitia UGGp ‘‘fits perfectly’’ with the positive attributes assessed. The total score for place meaning rose from 3639 to 3900 units. Participation in the summer school significantly enhanced participants’ perceptions of the symbolic meanings of Sitia UGGp, reinforcing its cultural, ecological, and aesthetic value.

The analysis of the ‘‘Geoethical Awareness’’ section revealed significant shifts in participants’ perceptions regarding geoethical issues before and after attending the summer school (Table 4).

Table 4. Distribution of mean value, standard deviation, and total score for geoethical awareness.

Items		PRE M.V.	PRE S.D.	POST M.V.	POST S.D.	SUM PRE	SUM POST
C1	The preservation of geoheritage is essential for maintaining cultural and scientific values in Sitia Geopark.	4.33	0.112	4.70	0.081	143	155
C2	Public awareness programs about geoheritage in Sitia Geopark significantly enhance community appreciation and protection efforts.	4.42	0.098	4.70	0.081	146	155
C3	Effective geoconservation strategies in Sitia Geopark are crucial for protecting geological features from degradation.	4.39	0.106	4.64	0.085	145	153
C4	Geoconservation in Sitia Geopark should be integrated into local development plans to ensure the sustainable use of geological resources.	4.42	0.107	4.58	0.098	146	151
C5	Geotourism activities within Sitia Geopark should prioritize sustainability.	4.45	0.098	4.58	0.107	147	151
C6	The promotion of geotourism in Sitia Geopark can help boost local economies without compromising geological integrity.	4.30	0.141	4.52	0.098	142	149
C7	It is important to recognize and protect the geodiversity of Sitia Geopark as it contributes to ecological balance.	4.48	0.098	4.58	0.098	148	151
C8	Educational programs about geodiversity in Sitia Geopark can foster a deeper understanding of geological processes among visitors.	4.33	0.120	4.55	0.098	143	150
C9	The protection of biodiversity within Sitia Geopark is as important as preserving geological features.	4.18	0.187	4.73	0.079	138	156
C10	Biodiversity and geodiversity conservation in Sitia Geopark should be managed in a complementary manner.	3.88	0.167	4.15	0.175	128	137
C11	Responsible use of georesources within Sitia Geopark can support local communities without harming the environment.	4.09	0.159	4.42	0.098	135	146
C12	Regulations on the extraction of geosources in Sitia Geopark are necessary to prevent environmental degradation.	4.12	0.183	4.58	0.107	136	151
C13	Sustainable water management practices are essential to maintain the ecological balance within Sitia Geopark.	4.30	0.119	4.58	0.087	142	151
C14	Community involvement in water management decisions within Sitia Geopark can lead to more effective conservation outcomes.	4.18	0.119	4.55	0.098	138	150
C15	Sitia Geopark should implement strategies to mitigate the impacts of the climate crisis on its geological and biological resources.	4.33	0.128	4.48	0.116	143	148

C16	Raising awareness about the climate crisis in Sitia Geopark can motivate visitors and locals to adopt more sustainable practices.	4.27	0.117	4.45	0.116	141	147
C17	Risk prevention measures are necessary to protect both geological and human resources within Sitia Geopark.	4.39	0.115	4.42	0.098	145	146
C18	Adequate infrastructure and planning can significantly reduce the risks of natural disasters within Sitia Geopark.	4.18	0.134	4.45	0.107	138	147
C19	Sitia Geopark must develop adaptive strategies to cope with environmental changes and their impacts.	4.06	0.130	4.36	0.114	134	144
C20	Continuous research and monitoring are vital for effective adaptation to changing conditions within Sitia Geopark.	4.33	0.104	4.58	0.098	143	151
C21	All activities within Sitia Geopark should be guided by principles of sustainability to ensure long-term conservation.	4.55	0.107	4.70	0.081	150	155
C22	Sustainable development within Sitia Geopark can serve as a model for other protected areas.	4.36	0.114	4.48	0.088	144	148
C23	Enhancing the resilience of Sitia Geopark's ecosystems is crucial for coping with environmental pressures.	4.00	0.179	4.39	0.123	132	145
C24	Community resilience in Sitia Geopark can be bolstered through education and involvement in conservation efforts.	4.15	0.158	4.55	0.098	137	150
C25	Active community engagement is crucial for the success of conservation initiatives in Sitia Geopark.	4.33	0.104	4.48	0.116	143	148
C26	Local communities should have a significant role in decision-making processes related to Sitia Geopark.	4.18	0.134	4.45	0.116	138	147
C27	Strong environmental advocacy initiatives are essential for raising awareness about conservation issues within Sitia Geopark.	4.42	0.098	4.67	0.083	146	154
C28	Collaborating with environmental advocacy groups can amplify the impact of conservation efforts within Sitia Geopark.	4.42	0.087	4.45	0.163	146	147
C29	Programs that connect visitors emotionally to Sitia Geopark can lead to stronger conservation efforts.	4.30	0.111	4.52	0.098	142	149
C30	Ecological experiences within Sitia Geopark should be designed to foster a sense of responsibility towards nature.	4.45	0.116	4.70	0.092	147	155
C31	Geoenvironmental education programs are essential for raising awareness about the importance of geological conservation in Sitia Geopark.	4.27	0.109	4.39	0.162	141	145
C32	Schools and educational institutions should be actively involved in geoenvironmental education initiatives within Sitia Geopark.	4.52	0.098	4.61	0.097	149	152
Total (geoethical awareness)		4.30	0.770	4.53	0.069	4536	4784

Note: Items 1–2 evaluate the geoheritage value; items 3–4 focus on the geoconservation; items 5–6 examine geotourism; items 7–8 address the geodiversity; items 9–10 pertain to the biodiversity; items 11–12 consider georesources; items 13–14 discuss water management; items 15–16 relate to climate crisis issues; items 17–18 involve risk prevention; items 19–20 explore adaptation to changes; items 21–22 assess sustainability; items 23–24 reflect on resilience; items 25–26 cover community engagement; items 27–28 focus on environmental advocacy; items 29–30 evaluate the value of concrete ecological feelings; and items 31–32 consider the geoenvironmental education potential. The instrument uses a Likert scale as follows: 1 corresponds to ''Strongly disagree,'' 2 to ''Disagree,'' 3 to ''Neither disagree nor agree,'' 4 to ''Agree,'' and 5 to ''Strongly agree.''

Overall, the average rating for geoethical awareness increased from 4.30 (S.D. = 0.770) to 4.53 (S.D. = 0.069), with total scores rising from 4536 to 4784, highlighting the program's positive impact on participants' understanding and attitudes towards geoethical issues. These findings demonstrate a marked enhancement in geoethical awareness, with increased agreement on management, sustainability, preservation, community involvement, and advocacy. The summer school enhanced participants' commitment to geoethical principles, supporting geoconservation efforts in Sitia UGGp.

To explore the relationships between key scales of the questionnaire —place attachment (Scale A), place meaning (Scale B), and geoethical awareness (Scale C)—Spearman's rho correlation coefficients were calculated. The strongest correlation was observed between place attachment and place meaning ($\rho = 0.734$, $p < 0.001$, $N = 33$), indicating a strong link between emotional connection and perceived significance. Place meaning and geoethical awareness also showed a significant correlation ($\rho = 0.699$, $p < 0.001$), as did place attachment and geoethical awareness ($\rho = 0.664$, $p < 0.001$). All correlations were positive and significant, indicating interconnectedness of the scales and suggesting that the summer school enhanced participants' understanding of geoethical issues at Sitia UGGp.

A Wilcoxon signed-rank test was used to evaluate the impact of the summer school program on participants' connection to Sitia UGGp by comparing median place attachment levels before (APRE) and after (APOST) the program. This test is suitable for related samples. Notably, 30 of 33 participants reported a stronger connection post-program, while only 2 reported a decrease, and 1 remained unchanged. The test showed a statistically significant difference ($Z = -4.785$, $p < 0.001$), confirming the changes were not due to chance. The median place attachment score increased from 41.00 to 45.00, indicating a stronger connection to Sitia UGGp. The total scores for place attachment for each participant illustrate a clear trend toward stronger connections with

Sitia UGGp (Figure 1).

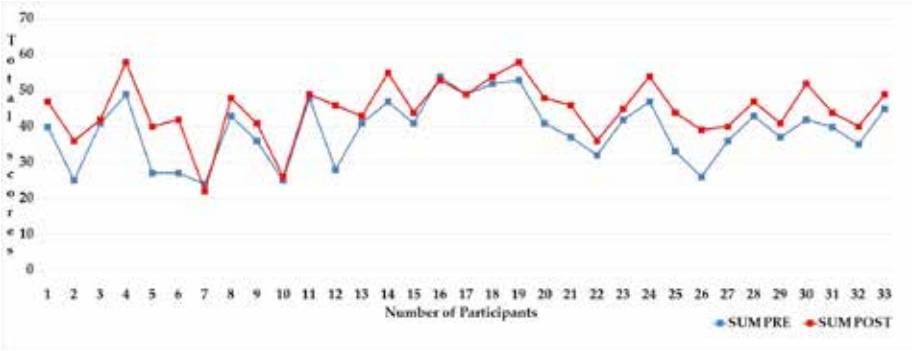

Figure 1. Distribution of total place attachment scores among summer school participants.

The results from the Wilcoxon signed-rank test and descriptive statistics demonstrate that the summer school significantly enhanced participants' attachment to Sitia UGGp. The increased median scores and the large number of participants reporting stronger connections highlight the program's success in deepening emotional and cognitive bonds with Sitia UGGp. This underscores the effectiveness of the summer school in fostering greater appreciation and attachment among participants.

To assess the summer school's impact on participants' perceptions of the Sitia UGGp's significance, a Wilcoxon signed-rank test compared median place meaning scores before (BPRE) and after (BPOST) the program. Of the 33 participants, 28 reported an enhanced perception of the site's importance, while only 2 noted a decrease, and 3 remained unchanged. The test showed a statistically significant difference ($Z = -4.282$, $p < 0.001$), indicating the changes were not due to chance. The median score for place meaning increased from 110.00 to 121.00 after the program. The upward shift in total scores for place meaning reflects a notable enhancement in participants' valuation of the Sitia UGGp, attributable to the summer school experience (Figure 2).

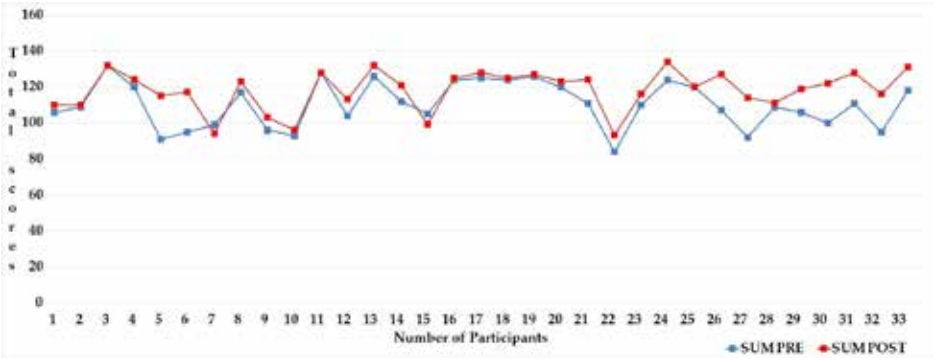

Figure 2. Distribution of total place meaning scores among summer school participants.

The results show that the summer school positively influenced participants' perceptions of the importance of the Sitia UGGp. The significant increase in median place meaning scores underscores the program's effectiveness in enhancing appreciation and recognition of the site's cultural and natural value. This highlights the role of educational initiatives in elevating the significance of heritage sites.

A Wilcoxon signed-rank test was also used to evaluate the impact of the summer school on participants' geoethical awareness, comparing median scores before (CPRE) and after (CPOST) the program. Among 33 participants, 26 reported increased geoethical awareness, 4 experienced a decrease, and 3 showed no change. The test revealed a statistically significant difference ($Z = -4.085$, $p < 0.001$), indicating the changes were not due to chance. The median geoethical awareness score rose from 139.00 to 152.00, demonstrating a significant improvement following the summer school. The notable increase in total scores for geoethical awareness indicates a positive shift in participants' geoethical perceptions of the Sitia UGGp, reflecting the summer school's effectiveness in enhancing their awareness (Figure 3).

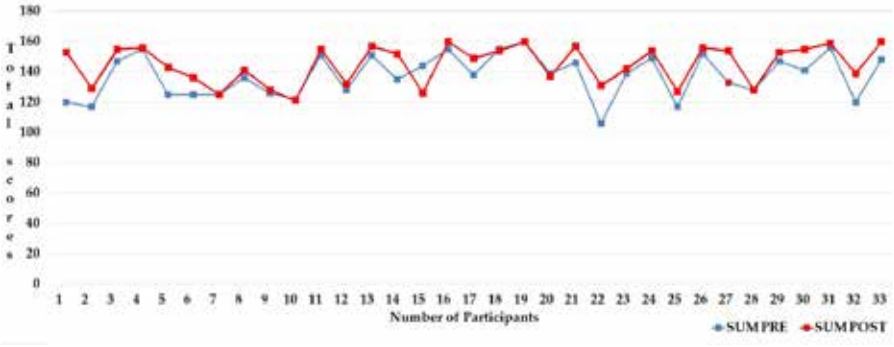

Figure 3. Distribution of total geoethical awareness scores among summer school participants.

The results show that the summer school significantly enhanced participants' geoethical awareness regarding the Sitia UGGp. The increase in median scores underscores the program's success in deepening understanding of ethical considerations. These findings affirm the summer school's effectiveness in enhancing geoethical perspectives and achieving its educational goals.

To explore the potential for predicting geoethical awareness (CPRE), a multiple linear regression analysis was conducted. The goal was to identify variables that reliably predict geoethical awareness before the summer school. Independent variables included place attachment (APRE), place meaning (BPRE), gender, years of teaching experience, and other factors related to environmental involvement. The stepwise procedure revealed that place attachment (APRE) and place meaning (BPRE) significantly contributed to the model, with an adjusted R^2 of 0.583, explaining 58.3% of the variance in geoethical awareness. ANOVA confirmed statistically significant differences for place attachment [$F(1,29) = 34.330$, $p < 0.001$] and place meaning [$F(2,28) = 21.990$, $p < 0.001$]. The regression equation is: Geoethical Awareness = 2.128 + 0.281 × Place Attachment + 0.332 × Place Meaning. A one-unit increase in place attachment predicts a 0.281 unit increase in geoethical awareness, while a one-unit increase in place meaning predicts a 0.332 unit increase. Place attachment showed a stronger effect, with a standardized coefficient B = 0.458. Multicollinearity checks showed no significant issues (max VIF < 5, Tolerance > 0.2), and the Durbin–Watson value (1.928) indicated independent residuals. Residuals met normal distribution assumptions, with Spearman's rho showing no significant correlation ($\rho = -0.128$, $p = 0.477$).

In summary, place attachment and place meaning are significant predictors of geoethical awareness, with place attachment being a stronger predictor. The model's reliability is confirmed by meeting statistical assumptions, highlighting the importance of emotional and cognitive connections in fostering geoethical awareness.

Conclusions

In the realm of geosciences, safeguarding biotic, abiotic, and cultural elements is crucial for sustainability and resilience. Geoconservation emphasizes geodiversity and biodiversity, highlighting biological, geological, and cultural heritage. Developing a strong sense of place can foster a responsible and cooperative world, enhancing emotional connections and promoting protective behaviors. Geoethics provides a framework for viewing Earth as a system of complex relationships, advocating sustainable practices.

This study on sense of place and geoethics at the Sitia UGGp found high reliability in scales measuring place attachment, place meaning, and geoethical awareness, both before and after summer school. Significant increases in these scales indicated enhanced emotional connections and understanding. Positive correlations among the scales highlighted their interrelation, with regression analysis confirming place attachment and place meaning as predictors of geoethical awareness.

Future research could explore changes in geoethical awareness over time, use interdisciplinary approaches for holistic understanding, and conduct comparative studies across UGGps. Investigating how awareness translates into behaviors and evaluating geoenvironmental education programs could enhance effectiveness. Validating the geoethical awareness scale in diverse contexts is also important.

This research has limitations, including a small sample size, lack of a control group, and potential biases. The focus on Sitia UGGp may limit applicability to other regions.

Acknowledgements

The authors want to express gratitude to the 4th Summer School of Environmental Education on Geotopes and Sustainability organizing committee at Sitia UNESCO Global Geopark and all the participants involved in our study. They also extend their heartfelt thanks to the organizing committee of the 17th International Congress of the Geological Society of Greece and the anonymous reviewers for their thorough consideration of this extended abstract.

EXTENDED ABSTRACT 175

Fault–based recurrence models and occurrence probabilities of large earthquakes (M≥6.0) in the Corinth Rift, Greece

Kourouklas C. [1], Bonatis P.[1], Papadimitriou E.[1], Karakostas V.[1]

(1) Geophysics Department, School of Geology, Aristotle University of Thessaloniki, Thessaloniki, Greece, ckouroukl@geo.auth.gr.

Research Highlights

- The $M^3$6.0 earthquakes recurrence times, T_r, exhibit high variability from 40 to 1500 years, with the southern Corinth Rift fault segments reaching values up to 350 years and their antithetic ones ranging from 400 to 1500 years.
- The fault segments in the Corinth Rift can be devided into three groups, according to their recurrence behaviour, with some of them exhibiting significantly lower renewal model probabilities than the Poisson model, others showing nearly equal probabilities, and one segment where the renewal model probabilities are much higher than the Poisson one.
-

Introduction

The main objectives of the current study include the determination of the mean recurrence time, T_r, of large ($M^3$6.0) earthquakes associated with the major fault segments of the Corinth Rift, Greece, and the estimation of the conditional occurrence probabilities of an impending $M^3$6.0 earthquake on each major fault segment.

The recurrence behavior of large earthquakes (e.g. $M^3$6.0) on specific fault segments is one of the primary input parameters for developing long–term Earthquake Rupture Forecast (ERF) models. These models integrate a series of parameters (maximum observed magnitude, fault dimensions, long–term slip rates, available recurrence times) to estimate the occurrence likelihood of nearly characteristic magnitude earthquakes in a specific time span. The primary output of such models is the mean recurrence time, which can later be used for the application of statistical models, which, in turn, return the likelihood of the occurrence of near characteristic magnitude earthquakes over specific time intervals and can be based on either a time–independent or an elastic rebound motivated renewal assumption.

A precise and robust estimation of T_r requires the inclusion of as many large earthquakes associated with individual fault segments as possible, including both historical and instrumental data along with the selection of the appropriate statistical model. However, large earthquakes associated with specific fault segments are often limited, with only a few cases having about 3 to 10 observations due to the long duration required for stress accumulation and the short time span of available large earthquake records.

To address these challenges and limitations, an alternative approach is the estimation of T_r through the application of the seismic moment rate conservation method (Field *et al.*, 1999). This method defines the mean recurrence time as the ratio of the maximum expected seismic moment corresponding to a large earthquake with the maximum observed magnitude (M_{max}) occurring on a given fault segment, to the seismic moment that might be released by the respective fault segment due to the tectonic loading, assuming a nearly characteristic earthquake model. This approach can provide more precise T_r estimates because the overall rate and size distribution of earthquakes should reflect the tectonic loading in the brittle part of the crust, and this function is typically constrained by the principle of seismic moment rate conservation.

Seismotectonic Setting of Corinth Rift

The Corinth Rift, a prominent E–W oriented elongated graben stretching over 100 km in length, separates the Peloponnese from mainland Greece. It exhibits a remarkable extension rate that varies spatially, with the western section extending at approximately 10 mm/yr and the eastern section at around 5.5 mm/yr (Briole *et al.*, 2021). As a result, the Corinth Rift is one of the most seismically active regions, frequently experiencing large ($M^3$6.0) earthquakes during both the instrumental and historical seismicity periods (Papazachos & Papazachou, 2003), with the most recent one being the 1995 M_w=6.5 Aigion earthquake (Bernard *et al.*, 1997). The intense seismic activity along the Corinth Rift has made it one of the most well studied areas, resulting in the detailed determination of its main fault segments. Information on the M≥6.0 earthquakes are derived from the catalogue provided by Papazachos & Papazachou (2003) and regional parametric earthquake catalog of the Geophysics Department of the Aristotle University of Thessaloniki, consisting of 35 large earthquakes since 373 BC. Studies by Console *et al.* (2013, 2015), after concluding that the large earthquakes catalog could be considered as complete after 1700 AD (since 1714 AD) as well as Kourouklas (2022), suggest that they are not regularly distributed but they are clustered in time. This latter dataset includes 22 M≥6.0 earthquakes (Figure 1).

The southern margin of the Corinth Rift is bounded by eight (8) normal faults, listed from west to east as Psathopyrgos (FS 01), Aigion (FS 02), Eliki (FS 03), Akrata (FS 04), Xylokastro (FS 05), Perachora (FS 06), Skinos (FS 07) and Alepochori

(FS 08) fault segments (Figure 1). Their strike values are almost the same 260° – 280° and their dip angles vary between 30° and 45°. The northeastern boundary of study area is demarcated by the Kapareli fault segment (FS 09), also a normal fault with a strike of 50° and a dip angle of 50°. The fault segment lengths range from 8 km (Akrata Fault Segment) to 22 km (Eliki Fault Segment). All their geometrical and kinematic were summarized by Console *et al.* (2013, and references therein). To the north the Delfoi (FS 10), Makrygialos (FS 11), Sykia (FS 12) and Marathias (FS 13) fault segments are defined from east to west (Figure 1; Ganas 2024, and references therein). Their lengths range from 10 km (Makrygialos and Sykia fault segments) to 18 km (Delfoi fault segment).

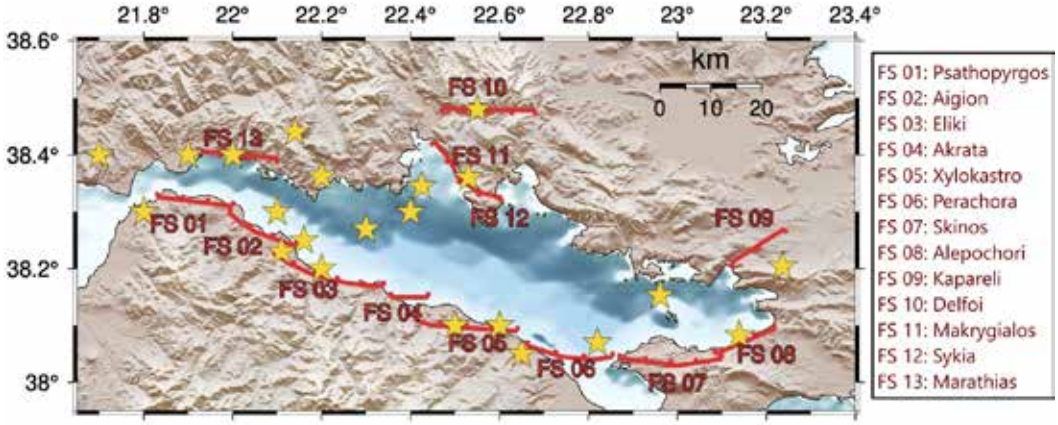

Figure 1. Geomorphological map of Corinth Rift, where the major normal fault segments are represented by red solid lines. Yellow stars depict the M^s6.0 earthquakes occurred in the study area since 1714.

Although the number of large earthquakes (both historical and instrumental) is adequate for regional statistical studies, the number of recurrence intervals become limited when subdivided into subsets associated with specific fault segments. For this reason, Kourouklas (2022, and references therein) attempted to associate the 22 M≥6.0 earthquakes since 1714 with their respective causative fault segments. The analysis suggested that 2 out of 8 fault segments of the western Corinth Rift were associated with two (2) M≥6.0 earthquakes each (Psathopyrgos and Eliki). The Aigion fault segment was linked to four (4) events, whereas the Xylokastro and Perachora segments were each associated with three (3). The Alepochori and Skinos fault segments were associated with one (1) M≥6.0 earthquake each. It is noteworthy that the Akrata fault segment, the shortest in length, has not been associated with any M≥6.0 earthquake since 1714. Similarly, the Kapareli fault segment was also associated with only one (1) M≥6.0 earthquake. In the northern part, the Delfoi, Makrygialos and Sykia segments were associated with one (1) M≥6.0 historical earthquake each, whereas the Marathias fault was linked to two (2) such events. Thus, although the study area is among the most seismically active areas where several large earthquakes rather frequently take place, the insufficient number of M≥6.0 earthquake events per segment restricts the ability to determine T_r by using their observational recurrence intervals as input.

Method

We estimated the mean recurrence time, T_r, by applying the seismic moment rate conservation technique (Field *et al.*, 1999) in the absence of a sufficient number of recurrence intervals for each of the 13 normal faults in the Corinth Rift. This technique assumes that a large earthquake of nearly characteristic magnitude can release the total accumulated seismic moment on a fault. It takes into account the maximum observed magnitude (M_{max_obs}) and its corresponding uncertainty (ΔM) and the maximum seismic moment corresponding to the accumulated strain on the specific fault segment due to tectonic loading. The mean recurrence time is then calculated as the ratio of the seismic moment rate that can be released by the maximum magnitude earthquake to the seismic moment due to strain accumulation on the fault:

$$T_r = \frac{M_{o\,max}}{\mu L w V} \quad (1)$$

where $M_{o,\,max}$ is the maximum possible seismic moment released by a large earthquake with a magnitude within the range $M_{max_obs} \pm \Delta M$. μ is the shear modulus, whose typical value for faults in the Earth's crust is equal to 3.3×10^5 bar ($\mu = 3.3 \times 10^5$ bar), L and w are the length and width of the fault segment (in km), respectively, and V the long–term slip rate.

The maximum expected seismic moment is computed via the definition of seismic moment. The variability of T_r is also computed via the method of formal error propagation technique proposed by Peruzza *et al.* (2010), considering the uncertainties related

to the maximum magnitude and slip rate values. Knowing the variability of mean recurrence time, the standard deviation, σ, can then be easily calculated. The advantage of this approach is that, once T_r and σ are estimated, the corresponding aperiodicity values, α, can be calculated as the coefficient of variation, C_v, of T_r, which is the second appropriate parameter of renewal model applications (Pace *et al.*, 2016).

Using the estimated T_r and σ as the primary inputs, we model the M≥6.0 earthquakes recurrence times by applying both the time–independent Poisson model and the Brownian Passage Time (BPT; Matthews *et al.*, 2002) renewal model, aiming at the estimation of the occurrence probabilities of the next M≥6.0 earthquake to be occurred on each fault segment for the next 10, 20 and 30 years, starting from 1 January 2025.

The Poisson process can be expressed by the exponential distribution with probability density function (pdf) given by:

$$f(t|T_r) = \frac{1}{T_r}\exp\{-\frac{t}{T_r}\} \quad (2)$$

where T_r is the mean recurrence time of large earthquakes associated with a specific fault segment. To model the occurrence of large earthquakes as a renewal process, the BPT distribution is applied. The PDF of the BPT model is given by:

$$f(t|T_r,\alpha) = \left(\frac{T_r}{2\pi\alpha^2 t^3}\right)^{1/2}\exp\{-\frac{(t-T_r)^2}{2T_r\alpha t}\} \quad (3)$$

where T_r is also the mean recurrence time and α is the aperiodicity, which can be considered as analogous to the coefficient of variation, C_v, of the normal distribution.

The occurrence probabilities of a next large earthquake on certain fault in a specific time span can be computed by applying the simple Poisson probability model given by:

$$P(t \le T \le t+\delta t) = 1 - e^{-\delta t/T_r} \quad (4)$$

where $\delta t\delta t$ is the forecast duration and the conditional probability corresponding to the BPT renewal given by:

$$P(t \le T \le t+\delta t) = \frac{\int_t^{t+\delta t} f(t)dt}{\int_t^{\infty} f(t)dt} \quad (5)$$

where t is relative to the date of last earthquake, conditioned by the fact that it has been $t+\delta tt+\delta t$ years since the last one.

Alternatively, the occurrence probabilities of the next large earthquake can be evaluated by the estimation of the hazard function, $H(t)$, of both Exponential and BPT models. This analysis is particularly useful for predicting future rupture scenarios as the values of the hazard function or, in other words, the hazard rate is equivalent to the conditional probability estimate within a specific time span. The hazard function of a given distribution can be easily defined using its corresponding probability density, $f(t)$, and cumulative density, $F(t)$, functions as follows:

$$H(t) = \frac{f(t)}{S(t)} = \frac{f(t)}{1-F(t)} \quad (6)$$

where $S(t)$ is the survival function of the distribution.

Application & Results

The mean recurrence times, T_r, of M≥6.0 earthquakes are estimated through Equation (1) after defining all the appropriate parameters for the application of the seismic moment rate conservation method. These parameters include the fault dimensions (L, w), the maximum observed magnitude, M_{max_obs}, their long-term slip rates (V) and the corresponding uncertainties (ΔM and σV, respectively) which are summarized in Kourouklas (2022). It should be noted that for the definition of the long-term slip rates assigned to each fault segment, 60% of the geodetic slip rates proposed by Briole *et al.* (2021) are used. As previously mentioned, the Akrata fault segment was not associated with any M≥6.0 earthquake and the estimation of the mean recurrence time and the maximum expected magnitude, were calculated using scaling relations, The absence of any M≥6.0 earthquake associated with this fault segment prevents the estimation of any elapsed time, which is necessary for renewal recurrence modeling. For this reason, the Akrata fault segment is excluded from the next steps of the statistical analysis.

The estimated T_r values (Figure 2a) range from a few years (Akrata fault segment; T_r=35 years) to about 1500 years (Makrygialos fault segment; T_r=1511.5 years). These variations are clearly related to the dimensions and slip rates of each segment, which results in different stressing rate values and maximum observed magnitudes. Starting from the southern Corinth Rift fault zone (excluding the Akrata fault segment), mean recurrence times vary from almost 120 years (Psathopyrgos fault segment; T_r=119.4 years) to 359 years (Skinos fault segment; T_r=359.3 years) (Figure 2a). The T_r of M≥6.0 earthquakes increase from the western

part to the eastern one (Figure 2a), due to the gradual decrease of deformation rates from the western to eastern part of our study area. Regarding the respective *Cv* values, it is reported that they exhibit minimal variations, ranging from 0.6 to 0.7 in 6 out of 7 cases (Psathopyrgos, Aigion, Xylokastro, Perachora, Skinos, Alepochori). This suggests that the recurrence behavior of $M \geq 6.0$ earthquakes associated with these fault segments can be characterized as slightly aperiodic. On the other hand, results of our analysis for $M \geq 6.0$ earthquakes associated with the Eliki fault segment indicates that its recurrence behavior can be characterized as highly aperiodic (almost random), given that its *Cv* value is equal to 0.9 ($Cv=0.9$).

Moving to the mean recurrence time results for the northern part, higher values are reported, ranging from 426 years to 1511 years. Specifically, the T_r of $M \geq 6.0$ earthquakes associated with the Kapareli fault segment is found equal to 426 years, with a *Cv* value of 0.6. The mean recurrence time for the Delfoi fault segment is equal to $T_r=933.1$ years, whereas the T_r of $M \geq 6.0$ earthquakes associated with Makrygialos and Sykia fault segments are even larger, with $T_r=1511.5$ years and $T_r=1070.1$ years, respectively. The mean recurrence time of $M \geq 6.0$ earthquakes associated with the Marathias fault segment is $T_r=546.1$ years. The coefficient of variation for all four these cases (Delfoi, Makrygialos, Sykia, Marathias) is estimated equal to $Cv=0.7$.

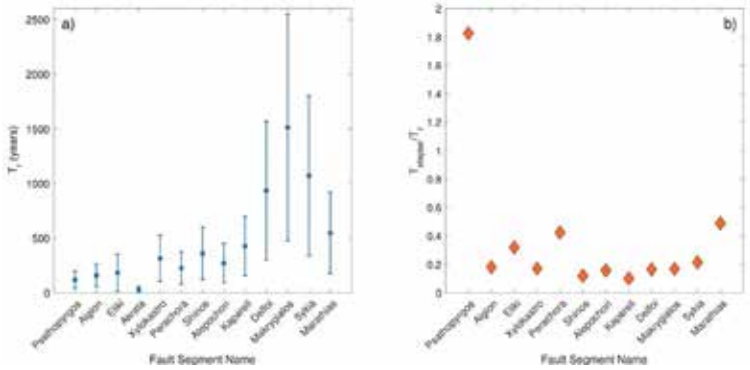

Figure 2. (a) Mean recurrence time, T_r, estimates of $M \geq 6.0$ earthquakes (blue circles), along with their ±1σ (vertical blue solid line) for the 13 normal fault segments of the Corinth Rift. (b) The ratio of elapsed time, T_e, of the last $M \geq 6.0$ earthquake that occurred in each fault segment (except from Akrata fault segment) and the mean recurrence time, T_r, estimates.

One more important factor for the statistical modeling of T_r, especially for time–dependent approaches, is the elapsed time, T_e, since the last earthquake. Specifically, the ratio of T_e over T_r can serve as an initial indicator of the stage of the earthquake cycle for a given fault. Values of this ratio approaching zero indicate the early stage of a new earthquake cycle, while more increased values indicate that the fault is closer to the next rupture. Figure 2b shows the ratio of the elapsed time to the mean recurrence time for the seven fault segments. The smallest value is reported for the Aigion fault segment, which is the most recently ruptured (T_e = 28.57 years). For 10 out of the other 11 fault segments, the ratio ranges between 0.17 and 0.55, also showing that the elapsed time is considerably shorter than the mean recurrence time. This suggests that these faults are likely in the early stages of their seismic cycle. The only case in which the ratio is larger than 1.0 is the Psathopyrgos fault segment (Figure 2b), meaning that the elapsed time since the last $M \geq 6.0$ is much larger than the estimated T_r.

Next, we applied the exponential and BPT distributions, representing the Poisson and renewal models, using the mean recurrence time, T_r, and *Cv* values obtained from the seismic moment rate conservation approach. The ultimate goal is to model the recurrence behavior of the $M \geq 6.0$ earthquakes associated with the normal faults of the study area. We focused primarily on the hazard functions of both statistical models, as their (hazard) rates can be considered equivalent to the conditional probability estimates over a specific time span. Figure 3 shows the hazard functions of the exponential and BPT distributions for the seven (7) fault segments of the southern part (Psathopyrgos, Aigion, Eliki, Xylokastro, Perachora, Skinos and Alepochori), in which their significant differences in modeling T_r are highlighted.

Starting from the Psathopyrgos fault segment (Figure 3a) the constant hazard rate of the Poisson model (blue solid line) is considerably lower than the hazard rate of the BPT model (red solid line), which exhibits a decreasing trend, at the time corresponding to T_e (until 31-12-2024). On the other hand, in the case of the Aigion fault segment (Figure 3b), the most recently ruptured segment in the study area, the hazard function values of the Poisson model (blue solid line) are considerably larger than the values obtained from the application of the BPT, at the time corresponding to T_e. The BPT model application on the Eliki fault segment (Figure 3c) reports hazard rates slightly higher than those of the Poisson model around the time corresponding to the elapsed time (black dashed line in Figure 3c). More specifically, the BPT hazard function values exhibit an increasing trend for the next 10, 20 and 30 years after 31-12-2024. Similarly, for the Aigion fault segment, the hazard function values of the Poisson model (blue solid line) are considerably larger than the values of the BPT model for the recurrence behavior of the $M \geq 6.0$ earthquakes associated with the Xylokastro fault segment (Figure 3d), indicating that the fault segment is at an early stage of a

new earthquake cycle at time *t* corresponding to the elapsed time. For the Perachora fault segment both models report almost equal hazard rates (Figure 3e) and lastly, for the Skinos and Alepochori fault segments (Figures 3f and 3g, respectively) the hazard function values of the BPT model are significantly lower than the ones of the Poisson model at time *t* corresponding to the elapsed time, highlighting that both segments are at an early stage of a new earthquake cycle according to the renewal model.

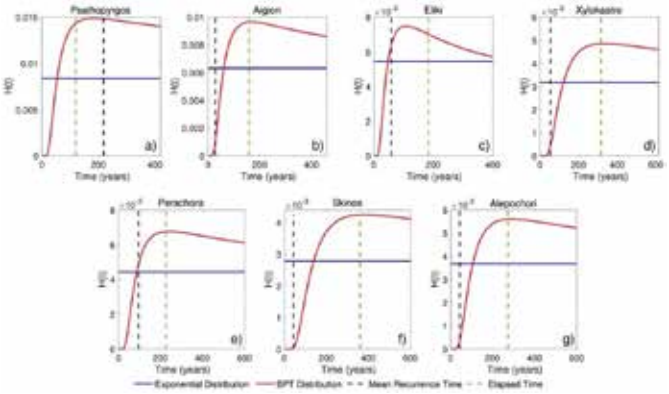

Figure 3. Hazard functions, *H(t)*, for the Psathopyrgos (a), Aigion (b), Eliki (c), Xylokastro (d), Perachora (e), Skinos (f) and Alepochori (g) fault segments according to the Exponential (blue solid lines) and the BPT (solid red lines) distributions. Vertical dashed lines denote the elapsed time since the last *M*≥6.0 earthquake (*t* = 0) occurred on each fault segment, whereas the vertical dashed black lines denote the mean recurrence time of *M*≥6.0 earthquake for each fault segment.

Focusing on the recurrence modeling results for the five (5) fault segments of the northern Corinth Rift fault zone, in 4 out of 5 cases the hazard rate values of the renewal model are significantly lower than those of the Poisson model. Specifically, the statistical modeling of *M*≥6.0 earthquakes associated with the Kapareli (Figure 4a), Delfoi (Figure 4b), Makrygialos (Figure 4c) and Sykia (Figure 4d) fault segments show that the hazard rate estimates of the time–independent Poisson model are considerably higher (blue solid lines in Figures 4a, 4b, 4c and 4d) than the ones of the BPT model (solid red lines). More specifically, for the Kapareli fault segment, the BPT model hazard function values are almost zero at the time corresponding to the elapsed time, whereas the constant hazard rate of the Poisson mode is equal to 2.4×10^{-3}. Statistical modeling for Delfoi, Makrygialos and Sykia fault segments indicates slightly different results for the renewal model, with its hazard function values exhibiting an increasing trend for the next 10, 20 and 30 years after elapsed time (vertical dashed black lines in Figures 4b, 4c and 4d) in all cases. On the contrary, the recurrence modeling of *M*≥6.0 earthquakes associated with the Marathias fault segment (Figure 4e) reports hazard rates slightly higher than the ones of the Poisson model around the time corresponding to the elapsed time.

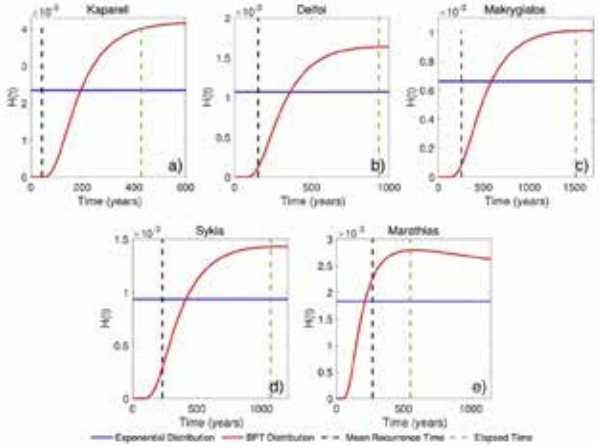

Figure 4. Hazard functions, *H(t)*, for the Kapareli (a), Delfoi (b), Makrygialos (c), Sykia (d) and Marathias (e) fault segments according to the Exponential (blue solid lines) and the BPT (solid red lines) distributions. The vertical dashed lines denote the elapsed time since the last *M*≥6.0 earthquake (*t* = 0) occurred on each fault segment, whereas the vertical dashed black lines denote the mean recurrence time of *M*≥6.0 earthquake for each fault segment.

Conclusions

In this study, we present both time–dependent and time–independent recurrence models to investigate the mean recurrence time of $M \geq 6.0$ earthquakes associated with the main normal faults of the Corinth Rift. We used the most detailed available input data (fault network model, long–term slip rates) for the estimation of the mean recurrence time, T_r, by applying the physics–based seismic moment rate conservation method. The results show that T_r ranges from about 40 years to almost 1500 years, depending on the combination of the input parameters. The statistical analysis of T_r via the Exponential and BPT distributions (representing the Poisson and a renewal model, respectively) reveals that the recurrence behavior of the Corinth Rift fault segments can be divided into three distinct groups. The first group includes fault segments where the elapsed time since the last earthquake is considerable smaller than the T_r. This group includes the Aigion, Xylokastro, Skinos, Alepochori, Kapareli, Delfoi, Makrygialos and Sykia fault segments. For all these cases the renewal model's hazard function values and the corresponding conditional occurrence probabilities for the next 10, 20 and 30 years show significant differences among the two applied models, with the BPT model yielding much lower values than the Poisson model. These findings indicate that the aforementioned fault segments are at an early stage of a new earthquake cycle according to the renewal model. The second group includes the Eliki, Perachora and Marathias fault segments for which the hazard rates of both models are almost equal, resulting in similar occurrence probabilities for the next 10, 20 and 30 years. The last group includes only the Psathopyrgos fault segment for which the BPT model reports significantly larger hazard rate values than the Poisson model. The Psathopyrgos fault segment is the only case where the elapsed time since the last $M \geq 6.0$ earthquake exceeds the mean recurrence time, indicating that from a statistical point of view, it is at a later stage of a new earthquake cycle. Consequently, the occurrence probabilities for the next $M \geq 6.0$ earthquake to occur in the next 10, 20 and 30 years are the highest within the study area. The results of our analysis could serve as the basis for fault–based large earthquake occurrence models. By considering time–dependent occurrence models in probabilistic seismic hazard analysis (PSHA) one can account for epistemic uncertainties, quantify the range of seismic hazard for a given exceedance probability and illustrate which model assumptions lead to the most significant variations in the estimated seismic hazard (Akinci *et al.*, 2017). By utilizing these models, stakeholders can better determine when and where protective measures are most urgently needed, particularly in regions with higher short-term earthquake probabilities, leading to more effective seismic risk management.

Introduction

Volcanism in the Aegean results after the subduction of the African plate beneath the European. The present-day active volcanic arc consists of five major volcanic centers (Sousaki, Methana-Aegina, Milos-Antimilos, Santorini-Kolumbo, and Nisyros-Kos). In the eastern Aegean, several large-scale volcanic eruptions took place during Late Pleistocene, which produced large quantities and relatively thick layers of pumice and vitric ash. These were distributed throughout various regions, but they are more evident in proximity to the volcanic centers. Their origin is mainly associated with the phreatomagmatic volcanic eruption of Nisyros volcano at eastern flank, which corresponds to the Kyra sequence at 161 ka (Sterba, 2007; Sterba *et al.,* 2011). Pyroclastic deposits in the form of pumice from this eruption have been recorded not only to the southeast at Tilos island but also to the north at Kalymnos Island, and to the east at Datça peninsula in Turkey, expanding over an area of approximately 3000 km^2. KPT pyroclastic deposits have been investigated by Smith *et al.* (1996) and Steinhauser *et al*. (2007) in order to refine the chemical fingerprint of the KPT eruption

Explosive rhyolitic eruptions form one of the most hazardous catastrophic events that can occur on earth (Allen 1999). The eruption of the Kos Plateau Tuff (KPT) produced massive rhyolitic fallout, high-density pyroclastic flows, and massive ignimbrites (Allen, 2001). The inflow of seawater to the magmatic chamber at the early stages of the eruption can be considered as the mechanism that led to a phreatomagmatic type of eruption. The fact that the lithic breccia is followed by the deposition of ignimbrites forms an important volcanological feature which implies the collapse of the caldera and links with its initial stages. This feature has also been noticed in the Minoan eruption of Santorini (Heiken and McCoy,1984). During caldera collapse, the pressure and the mass flux increase simultaneously (Wilson *et al.,* 1980; Carey and Sparks, 1986; Carey and Sigurdsson, 1989). Pyroclastic deposits withhold information about the eruption and/or mass flux nevertheless the precise classification of internal stratigraphy and lithofacies combined with petrographical and geochemical results can pose fundamental objectives regarding the dynamics of the eruption.

Geological Setting

The non-volcanic island of Tilos lies to the southeast of the volcanic islands of Kos and Nisyros. Stratigraphically, Tilos consists of biosparudites limestones and dolomites, locally representing the 'Hallstatt' phase. These rocks date from Triassic to the Lower Jurassic. Furthermore, it consists of Upper Jurassic thin-bedded pelagic plate micritic limestones, Upper Cretaceous pelagic biomicritic limestones as well as pyroclastic deposits from the KPT eruption (Stadlbauer, 1988; Johannes and Sterba, 2007). The pyroclastic rocks are mostly represented by tuffs and pumices, which in most cases correspond to acid compositions (e.g., rhyolite), and date to the Quaternary. According to Allen and Cas (1998), Tilos pyroclastic rocks are subdivided into i) ash-rich facies (~1 meter), ii) pumice-rich facies (~50 centimeters) and iii) pumiceous ignimbrites. The pumiceous ignimbrites, which are correlated with the E stromatographic unit of Nisyros (Allen and Cas, 1998), contain basaltic lithic fragments (Figure 1a) and are rather restricted in only a few outcrops in the field. Based on field observations, pumice-rich facies underlain the ash-rich facies. The ash-rich facies are coarse-grained and exhibit internal wavy and irregular bedforms (Figure 1b), whilst pumice-rich facies display fine lithic lapilli. The lithic clasts of this layer are rather small in size (< 40 centimeters) and the matrix material is fine-grained compared to the overlying pumiceous ignimbrite.

Figure 1. (a) Field photograph from the lower pyroclastic unit, comprising of lithic fragments, many of which are basaltic, (b) Field photograph from pumice succession of pyroclastic tuffs.

Materials and Methods

Twenty rock samples were collected from Tilos Island. These were macroscopically classified into two major groups i) pumices and ii) basaltic lithic fragments taking into account field observations as well. All samples were subsequently crushed and pulverized for conducting bulk mineralogy investigation through X-ray Diffractometry (XRD) as well as polished thin sections were prepared for conducting petrographic examination through transmitted light optical microscopy. Bulk mineralogy of the studied samples was determined using a Bruker D8 Advance Diffractometer with Ni-filtered CuKα radiation at the Research Laboratory of Rocks and Minerals of the University of Patras. The scanning angle (2θ) interval was 2–70° with an angular step size of 0.015° and a time step of 0.1 s. Subsequently, mineral phases were determined using the DIFFRACplus EVA 12® software (Bruker-AXS GmbH, Karlsruhe, Germany) and the ICDD Powder Diffraction File of PDF-2 2006. Petrographic examination was performed using a polarizing petrographic microscope (Leitz Ortholux II POL-BK Ltd., Midland, ON, Canada) at the Research Laboratory of Rocks and Minerals of the University of Patras.

Results-Discussion

In the present study, three main types of pyroclastic rocks were observed based on field observations. Most of the thin layers are ash-rich layers and pumice-rich layers that collapsed and flattened as they were re-heated, whereas in some cases the pumice clasts have relatively high vescularity, revealing high intensity phases. The matrix material is quite friable and finely crystalline, with yellow ash dominating the most outcrops. Lithic fragments show a diversity (e.g., basaltic, pumice) and in restricted outcrops has also established obsidian. Basaltic lithic fragments are mainly found within the lower pyroclastic unit (Figure 1a) are well preserved and have been subjected to only minor alterations. Pumice samples show an excellent color contrast between the various clasts (red, orange, brown, etc.) and the compressed ash (white). The pinkish to brownish hue characteristic for some samples is mainly due to oxidation but could also related to the presence of xenoliths (i.e., basaltic blocks; Figure 2b).

Pyroclastic rocks present vitrophyritic texture and contain plagioclase (mainly albite-oligoclase), clinopyroxenes (augite) and alkali feldspars. They also contain tubular fragments of pumice as well as bonded clay margins on glassy and crystalline surfaces, which record the initial stage of diagenesis in this semi-molten pumice breccia. These clay margins in many cases enclose crystalline and glassy fragments. In some cases, microfossils were also established within the matrix. The pyroclastic texture of most tuffs is not so evidently identified. Basaltic lithic fragments contain plagioclase, clinopyroxene, and alkali feldspars (Figure 3). Despite the glassy and fine-grained nature of the studied rocks, they display trachytic texture and, in some cases, glomeroporphyritic textures (Figure 3).

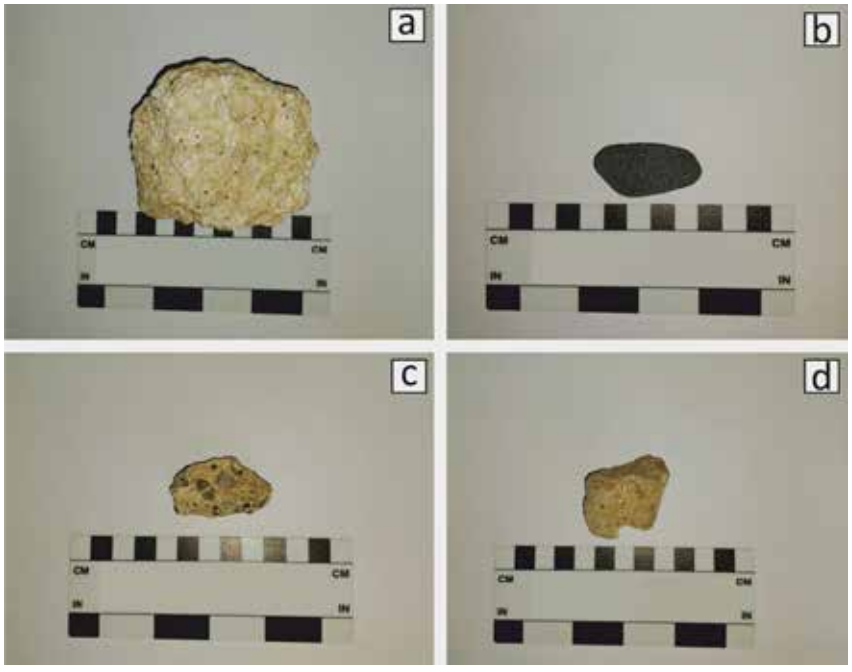

Figure 2: Representative samples from Tilos Island, a) Vesicular pumice, b) Basaltic lithic fragment, c) Pumice with individual clasts, and d) Pumice with low porosity.

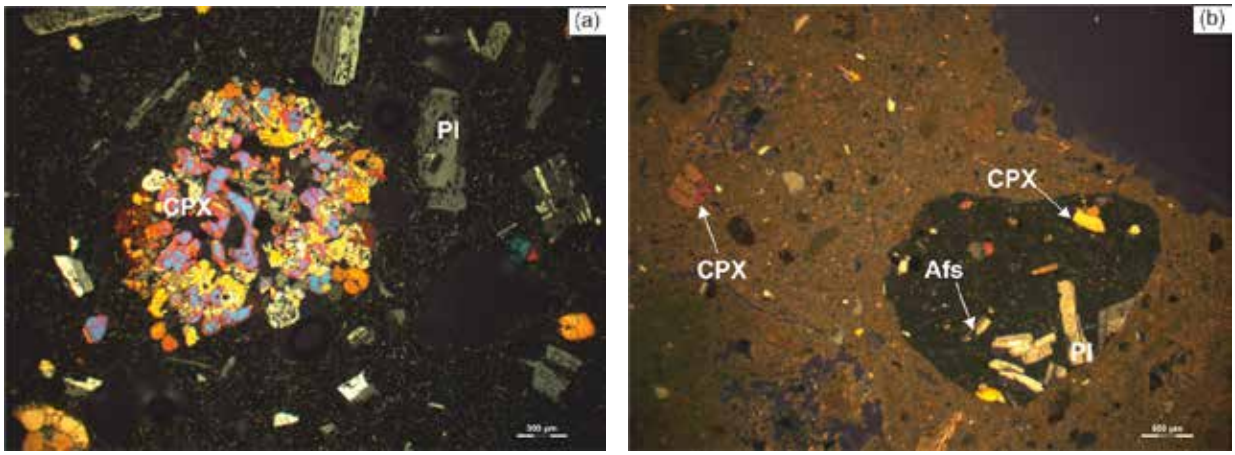

Figure 3. Photomicrographs of: (a) hornblende basaltic lithic fragment with quenched glomerophyric clinopyroxenes (CPX) and plagioclase (Pl) and b) pyroclastic lapilli tuff with devitrified glass with clinopyroxene (CPX) phenocryst and basaltic lithic fragment with clinopyroxene phenocrysts (CPX), plagioclase (Pl) and alkali feldspar (AFS).

Conclusion

The internal stratigraphy and the deposition of the lithofacies reflect a dynamic high-intensity eruption. In particular, the deposition of these basaltic lithic fragments seems to be vent-derived, resulting from the deposition of voluminous ignimbrites. For the case of Tilos, the conduit type of lithic fragments can be an eruptive indicator. Also, the textural changes in the vesicularity of the pumice show possibly two stages of depressurization and the influence of the volatiles during the phreatomagmatic eruption. These patterns have a strong impact, and their understanding would be critical for potential hazard assessment. Through a more comprehensive volcanological view, further investigation combining field observations and detailed mineral chemistry analyses of the fluid inclusion on the lithic fragments and the pumice will highlight the importance of volatiles in post-caldera forming reactions.

EXTENDED ABSTRACT 177

A preliminary petrographic approach of the altered Triassic volcanic lavas in Argolis, Greece

Petros Koutsovitis[1], Aikaterini Papaioannou[1]
(1) University of Patras, Department of Geology, GR-26504 Patras, Greece
E-mail address: pkoutsovitis@upatras.

Introduction

In the northeastern Peloponnese lies the region of Argolis, an area of significant geological interest, as its geotectonic position belongs to the Sub-Pelagonian zone, characterized by intense and extensive tectonism, involving the presence of five distinct tectonic units. These comprise of: i) Trapezona Unit (M. Triassic - L. Jurassic: limestones, radiolarites, lavas), ii) Demaina Ophiolite Unit (L. – L. Cretaceous: ophiolites, basalts, pillow lavas, limestones, radiolarites, dolerites), iii) Adheres Melange Unit (Palaeocene – Eocene: silt, sandstone, marl and Triassic: limestones, radiolarites and Jurassic: metagranodiorites, andesites, basalts, mineralized sediments, dolomites), iv) Iliokastron Melange Unit (ophiolite melange), v) Faniskos Unit (L. Cretaceous: above the “Trapezona” and “Demaina Ophiolite Unit” units). The region primarily consists of Triassic and Jurassic-aged rocks (Bortolotti et al., 2003; Celet & Ferriere, 1978; Jacobshagen et al., 1978; Gioni, 2021). The study was mostly focused on the Middle Unit, occurring in Central and Northern Argolis (Bortolotti et al., 2001, 2002; Baumgartner, 1985). This investigation integrates field observations with detailed microscopic analyses of the most representative rock samples. Emphasis was given to interpret alteration effects that are a key characteristic of these rocks. The Triassic basaltic rocks of the Middle Unit are classified as trachybasalts (Saccani et al., 2015), mostly in the form of pillow lavas, with OIB and E-MORB geochemical signatures (Baumgartner, 1985; Dostal et al., 1991). The vast majority of these exposed rocks in the field exhibit evidence of low-grade metamorphism and metasomatic processes. The research focuses on characterizing the secondary processes that influenced the Triassic volcanic lavas of the area, with an emphasis on their petrographic and mineralogical classification.

Results - Discussion

The most representative samples were selected for the preparation of thin sections. Through pulverization, the samples were prepared for analyses via X-ray diffractometry (XRD). In addition, the Petrographic study was carried out using an optical microscope for observation of the rocks’ mineralogical characteristics.

Residual phases of primary minerals were recorded, due to the significant degree of alteration. These mainly include clinopyroxene (Cpx) and plagioclase (Pl), with the presence of plagioclases being more Ca-rich in their center (An) and more Na-rich at the periphery (Ab), exhibiting the albitization phenomenon. The microcrystals of clinopyroxene appear altered and with intense colors throughout the fundamental mass of the samples. It is observed that the entire glass has been transformed into secondary chlorite, actinolite, and montmorillonite. Additionally, we have the presence of accessory mineral of ilmenite (Ilm), as well as secondary alteration of primary mineralogical components with concurrent formation of chlorite (Chl), epidote (Ep), prehnite (Prh), calcite (Cc) with characteristic zoning and the form of spherical mineral amygdales, while in small-length veinlets analcime (Anl), as well as other zeolites (Zeo), are present.

Additionally, in certain samples, actinolite (Act) and tremolite (Tr) were observed replacing clinopyroxene (Cpx), while there are also microlites of alkaline feldspars (K-feld) and paragonite (Pg). The phenocrysts of quartz (Qz) represent a secondary phase, complementary to chlorite, and they are intensely deformed. The modal composition of secondary zeolites found in some of the samples is estimated to be ~10 vol.%. The type of zeolite observed in most of the samples from the area is Mordenite, as well as Analcime. Specifically, the zeolites appearing in the form of small-sized crystals were observed filling voids and microfractures, indicating hydrothermal processes and a low degree of metamorphism.

The petrographic study of the Triassic lavas of Argolis reveals the significant secondary processes that occurred after the intense volcanic activity during the Triassic period. These processes are generally common for the various Triassic lavas of the Hellenic region (Castorina et al. 2020 - Koutsovitis et al. 2012 - Magganas et al. 1997 - Magganas and Kyriakopoulos 2005 - Pe-Piper and Piper 2002). However, in the study area, the significant involvement of zeolites in the secondary phases stands out, as they locally constitute the dominant metasomatic phase, fully replacing the primary phases. A more precise characterization of the zeolitic phases requires further investigation through mineral chemical analyses methods, while it is also deemed necessary to conduct geochemical analyses to detect trace

element variations during the secondary processes.

Petrographic evidence for the metamorphic conditions in ultramafic rocks at Makrymalli - Evia Island

Petros Koutsovitis[1], Konstantinos Tetisis[1], Georgia Kolovadi[1]
(1) University of Patras, Department of Geology, GR-26504 Patras, Greece
E-mail address: pkoutsovitis@upatras.gr

Introduction

The aim of this announcement is to highlight the greenschist facies as the main metamorphic facies that affected the ultramafic rocks of the Makrymalli area, based on petrographic data. Makrymalli is a region in central Evia (Central Greece). In geotectonic terms, the region belongs to the Pelagonian zone and is mainly comprised of mafic and ultramafic volcanic and sedimentary rocks (Danelian and Robertson, 2001). The extensive ophiolitic complex that represents the ultramafic rocks of the area consists mainly of harzburgites (Danelian and Robertson, 2001), variably serpentinized, including both serpentinites and serpentinized harzburgites, although serpentinized lherzolites were also identified. Their metamorphic grade is classified as greenschist facies, though some evidence suggests that, on local scale, metamorphic conditions may have been more intense (Simantov et al., 1990). These ophiolites are related to the subduction of the oceanic crust of the Tethys Ocean and the subsequent closure of the Pindos and Vardar Oceanic basins; the Pelagonian platform host ophiolitic thrust sheets from both basins.

Results- Discussion

The samples analyzed in this study comprise of serpentinized harzburgites, lherzolites and also serpentinites. They are clearly serpentinized, with lizardite and antigorite occurring in rather balanced amounts. Serpentinization occurs at rates of 75% to 85% on average in microscopic sections. Uralitization is also observed in certain lherzolites, at the expense of relict clinopyroxene. Mesh textures are frequently observed especially in the highly serpentinized varieties. The presence of lizardite and antigorite in the ultramafic rocks of Makrymalli in rather balanced amounts, suggests that metamorphism did not exceed greenschist facies (~320°C - 340°C, P ≈ 6-7 kbar; Guillot et al., 2015). This is further supported by the fact that spinel rims were not altered to Cr-magnetites but also because orthopyroxene bastites were pseudomorphically retained their former crystal appearance. These metamorphic conditions are evidently lower than those that were established for the adjacent East Thessaly serpentinites, where the predominance of antigorite corresponds to blueschist facies metamorphism (~ 360–400 °C, P ≈ 11–12 kbar) (Koutsovitis, 2017). Furthermore, thin crosscutting chrysotile veinlets, as well as the presence of talc and minor chlorite, point to retrograde low-metamorphic conditions during exhumation. Serpentinization subsequently led to the formation of Fe-oxides such as magnetite in the serpentinite matrix. In some of the serpentinized lherzolites, distinct deformation and undulose extinction was observed in clinopyroxene crystals, suggesting local deformation phenomena. Serpentinites in few cases were locally subjected to local mylotinization and even brecciation, being characterized by their mylonitic fabric and by the higher modal amount of antigorite.

Introduction

St. Martin is located at the northern parts of the Lesser Antilles (Caribbean). Oligocene magmatic rocks include plutonic intrusions and volcanics (Davidson et al., 1993). Their age has been determined between 26 to 31 Ma relying upon K-Ar data (Davidson et al., 1993). The plutonic granitoids mostly comprise of tonalites, quartz-monzodiorites and granodiorites (Davidson et al., 1993, Noury et al. 2021, Koutsovitis et al. 2025). Granitoid plutonism is assigned to subduction and subsequent convergence of the Farallon, South American and North American plates (Lidiak and Jolly, 1996).

For the purposes of the present announcement, we briefly outline some of the findings, recently outlined in detail by Koutsovitis et al. (2025), concerning some of the St. martin granitoids that encompass relatively high modal amounts of mafic minerals.

Results

The recently reported St. Martin melatonalites (Koutsovitis et al. 2025), clearly correspond to granitoids, with their total modal composition of quartz, plagioclase and alkali feldspars exceeding 50 vol.%. Most participating mineral phases are medium grained, suggesting plutonic crystallization condition. Their modal composition was determined through point counting and CIPW calculations. Accessory minerals were determined through microprobe facility. Classification relied upon normative Q, A, P percentages. Their M' colour index, based on the mafic minerals, suggests that these are in fact melatonalites with elevated M' values. They are also characterized by the following features: i) relatively restricted modal amount of quartz, ii) higher normative anorthite than albite, iii) participation of cordierite, orthopyroxene and phlogopite. iv) low LOI contents, in accordance with the presence of phlogopite and complete absence of any alteration effects. Accessory minerals comprise of ilmenite, Ti-magnetite and apatite.

Plagioclase of the St. Martin melatonalites are characterized by their relatively high An components, displaying normal compositional zoning (Koutsovitis et al. 2025); K-feldspars are absent. Orthopyroxenes are enstatites with moderate Mg#, low Al, Cr and Ni contents (Koutsovitis et al. 2025). Clinopyroxenes and amphiboles are absent, in contrast to the other granodiorites present in St. Martin. Phlogopites display rather enhanced Ti and Ba contents, whereas cordierites exhibit rather high Mg values. Geochemical results show that the melatonalites are characterized by their enhanced Ti, Fe and Mg contents (Koutsovitis et al. 2025). Based upon various geochemical classification plots, these rocks correspond to low-K, calcic and magnesian granitoids, with a transitional character between calc-alkaline to tholeiitic (Koutsovitis et al. 2025).

Discussion-Conclusions

Apparently, the presence of cordierite within the melatonalites signifies that these may correspond to S-type granitoids. This is further supported by their peraluminous character (Koutsovitis et al. 2025). However, this is not consistent with their very low-K, as well as their behavior in Harker binary plots, pointing to an I-type character. Furthermore, additional major and trace element ratios comply with restricted involvement of sediments in the source and were more affected by hydrous and slab-derived fluids (Koutsovitis et al. 2025). Geothermometry applications reveal relatively high temperatures for the melatonalites compared to the other granitoids. Pressure calculations show that these were crystallized at the relatively deep parts of the arc (Koutsovitis et al. 2025). It seems that these rocks

formed at the early stages of subduction and may likely represent one of the few traces of CLIP influence, associated with early hybridization of the mantle wedge (Koutsovitis et al. 2025).

Introduction and objectives

Mafic sulfide deposits in Cyprus were studied by Hannington et al. (1998) and Adamides et al. (2010). They are composed mostly of pyrite (Parvaz, 2014). The acid mine drainage (AMD) is the result of sulfide minerals and waste oxidation due to exposure to water and oxygen conditions affecting large areas. The case study is the Memi inactive pyrite mine in Nicosia, Cyprus. Herein, we applied Remote Sensing (RS) techniques for the monitoring of the mine area. To this purpose, the Visible Near Infrared and Shortwave Infrared (VNIR-SWIR) spectral bands of multispectral (MSI) and hyperspectral satellite imagery (HSI) were used. More specifically, a combination of Sentinel-2, WorldView-3 (WV3), both VNIR and SWIR, and Environmental Mapping and Analysis Program (EnMap) data were employed. Two different spectral libraries, namely the United States Geological Survey (USGS) and Jet Propulsion Laboratory (JPL) spectral libraries, and three spectral processing methods were selected to analyze the data in the frame of the m4mining project.

The m4mining project aims to provide an integrated remote sensing approach for mapping and monitoring active and inactive mining sites. MSI and HSI imaging are combined with in situ measurements and are utilized for material identification from the detailed mine face to the site scale using unmanned aerial vehicles (UAVs) and satellite sensors. Central to the proposed work is a synergistic combination of UAV and satellite-based processing algorithms, workflows, and decision-making tools at timescales required to impact active operations and environmental and risk management of tailings and waste sites.

This study aims to investigate the suitability of EnMap, Sentinel-2, and WV3 data for the detection and mapping of minerals related to pyrite -AMD.

Data and methodology

The Memi mine is located in Nicosia district, Cyprus (35° 2'30.11"N, 33° 2'19.61"E). Six minerals (Table 1, Figure 1) namely hematite, goethite, ferrihydrite, jarosite, schwertmannite, and copiapite (hereafter endmembers) were selected for AMD identification within the inactive pyrite mine study area. USGS and JPL spectral libraries were used to retrieve the spectral signatures of hematite, goethite, and jarosite which were convolved to EnMap, Sentinel-2, and WV3 spectral bands while spectral signatures of ferrihydrite, schwertmannite, and copiapite were not available in the JPL library.

The endmember selection criteria were the grain size and the spectral purity of the sample. A spectral signature with fine to medium grain size approximated the grain size of the minerals in the study area while the spectral purity defined the presence and/or the absence of contaminants. We selected spectral signatures with the least possible contaminants and a fine to medium grain size.

Table 1. Description of endmembers used in this study. For each mineral in the second column, the first row corresponds to the spectral signature name in the USGS spectral library, and the second row corresponds to the spectral signature name in the JPL spectral library. The spectrum title and information were retrieved from the corresponding ancillary file of each mineral from each spectral library.

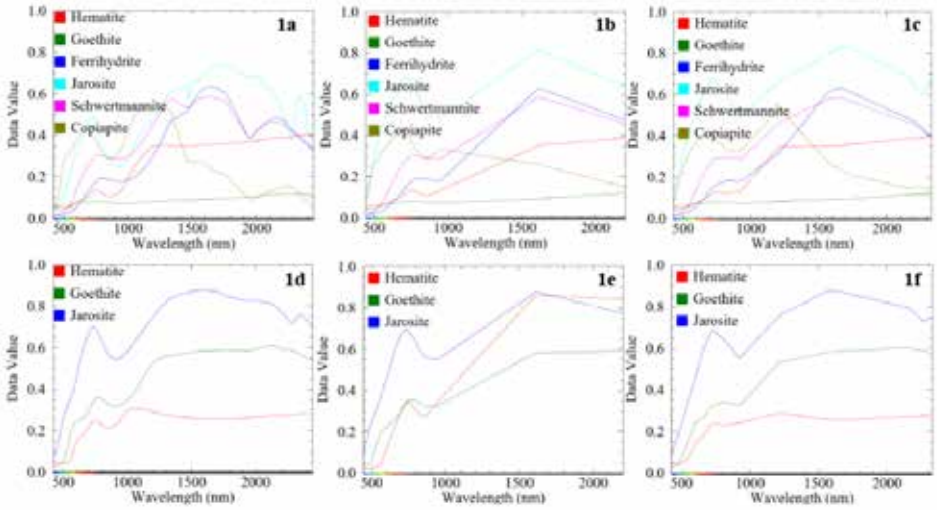

Figure 1. Mineral spectral signatures used in this study, (a) retrieved from the USGS spectral library convolved to the EnMap spectral bands; (b) retrieved from the USGS spectral library convolved to the Sentinel-2 spectral bands; (c) retrieved from the USGS spectral library convolved to the WV3 VNIR and SWIR spectral bands; (d) retrieved from the JPL spectral library convolved to the EnMap spectral bands; (e) retrieved from the JPL spectral library convolved to the Sentinel-2 spectral bands; (f) retrieved from the JPL spectral library convolved to WV3 VNIR and SWIR spectral bands.

For the purpose of this study, a Sentinel-2 Level 2A VNIR-SWIR image (12 spectral bands) was used, acquired on 2024/07/26. The archived WV3-VNIR and SWIR datasets (16 spectral bands) were also used (acquired on 2018/04/03-VNIR and 2020/09/12-SWIR). The WV3 data were atmospherically corrected by ReSe Applications. Although the WV3 data were acquired on two different dates, namely 2020 and 2018, after atmospheric corrections they were handled as one dataset (a total of 16 spectral bands). The atmospherically corrected EnMap data (acquired 2024/07/14) VNIR-SWIR (224 spectral bands) were conceded by the Helmholtz Centre Potsdam - GFZ German Research Centre for Geosciences (GFZ). The EnMap spectral bands 131-135 (1342.82-1390.48nm) were set as bad bands and excluded from the analysis. The spatial resolutions of EnMap, Sentinel-2, and WV3 data used in this study are 30m, 10m, and 3.7m respectively. The EnMap, Sentinel-2, and WV3 datasets were analyzed as layer-stacked (VNIR-SWIR) data: one layer stack for each sensor (EnMap, Sentinel-2, and WV3). To discriminate the spectral bands between the different types of sensors, we hereafter named the EnMap spectral bands Ebx (e.g. Eb1), the Sentinel-2 ones Sbx (e.g. Sb1), and WV3 ones Wbx (e.g. Wb1). The reflectance values were between 0 and 1 and each scene was cropped to the mine area extent. The mineral reflectance values issued from the spectral libraries vary between 0 and 1 as well. An NDVI threshold of 0.25 was applied to mask vegetation.

Three different processing methods were employed: spectral indices (SI), band depth (BD) analysis using continuum removal, and spectral angle mapping (SAM). The selected spectral indices used in this study are given in Table 2 and some of the results are presented in Figure 2. For BD and SAM calculations, six USGS endmembers and three JPL endmembers were used to detect the wavelength/band of the minerals' diagnostic absorption features (Sykioti et al, 2023) and compare the spectral angle between the spectral vectors of image pixels and reference spectra, respectively. Moreover, in BD, pixels with absorption <0.01 were masked while the threshold angle for SAM was set to 0.35 for EnMap (USGS endmember), 0.30 for EnMap (JPL endmember), 0.40 for Sentinel-2 (USGS & JPL endmembers), and 0.25 for WV3 (USGS and JPL endmembers).

Table 2. Overview of used spectral indices applied to this study. The SIs for EnMap and Sentinel-2 were retrieved from van der Meer et al. (2014), Ge et al. (2020), and the Index DataBase (https://www.indexdatabase.de/, accessed 02/11/2025). The SIs for WV3 were retrieved from Hildebrand (2022).

Spectral Index	EnMap	Sentinel-2	WV3
Ferrous Iron	(Eb216/Eb60) + (Eb22/Eb37)	(Sb12/Sb8a) + (Sb3/Sb4)	(Wb13/Wb7) + (Wb3/Wb5)
Ferric Iron	(Eb37/Eb22)	(Sb4/Sb2)	Wb5/Wb3
Ferric Oxides	(Eb164/Eb60)	(Sb11/Sb8a)	Wb11/Wb7

Results and Conclusions

SI maps: Using the SIs, we mapped ferric iron, ferrous iron, and ferric oxides in different spectral and spatial resolutions (Figure 2). As seen in Figure 2, generally, the SI ferrous iron values obtained were higher than the SI ferric iron ones. Furthermore, the EnMap and Sentinel-2 ferric iron maps were presented a similar spatial pattern and generally the same SI values. On the other hand, the SI ferrous iron showed higher values in EnMap data than in Sentinel-2 data. As for WV3, we observed locally high values (mostly on the roads) but generally, the SI values were lower than the corresponding ones in the EnMap and Sentinel-2 data.

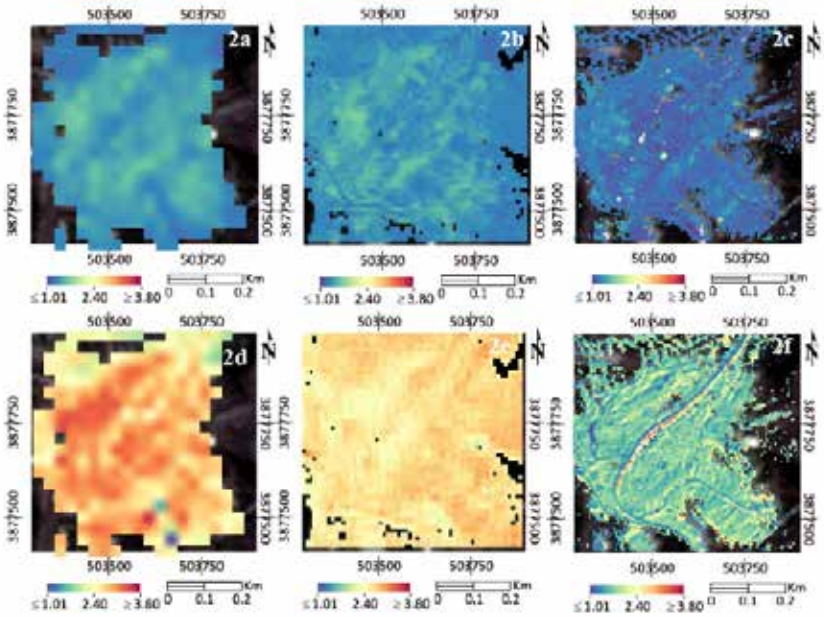

Figure 2. SI maps of ferric iron index applied on (a) EnMap (2024/07/14); (b) Sentinel-2 (2024/07/26); and (c) WV3 (2020/2018) and ferrous iron index applied on (d) EnMap (2024/07/14); (e) Sentinel-2 (2024/07/26); and (f) WV3 (2020/2018). For comparison purposes, all images have a common color scale (1.01-3.80). The background image is the TCI of Sentinel-2 (2024/07/26). SI values <1.01, indicating the absence of the material, are masked.

Absorption maps: the absorption feature maps (BD method) were also created from each one of the EnMap, Sentinel-2, and WV3 datasets. Based on the maximum absorption features observed within each endmember spectrum (issued from both the USGS and JPL spectral libraries and for each endmember), we located the unique diagnostic feature

which was not observed in the other mineral spectral signatures and thus, it spectrally differentiates the specific mineral from the others. The spectral bands/wavelengths corresponding to these absorption features were presented in Table 3 and Figure 3. In Figure 3, we presented indicative the hematite, goethite, and jarosite absorption maps. In particular for the EnMap dataset, we identified more than one characteristic absorption features for each endmember. However in Table 3, for EnMap, we presented the spectral band with the highest absorption of all other bands.

Table 3. Wavelength position (and corresponding band) and corresponding band depths (in the continuum removed (CR) spectra) of the characteristic diagnostic absorption feature of each one of the six minerals, namely hematite, goethite, ferrihydrite, schwertmannite, copiapite, and jarosite in (a) EnMap, (b) Sentinel-2 and (c) WV3 spectral bands retrieved from both USGS and JPL spectral libraries. Not available: mineral's spectral signature was not available in the specific spectral library, and -: no spectral feature was detected that differentiates this mineral from the others.

	EnMap		**Sentinel-2**	**WV3**	
Endmember	USGS	JPL	JPL	USGS	JPL
Hematite	871.7nm (Eb76) CR value 0.45	540.4nm (Eb26) CR value 0.40	864.7nm (Sb9) CR value 0.63	660.3nm (Wb5) CR value 0.64	546.6nm (Wb3) CR value 0.53

Copiapite	879.6nm (Eb77) CR value 0.59	Not available	Not available	-	Not available

Concerning the USGS endmembers, for hematite the characteristic absorption features were possible to define with EnMap and WV3 data. For goethite, ferrihydrite, jarosite, schwertmannite, and copiapite, this was possible only with the EnMap dataset. For Sentinel-2 data, no characteristic absorption feature was identified for these minerals. As for the JPL endmembers, hematite and goethite were differentiated with EnMap, Sentinel-2, and WV3 data while jarosite only with EnMap and WV3. The corresponding absorption maps (1-CR values) are presented in Figure 3.

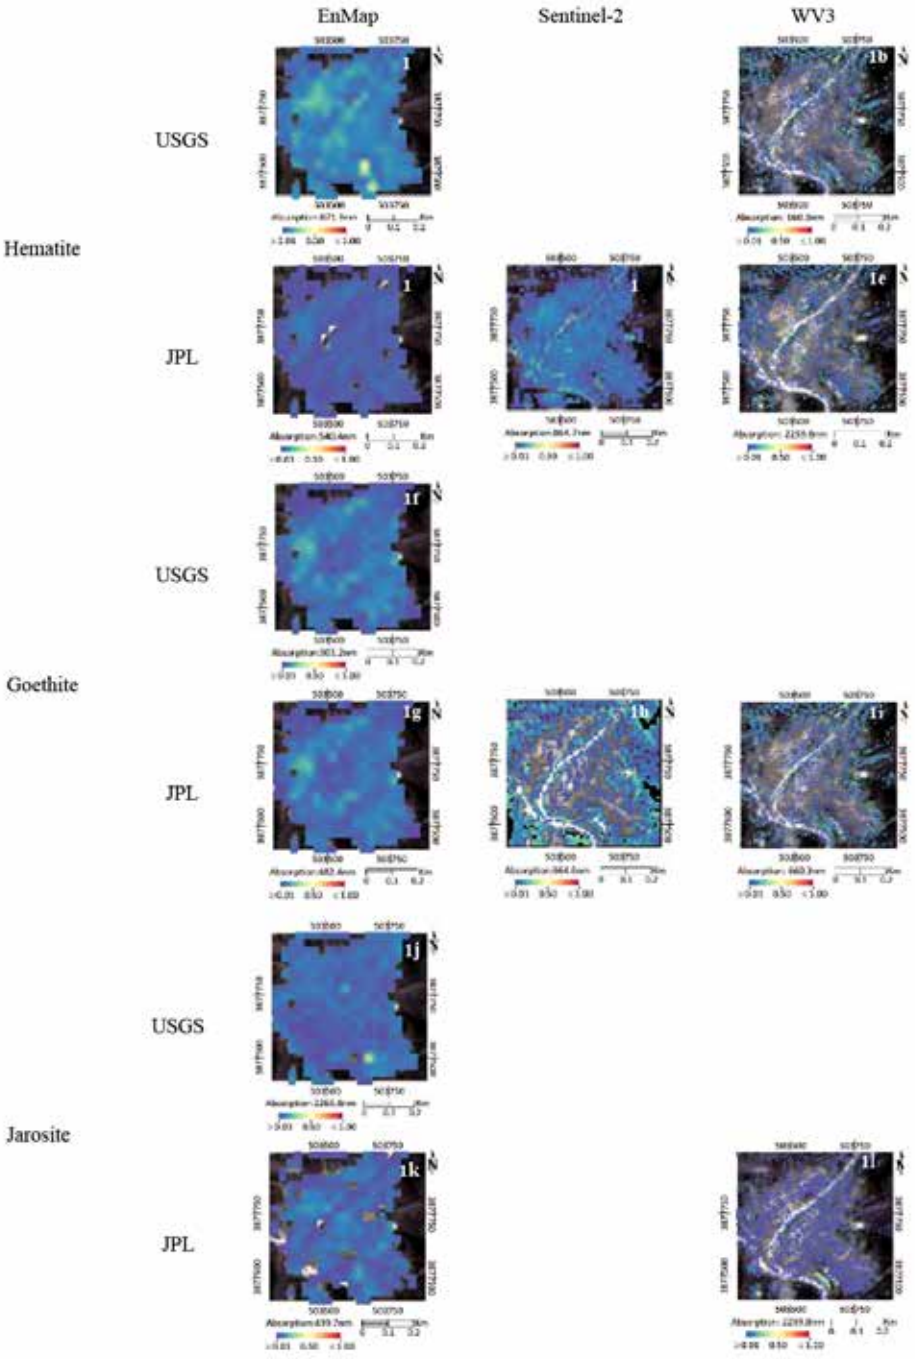

Figure 3. Absorption (1- CR) maps: Hematite-USGS (a) EnMap (2024/07/14) centred at 871.7nm; (b) WV3 (2020/2018) centred at 660.3nm. Hematite- JPL (c) EnMap (2024/07/26) centred at 540.4nm; (d) Sentinel-2 (2024/07/26) at 864.7nm; (e) WV3 (2020/2018) at 546.6nm. Goethite – USGS (f) EnMap (2024/07/14) centred at 501.2nm. Goethite -JPL (g) EnMap (2024/07/14) centred at 482.4nm; (h) Sentinel-2 (2024/07/26) centred at 664.6nm (i) WV3 (2020/2018) centred at 660.3nm. Jarosite-USGS (j) EnMap (2024/07/14) centred at 2265.7nm. Jarosite-JPL (k) EnMap (2024/07/14) centred at 439.7nm; and (l) WV3 (2020/2018) at 2259.8nm. The values range from 0.01 to 1 with 0.01 corresponding to minimum absorption and 1.0. to maximum absorption. The background image is the TCI of Sentinel-2 (2024/07/26)

SAM classification maps: Concerning SAM using the USGS endmembers (Figure 4), we mapped goethite, jarosite, copiapite, and schwertmannite with EnMap data with a threshold angle of 0.35, we mapped jarosite and copiapite with Sentinel-2 data using a threshold angle of 0.40, and all minerals with WV3 with a threshold angle of 0.25, except

from hematite. Concerning SAM using the JPL endmembers, we mapped hematite, goethite, and jarosite with EnMap data using a threshold angle of 0.30, we mapped hematite and jarosite with Sentinel-2 data using a threshold angle of 0.40, and we mapped hematite, goethite, and jarosite with WV3 data using a threshold angle of 0.25. Hematite and jarosite were mapped with all three datasets.

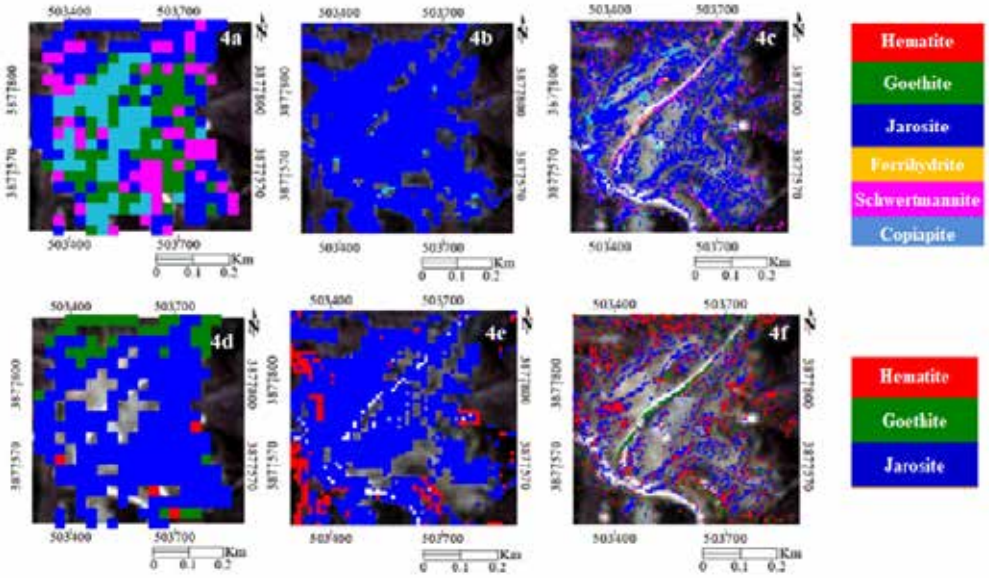

Figure 4. SAM classification maps. In the top row, SAM classification maps using the USGS endmembers for (a) EnMap (2024/07/14); (b) Sentinel-2 (2024/07/26); and (c) WV3 (2020/2018). In the bottom row, the SAM classification maps using JPL endmembers for (d) EnMap (2024/07/26); (e) Sentinel-2 (2024/07/26); and (f) WV3 (2020/2018). The background image is the TCI of Sentinel-2 (2024/07/26).

Overall, ferric iron, ferric oxides, and ferrous iron were mapped with EnMap, Sentinel-2, and WV3 data (SI method) (Figure 2). The presence of ferric iron could be considered as an indicator for the presence of several iron oxide/hydroxides minerals such as hematite, goethite, and ferrihydrite while the ferrous index for copiapite. In this case study, ferric and ferrous iron seem to be present within the entire study area but the highest SI values were observed in pixels corresponding to the weathered slope areas of the tailings. As expected, the SI maps issued from WV3 data provide more details due to the high spatial resolution of the dataset (3.7m). The observed higher ferrous iron values compared with the ferric iron ones could be attributed to the copiapite presence. It must be noted here, that the higher the value, the higher the probability of the mineral's presence within the pixel.

Based on the analysis of the characteristic absorption features (BD analysis), concerning the USGS endmembers, in EnMap data the higheest absorptions (1-CR) were observed for hematite (0.41), jarosite (0.39), and copiapite (0.40), and the lowest ones for goethite (0.23) and schwertmannite (0.23). In WV3, the corresponding hematite absorption is 0.50. As for the JPL endmembers, we identified hematite (0.11), goethite (0.23), and jarosite (0.15) with EnMap, hematite (0.23) and goethite (0.33) with Sentinel-2, and hematite (0.53), goethite (0.60), and jarosite (0.35) with WV3. The highest absorption values were obtained for hematite, goethite, and jarosite using WV3 data but for a relatively small number of pixels within the image located mainly at the weathered slope areas and in certain flat areas (the same locations observed in the SI maps). Among the JPL-endmembers, hematite and goethite were detected in all three types of datasets and among the USGS-endmembers, only hematite and jarosite were identified using EnMap and WV3.

In the case of SAM using USGS endmembers, we note that jarosite and copiapite were mapped using EnMap, Sentinel-2, and WV3. Goethite and schwertmannite were also mapped using EnMap and WV3 but by applying a different threshold angle. Jarosite seems to be the spatially dominant mineral in the Sentinel-2 image. In the case of SAM using the JPL endmembers, jarosite also seems to be present within most image pixels followed by hematite and goethite.

The multispectral and hyperspectral images were acquired under optimal conditions: between late spring and early autumn with high sun elevation and no precipitation weather conditions. The temporal pattern of the data does not affect the results while there were no terrain modifications (e.g., human interventions) in the area during the study

period. Results were not affected by possible vegetation changes while a) bare soil dominates the study area, b) a 0.25 NDVI threshold was applied to mask the sparse vegetation, or c) remained unchanged which cross-validated with historical Google Earth imagery. Finally, the viewing angle of each satellite is practically vertical and combined with the smooth terrain slopes in the study area, resulting in no shadow effects on one or more images.

Concluding, the detection of the specific minerals (using USGS or JPL endmembers) at different wavelengths using EnMap, Sentinel-2, and WV3 data seems to be influenced by each sensors' specifications (e.g. band wavelength position, spectral range, spectral band, spatial resolution, acquisition date etc.) and the inherent physical properties of the samples the spectral signatures of which are retrieved from the spectral library and used as endmembers (e.g. particle size, specific chemistry, environmental context). The SI, BD, and SAM indicate the presence of AMD-related minerals in the study area revealing higher values within the mine area. This is an ongoing work. The verification of the obtained results using in-situ samplings, chemical and mineral laboratory analyses, and in-situ spectral measurements is currently under study.

Research Highlights

Multi-Agent Systems offer a promising decentralized approach for integrated flood and drought management in arid Greek regions, enabling more effective responses to extreme weather events. A conceptual case study demonstrates the potential of this framework to improve real-time decision-making and promote sustainable water resource management in the face of climate change.

Introduction

In Greece, like worldwide, arid and semi-arid regions face the alternating challenge of water scarcity and erratic rainfall patterns (Kourgialas, 2021; Nabinejad et al., 2023; El-Hamid et al., 2024). Hence, they are highly vulnerable to both droughts and floods. Unfortunately, the frequency and intensity of such extreme weather events are increasing, making traditional management methods obsolete. As a result, both the scientific community and society are now looking for more dynamic and adaptive approaches. This paper studies a novel approach to integrated flood and drought management using Multi-Agent Systems (MAS), an Artificial Intelligence technology. The proposed MAS framework consists of a network of intelligent agents, each responsible for a specific aspect of water resource management, including real-time data collection, flood prediction, drought monitoring, water allocation, and infrastructure control. This distributed and adaptive approach enables autonomous agents to have common goals, allowing them to interact and cooperate to achieve them. As a result, they will contribute to effective responses in case of extreme weather events, promoting sustainable water resource management. More specifically, Intelligent Agents in the context of a water resource management system, can integrate diverse data sources, support real-time decision-making, and enable responses to floods and droughts. The rest paper presents the architecture of the proposed MAS, including the types of agents, their interactions, and the data they utilize. A case study for a representative arid region presents the added value of the proposed approach.

The Challenge of Flood and Drought Management

It is known that arid regions have a low rainfall average and limited water resources. Yet, something is changing revealing serious challenges. The frequency and intensity of droughts are constantly increasing but at the same time, extreme precipitation events are more frequent nowadays. This is quite confusing for the traditional approaches that are often based on historical data and centralized control. On one side, droughts create a shortage of water for agriculture and industry besides domestic use, on the other side, flooding destroys infrastructure and causes loss of life, while even water sources can be polluted. The aim, therefore, of this paper is to deal with such challenges, proposing an integrated MAS approach that will be able to deal with both flood and drought management at the same time. To this end, a complex architecture with various intelligent agents is needed. Agents like Sensor Agents, Prediction Agents, Decision-Making Agents, and Infrastructure Control Agents should be represented in the framework. Each of these agents types should have specific responsibilities and well-designed knowledge-based interaction strategies.

Multi-Agent Systems for Flood and Drought Management

Although Artificial Intelligence (AI) is not new, over the last few years it reached a broader audience since it seems to be everywhere. However, despite the available technology in so many fields, there is still a lack of scientific approaches that could be used effectively in environmental real-life problems. Typically, AI approaches tend to enable machines to perform tasks that typically require human intelligence. But what we really need is approaches that can think, act and decide like humans when there are complex phenomena, unusual pattern and urgent situations (Chen, 2022; Sarker, 2022). In this context, an AI technology that is promising is the intelligent agents (Anshuka, 2022). An intelligent agent is an autonomous entity that can monitor its environment through sensors and act upon that to achieve its goals. The simplest type of agents is the reactive agents but here we need the complex cognitive agents those that are equipped with knowledge base and inference capabilities. These agents are able to know facts about their environment, when needed they can use this knowledge for reasoning and decision-making. In atypical form, a knowledge base includes facts, rules, and other forms of structured information. This allow agents to deal with complex cases, learn from their experience, and even explain their actions. Hence, this type of agents is appropriate for

the needs of a water resource management systems, since they are capable of understanding complex hydrological processes and take critical decisions under uncertainty, and as such they are adopted in the current proposed approach.

The Architecture of the Multi-Agent System Approach

As already discussed, multi-agent systems are a promising solution for flood and drought management. The proposed MAS approach consists of a diverse network of intelligent agents, representing different roles and assigned with different responsibilities. The architecture of the system consists of five agent types (Figure 1); namely Sensor Agents, Prediction Agents, Decision-Making Agents, Infrastructure Control Agents, and Communication Agents.

Figure 1. Agent types in the Multi-Agent System approach.

Sensor Agents are able to collect real-time data from various sources. These may include weather stations, river gauges, soil moisture sensors, and reservoir levels. Prediction Agents then receive the data and feed hydrological models or machine learning algorithms to forecast, for instance, flood risks and drought severity. Later, the Decision-Making Agents based on these predictions and some pre-defined rules could make decisions depending on the case. The decision could be related to water allocation, reservoir operation, or flood control measures. Of course, these decisions should somehow be implemented, hence, the Infrastructure Control Agents will follow by implementing the decisions made by the decision-making agents. They could for instance control pumps, gates, and other infrastructure components. Finally, the Communication Agents are responsible for keeping the team informed and functioning by sharing the necessary information between agents. It is worth mentioning here that there are approaches where agents communicate and negotiate with each other without the need for communication agents, however, in this approach we adopted their use to ensure smooth information sharing, making the already complex architecture of the system more light. In this context, consider the following example; during a heavy rainfall event, sensor agents collect data on rainfall intensity and river levels. Prediction agents use this data to forecast flood risk. Decision-making agents then determine the appropriate flood control measures, such as opening floodgates or diverting water to retention basins. Infrastructure control agents execute these decisions.

The mathematical background of the proposed approach is quite complex since the Multi-Agent System (MAS) should deal with different cases of flood and drought. The agents should be able to provide specific functionalities complying with different upcoming events to remain flexible and efficient. Figure 2 presents the mathematical components for each agent type but it should be clear that in a specific use case or scenario, only some of these components are triggered based on the agents' strategies and some pre-defined rules that depict the potential case. More specifically, Sensor Agents primarily deal with data. Hence, their case is quite straightforward. For calibration purposes, they use linear or non-linear functions to convert raw sensor readings into meaningful units, such as voltage to water level. For purposes of filtering, they use some statistical methods like Kalman and Savitzky-Golay filters to reduce noise in the data. Finally, they can use common statistical measures like mean, median, and standard deviation for aggregation since they have to summarize data from multiple sensors or time steps. On the other hand, Prediction Agents are responsible for hydrological modeling and, in some cases, machine learning. Hence, they are the most mathematically intensive agents in the system. As far as it concerns the hydrological models, the approach is based on sound physical laws, like conservation of mass, momentum, and energy, and some empirical relationships which is more difficult to incorporate in the system. Some of the examples that are studied are the rainfall-runoff models, in an attempt to use equations for describing how rainfall translates into streamflow. The unit hydrograph theory is the core theory here but the Horton's infiltration equation will follow. Of course, these models are not enough, hence, hydraulic models are also studied in an attempt to describe water flow in rivers and channels. Manning's and Saint-Venant's equations are some of the studied approaches. In the cases in which machine learning is needed, namely, cases where we have plenty of datasets, linear, polynomial, and support vector regression are the core cases. These models learn patterns from data and can be used to predict water level or flow. Sometimes, we need to classify cases and predict the type of an event. In such cases, the decision trees, random forests, and neural networks are mainly used to predict flood risk in terms of low, medium, or high. It should be mentioned that optimization is not part of this approach yet but gradient descent, genetic algorithms, or particle swarm optimization seem promising for the aforementioned hydrological and machine learning models.

The following simplified example explains better the approach; a prediction agent that uses historical data to estimate the values

of a and b using the least squares regression method. The agent has to predict river flow (Q) based on rainfall (R). A simple linear regression model used by this agent is $Q = a + bR + \varepsilon$, where Q is the predicted river flow, R is the rainfall, a is the intercept, and b is the slope which represents the relationship between rainfall and flow, and ε is the error term. Now consider a more complex event like heavy rainfall. During the event, Sensor Agents collect data on rainfall intensity, river levels, and soil moisture. Prediction Agents have to use this data to forecast river flow and flood risk. Later the Decision-Making Agents will determine appropriate flood control measures, such as opening floodgates. For this example, the rainfall intensity r(t) will be constant at 20 mm/hr for 3 hours. So, $r(t) = 20$ mm/hr for $0 \leq t \leq 3$ hours, and $r(t) = 0$ otherwise. We also assume that the river water level h(t) is initially $h(0) = 1.5$ m while the initial soil moisture is $s(0) = 60\%$. For demonstration purposes, we assume that it remains relatively constant during the short period of the rainfall event. Firstly, we use a simplified unit hydrograph with a peak of 10 m^3/s/hr at t = 2 hours and a base width of 4 hours. For simplicity, we assume also that all the rainfall becomes excess rainfall r_e(t). So, $r_e(t) = r(t) = 20$ mm/hr for $0 \leq t \leq 3$ hours. We need to convert this to consistent units with the unit hydrograph (m^3/s), assuming a catchment area of 1 km^2 (10^6 m^2). So, $r_e(t) = (20 \text{ mm/hr}) * (1 \text{ m}/1000 \text{ mm}) * (10^6 \text{ m}^2) * (1 \text{ hr}/3600 \text{ s}) = 5.56 \text{ m}^3/\text{s}$ for $0 \leq t \leq 3$ hours. Based on the aforementioned simplified assumptions, the direct runoff will rise linearly to a peak and then fall linearly. Peak flow $q_{peak} = r_e * (\text{area under unit hydrograph}) = 5.56 \text{ m}^3/\text{s} * (0.5 * 4 \text{ hr} * 10 \text{ m}^3/\text{s/hr}) = 111.2 \text{ m}^3/\text{s}$ and time to peak 2 hours. Hence, the direct runoff q(t) will be a triangle, rising linearly from 0 to 111.2 m^3/s in 2 hours, then falling linearly back to 0 over the next 2 hours. Now, the machine learning model, an LSTM Network, will follow. Here we assume that the network is trained, so given the rainfall initial river level and soil moisture, predicts a peak flow of 120 m^3/s at t = 2.5 hours. The agent trusts the LSTM slightly more in this heavy rainfall scenario and uses weights $w_1 = 0.4$ for the unit hydrograph model, and $w_2 = 0.6$ for the LSTM. Hence, at the LSTM peak time, t = 2.5 hours, the fused prediction is $q_{fused}(2.5) = (0.4 * 111.2 \text{ m}^3/\text{s}) + (0.6 * 120 \text{ m}^3/\text{s}) = 44.48 \text{ m}^3/\text{s} + 72 \text{ m}^3/\text{s} = 116.48 \text{ m}^3/\text{s}$. Finally, the agent proceeds with the flood risk assessment which is simplified for the example since in real cases many factors beyond just river flow should be taken into account. Yet, in the context of the example. We set a flood warning threshold of 100 m^3/s. so, since $q_{fused}(2.5) > 100 \text{ m}^3/\text{s}$, the agent outputs a fused river flow forecast with a peak of approximately 116.5 m^3/s around 2.5 hours and gives a flood warning, like “High Flood Risk” or similar.

Following the work conducted from the prediction agents, Decision-Making Agents are responsible for decision making, proposing specific actions. These agents have to use the predictions provided by the aforementioned agents along with some pre-defined rules. Although, there various technologies that can be used, in this approach the agents are rule-based. This means that they are based mainly on if-then-else rules and thresholds. For instance, a simple example is “If water level > X, then open floodgate Y”. Hence, these agents are actually based on logic, pretty much like humans, making the decision-making process transparent and explainable. More specifically, the core of these agents is their knowledge base, which consists of a set of rules. Each rule has a set of conditions and an action. Typically, the conditions are comparisons between predicted values, like water level and flow rate, and predefined thresholds. The actions are specific guidelines like opening floodgates or adjusting pump rates. A typical rule is in the form of *IF (Condition 1) AND (Condition 2) AND ... AND (Condition N) THEN (Action)*. Below are presented some examples for purposes of better understanding. R1 and R2 are related to flood control, R3 and R4 are related to drought management while are related to water allocation.

R1: IF (Predicted Water Level > Flood Warning Threshold) AND (Rainfall Intensity > Heavy Rainfall Threshold) THEN (Open Floodgate Y to Level Z)

R2: F (Predicted River Flow > Critical Flow Rate) THEN (Activate Emergency Flood Protocol)

R3: IF (Soil Moisture < Drought Threshold) AND (Reservoir Level < Low Reservoir Threshold) THEN (Implement Water Restrictions – Level 1)

R4: IF (Groundwater Level < Critical Groundwater Level) THEN (Issue Drought Warning to Farmers)

R5: IF (Reservoir Level > Optimal Level) AND (Downstream Flow Requirements Met) THEN (Increase Water Release for Irrigation)

R6: IF (Water Demand Forecast > Available Water) THEN (Implement Water Conservation Measures)

It is clear from these examples that thresholds are crucial, since they define the boundaries that trigger specific actions. These thresholds can be pre-defined and fixed or dynamic, adjusted on real-time conditions or historical data. For example, the “Flood Warning Threshold” might be a fixed water level, or it could be dynamically adjusted based on the current river flow and downstream conditions. Sometimes Decision-Making Agents have to also use logical operators like AND, OR, and NOT to create complex rules with multiple conditions, like in the following example.

R7: IF (Predicted Water Level > Flood Warning Threshold) AND (Rainfall Intensity > Heavy Rainfall Threshold) AND (Downstream Reservoirs Not Full) THEN (Open Floodgate Y to Level Z)

Of course, all these rules would be useless without the proper inference engine. The inference engine checks the conditions of each rule and if they are met, the rule is “fired,” and the corresponding conclusion is extracted. Hence, this agent type is equipped with proper inference engines. Currently, explainability is not included in the system but it is still quite easy to understand why a particular action was taken because the rules are clearly defined. It is also worth mentioning that rules can be easily added, modified, or removed, making the system adaptable to changing conditions or new knowledge. This approach is actually mainly

based on rules because rule-based systems provide a good balance between complexity and performance which is convenient for many water resource management problems.

Next, Infrastructure Control Agents will take the conclusions and turn them into actions. For this purpose, depending on the available infrastructure, equations describing the behavior of pumps, gates, and other infrastructure components are used when there is an automation possibility. In cases where this is not possible, the information provided by the prediction agents can be used by humans to manually take the necessary actions. Finally, the Communication Agents will handle the information exchange throughout the whole procedure. Typically, they use graphs to create a communication network between agents allowing them to reach each other more easily.

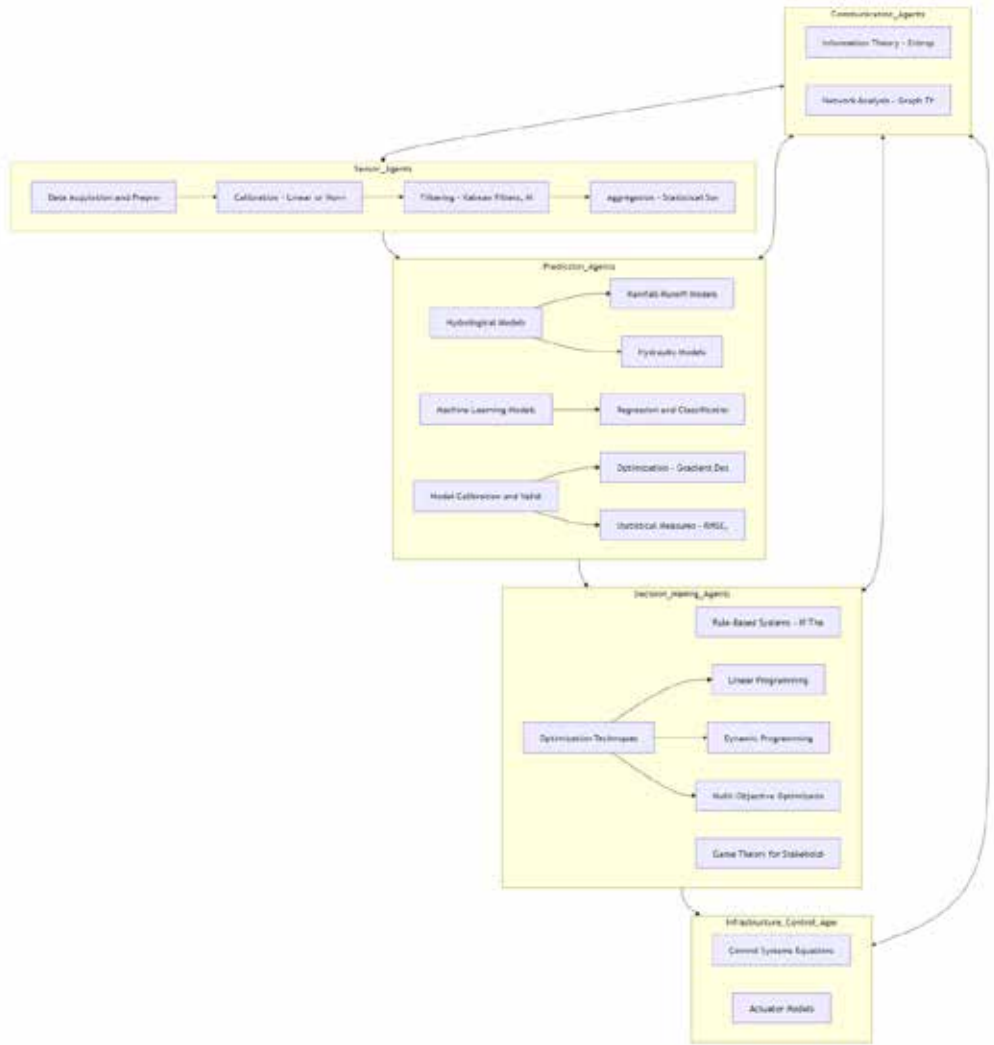

Figure 1. Background of the agent types.

The Technical Implementation of the Multi-Agent System

This section discuss core concepts of the technical implementation of the proposed Multi-Agent System. The chosen implementation language is Python which provided flexibility with several libraries for data handling, numerical computation, allowing integration with hydrological and machine learning models. The system implements the five aforementioned agent types as follows.

Each SensorAgent is initialized with a sensor_type, like “rainfall” or “river_level”, and a location identifier. For simulation purposes, the collect_data() method simulates the data acquisition process, generating a random value within a realistic range for the specified sensor type but in case of real datasets the method will process sensor data. Additionally, this method adds a timestamp to each data point, enabling temporal analysis which important when we have to adapt to pattern changes.

Each PredictionAgent is initialized with model_weights, allowing for flexible configuration of the weighting between different prediction models. The predict_flood_risk() method combines the outputs of a simplified unit hydrograph calculation and a

placeholder machine learning prediction. The unit hydrograph calculation is simplified for research purposes but it could be replaced with a proper SWAT model integration using a library like pyswat in a real application. Libraries like TensorFlow or PyTorch (Ansel et al., 2024) are used here. The outputs from the simplified unit hydrograph and the placeholder are combined using a weighted average, controlled by the model_weights.

Each DecisionMakingAgent is initialized with a set of rules. The make_decision() method iterates through the rules, evaluating the conditions using Python's eval() function. This allows for flexible definition of conditions using comparison operators and logical connectives. However, using eval() can pose security risks if the rules are defined by untrusted sources. Hence, in the future a safer rule evaluation method will be implemented. The agent returns the action associated with the first rule whose conditions are met. The rules as discussed are designed to trigger actions based on predicted flood risk, soil moisture levels, and river levels.

Each InfrastructureControlAgent uses the execute_action() method to receive the action as input and prints a simulated execution message or in cases that there is an APIs or hardware control interface this method can interface with the physical infrastructure like floodgates or pumps.

Each CommunicationAgents uses the broadcast_message() method to allow agents to communicate with each other. The log_data() method is also crucial for recording the simulation results. It uses the json library to store the data in a structured JSON format, making it easy to parse and analyze the results later.

The interactions between the agents follow a defined sequence where Sensor Agents collect data, which is then used by Prediction Agents to forecast flood risk. Decision-Making Agents use these forecasts and their rule base to determine appropriate actions. Finally, Infrastructure Control Agents execute these actions. The Communication Agent logs all relevant data at each time step.

Mention that sensor data is stored as a list of dictionaries within each SensorAgent. Each dictionary contains the timestamp, value, and location of the sensor reading while the CommunicationAgent uses the json library to log the data from all agents in a structured JSON format.

The current implementation uses placeholder values for the hydrological and machine learning models. Later, when the system will be used in real-world scenario some integrations will be needed such as the integration with SWAT by using a Python library like pyswat to interact with the SWAT model or the integration with a pre-trained LSTM network by loading the trained model, i.e. from a saved file, into the PredictionAgent. Libraries like TensorFlow or PyTorch are already used and could support this. For the current research phase, the simulation loop consists of a predefined number of time steps. At each time step, sensor data is collected, predictions are made, decisions are taken, actions are executed, and all relevant data is logged. This loop structure allows for simulating the system's behavior over time and analyzing its response to different events.

Conceptual Case Study: Thessaly, Greece

A conceptual case study for the Thessaly region in Greece demonstrates the added value of the proposed Multi-Agent System (MAS) approach. Thessaly is a representative arid region which is characterized by limited water resources, rainfall patterns, and a high vulnerability to both drought and flood events. This conceptual case study discusses how the MAS approach can address the challenges in the area by integrating real-time data, employing intelligent prediction, and facilitating coordinated decision-making. More specifically, thessaly is an agricultural region, heavily reliant on irrigation. Its water resources are under significant pressure due to increasing demand and decreasing rainfall. The region experiences frequent droughts, leading to water shortages and economic losses. Yet, the last years intense rainfall events triggered flash floods, causing life losses, damage to infrastructure and agricultural lands. This makes Thessaly a really complex hydrological case (Xafoulis, 2023).

The proposed MAS can integrate data from existing meteorological and hydrological networks in Thessaly since there are ready installed stations there. This includes mainly rainfall data from weather stations, but also some river level data from gauging stations, soil moisture data from dedicated sensors, and reservoir level data. Of course, additional sensor deployments in strategic locations would be needed to cover the area. For the purposes of this case study, the agents within the MAS are trained using historical data from these sources. This historical data are used to calibrate the hydrological models and train the machine learning modelsemployed by the Prediction Agents. In real-life, real-time data streams would continuously update the models and inform the decision-making process. For now, a simulated heavy rainfall event, similar in magnitude to historical flood events in Thessaly, is introduced into the model. The Sensor Agents collect "real-time" rainfall data, which are transmitted to the Prediction Agents. The Prediction Agents, utilizing the calibrated hydrological and machine learning models, forecast the river flow and potential flood inundation areas. The Decision-Making Agents, based on pre-defined rules and the flood forecast, then optimize reservoir operations, determining the appropriate release rates to minimize downstream impacts. Simultaneously, the MAS generate timely warnings to local communities through communication channels like, SMS alerts. The Infrastructure Control Agents execute the reservoir operation decisions, adjusting gate openings and water releases.

This simulation takes into account three locations, Larissa, Trikala, and Volos, where the Sensor Agents record the rainfall intensities during a simulated heavy rainfall event as depicted in Table 1.

Table 1. Simulation values for the heavy rainfall event.

Time (hours)	Larissa (mm/hr)	Trikala (mm/hr)	Volos (mm/hr)
0	5	7	3
1	15	20	10
2	25	30	18
3	20	25	15
4	10	12	8

Based on this rainfall data and other relevant inputs, the Prediction Agent predicts a peak river flow of 280 m³/s at 4 hours. Part of the Decision-Making Agent knowledge base is presented below.

Rule1: IF (Predicted River Flow > 250 m³/s) AND (Reservoir Level < 90%) THEN (Open Floodgate A to 70% and Floodgate B to 50%)

Rule2: IF (Predicted River Flow > 200 m³/s) AND (Reservoir Level < 80%) THEN (Open Floodgate A to 50%)

Rule3: IF (Predicted River Flow > 150 m³/s) THEN (Issue Flood Warning to Larissa and Trikala)

Hence, since the predicted river flow exceeds 250 m³/s, and assuming that the reservoir level is at 85%, Rule1 is triggered. The Decision-Making Agent instructs the Infrastructure Control Agent to open Floodgate A to 70% and Floodgate B to 50%. A flood warning is also issued to Larissa and Trikala (Rule3). As a result, the floodgates are opened, reducing the peak flow downstream to 220 m³/s.

Conclusion and Future Work

This paper proposed an integrated approach towards flood and drought management within an arid area using a MAS. The MAS framework consists of Sensor, Prediction, Decision-Making, Infrastructure Control, and Communication Agents presents a novel, decentralized solution for mitigating the challenges imposed by extreme weather events. The Python implementation of the MAS was developed in a flexible language with extensive libraries, detailing both the functionalities of each agent type and how they interact. A conceptual case study for the Thessaly region in Greece showcased the potential benefits from the MAS in managing a flood scenario. The obtained results were promising, although there are a number of limitations regarding the present research. The existing implementation is using simplified models and placeholder values. A subsequent step would be to embed real-world hydrological models, such as SWAT, along with the trained machine learning models, like LSTMs, into the Prediction Agents. This will involve access and processing of real-world datasets from the Thessaly region or elsewhere, including historical rainfall, river flow, soil moisture, and other relevant variables. Furhermore, the rule-based decision-making could be further enriched with fuzzy logic or defeasible logic, to handle uncertainties and increase the accuracy of decision-making. Interaction between agents may be explored further either by implementing negotiation protocols or other collaborative mechanisms. The Infrastructure Control Agents need to be connected with the real physical infrastructure through APIs or hardware interfaces, enabling automated control of floodgates, pumps, and other devices.

(2) Section of Dynamic, Tectonic and Applied Geology, Department of Geology and the Geo-environment, National and Kapodistrian University of Athens

Introduction / Background

The south Aegean Sea and its adjacent areas are a highly segmented tectonically active domain, characterised by high-rate extension and severe crustal thinning. The different segments (blocks) that make up the south Aegean crust are bounded by significant fault zones and/or dislocation surfaces whose relative motion varies in size and direction. Over the past several decades, the recorded seismicity of the S. Aegean was sparse, scarce, and of generally low intensity. Thus, it cannot assist in adequately resolving regional tectonics.

Hitherto knowledge of tectonic regime was mainly based on the sparse earthquake record, a significant number of shallow marine seismic surveys, minimal use of geophysical potential field data, bathymetry and Differential GPS measurements. All these efforts achieved remarkable results for the methods employed and some resulted in block tectonic models. One of the first approaches by McClusky et al. (2000) identified a South Aegean microplate and determined its motion. Later, Nyst and Thatcher (2004), observed NW-SE trending extension on the Dodecanese Islands, proposing as well that the Peloponnese and the Central and South Aegean belong to a block with internal deformation zones. Reilinger et *al*. (2006) suggested that the kinematics of the south Aegean could be explained by a three-microplate model. Floyd et *al*. (2010) introduced a 15-block model and Briole et *al*. (2021) a 5-block model consistent with known regional-scale structures of the area, but is also rather coarse and with awkwardly shaped blocks (e.g. that of the Central Aegean. Finally, by interpreting a combination of GPS and palaeomagnetic data Lazos et *al*. (2022) propose the existence of an NNE-SSW 'boundary' extending from the west coast of Chios Island and through Paros Island terminating offshore to the south of western Crete; this is referred to as the Mid-Cycladic Lineament and is suggested to delimit areas rotating clockwise to its west counterclockwise to it east.

Herein, we use Differential GNSS measurements augmented with Seismotectonic information and geophysical data to outline the regional tectonic structure and kinematics of the South Aegean Region. Most hitherto work based on GNSS data has studied the deformation of the S. Aegean area by *referring* the velocity or displacement vectors to *remote* locations, usually in Eurasia (e.g. Potsdam, Germany), or the ITRF system as in Fig. 2). While this approach is informative and very useful in studying the *large-scale (whole-plate)* deformation of the Aegean, *it fails* to *resolve* the kinematics/pattern of relative block motions at local- and regional-scales and, therefore, assist in understanding the regional tectonics regime(s). The present study *departs* from this norm by attempting to inquire about *relative block motions* using *local reference points*, thus assisting in understanding the regional pattern(s) of tectonic deformation. Along this vein, if the regional tectonic structure comprises a mosaic of moving rigid blocks separated by active major faulting, it is straightforward to study the motion of any given block *relative* to others by letting some fixed observation point on the immobile block define the origin of a *local reference frame* and subtracting the velocity vectors of *all* other observations points from the velocity vector of the origin. Effectively, the present work expands on that of Sakkas et al. (2020) but incorporates additional cGNSS measurements, strain field computations and seismotectonic information. The resulting tectonic model has significant similarities to that of Sakkas et *al*. (2020), albeit with differences in the configuration and boundaries of the crustal blocks.

Data and Methods

We use data from 54 permanent, continuously recording GNSS stations (cGNSS), all of which are onshore and distributed over the Cyclades, Dodecanese, Crete, Eastern Peloponnese, Attica and Euboea as shown in Fig. 1. They belong to several networks operated by different institutions and agencies. Specifically, two belong to the network of the National and Kapodistrian University of Athens; www.remsenslab.geol.uoa.gr), one to the COMET network (Centre for the Observation and Modelling of Earthquakes, Volcanoes and Tectonics; comet.nerc.ac.uk/), eight to the NCAD (National Cadastre and Mapping Agency S.A. (www.hepos.gr), nine to the NOANET (Geodynamic Institute of National Observatory of Athens; Ganas *et al.*, 2008; Chousianitis *et al.*, 2021) and 32 to the private sector METRICA S.A. network (www.metrica.gr/diktyo-hxgn-smartnet). All data sets span a mean period of five (5) years, but

their majority exceeds three years with many spanning almost one decade. The primary data were processed with the Bernese v5.2 software (Dach et *al*., 2015) to generate high-precision time series of daily coordinates. We also considered (processed) displacement time series from two stations of the Geodetic Laboratory of Nevada (MAGNET + Global GPS Network Map (unr.edu). The annual velocity of each station was obtained from the slope of the least-squares line best fitting the coordinate time series.

The observed velocity field in the ITRF 2008 reference frame was subjected to strain analysis using the *grid*_strain package by Pesci and Teza (2007), a grid with a cell dimension of 30km and no interpolation. The results are shown in Fig. 6. The recovered strain values correspond to high and mid-significance, so that only points sufficiently close to the cGNSS stations would be included in the calculations. This prevented the introduction of potentially misleading information in areas with sparse or no station coverage. Even so, in cases where the distribution of GNNS stations is one-sided, the calculated strain values should be interpreted with caution.

Finally, to further constrain the relative motion between blocks and the resulting tectonic model, we included seismo-tectonic information in the form of 1147 focal mechanisms of *crustal* (less than 30km deep) earthquakes with $M_w \geq 4$, spanning the period 1904–2022. This dataset is a combination of the data bank used by Kassaras *et al.* (2016), which covers the period 1904-2016, as augmented by the first Author to the year 2022 using the same criteria to ensure homogeneity. The focal mechanisms are also illustrated in Fig. 6.

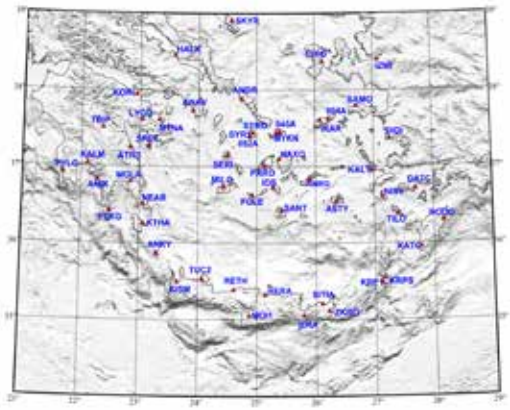

Figure 1. The continuously recording permanent GNSS network used in the analysis. See text for details.

Results

Motion Relative to the ITRF 2008 Reference Frame: The horizontal velocity vectors relative to the ITRF 2008 reference frame are shown in Figure 2. Error ellipses are drawn at the tips of the velocity vectors at the 95% confidence level (used throughout). In this frame, the motion of the entire South Aegean area appears quasi-uniform in a south-westerly direction and at rates of the order of 20mm/year. Minor local differentiations are evident in the rate and/or direction of the velocity vectors, but their interpretation in terms of local to regional kinematics is not easy, if at all possible. The same difficulty arises when the velocity is referred to a remote point on the surface, located in Eurasia or Africa. The local differentiations in crustal deformation can be resolved by using local reference points: herein we use the stations ASTY (Astypalaea Island in the Dodecanese), NAXO (Naxos Island in the Cyclades), ANAV (Anavyssos, Attica).

Motion Relative to ASTY (25.38°E, 37.10°N) on Astypalaea Island (Figure 3): Significant changes in the sense of motion can be observed (a) Relative to a NE-SW line joining the islands of Kos, Astypalaea (ASTY) and Anafi (ANF), and b) relative to a line between Anafi (ANF) and Kasos islands, extending in a NW-SE direction between Crete and Karpathos (KRP). In addition, the stations located in the north and west sectors of the study area *diverge* from those in the south and east sectors. Moreover, and importantly, the SE Dodecanese (Nisyros, Tilos, Rhodes etc.) appears to comprise a block moving to the east-northeast relative to the KOS-ASTY-ANF and ANF-Kasos lines in a sense *sinistral* with respect to the KOS-ASTY-ANF line. Accordingly, the KOS-ASTY-ANF and ANF–KASOS lines appear to be parts of significant tectonic boundaries.

Motion Relative to NAXO (25.38°E, 37.10°N) on Naxos Island (Figure 4): Here we observe a *very* significant change in the sense of motion relative to a NE-SW line joining Kalymnos (KALY), Amorgos (AMRG) and Santorini (SANT). The southeastern part of this line coincides with the southern boundary of the Anhydros Basin, forming between Amorgos and Santorini. All stations located in the Cyclades Archipelago generally drift with very low relative velocities associated

with significant error ellipses that hinder their interpretation, while they exhibit significantly non-uniform orientations. These may be attributed partly to their proximity to the local reference point (small displacement/ large error) and partly to small-scale distributed internal deformation in the "Cyclades Block" (non-uniform orientations). Exceptions to this pattern appear to be the islands Santorini (SANT) and Folegandros (FOLE), which diverge from the rest of the Cyclades relative to an NW-SE line extending between the islands Anafi (ANF) and Ios (IOS). In addition, there is evidence of convergence between east Crete (TUC2) - Anthikethyra (ANKY)and Kythera (KTHA) on one hand, and Santorini (SANT) – Folegandros (FOLE) on the other. Finally, the SE Dodecanese, to the south of the KOS-ASTY-ANF and east of the ANF-KASOS lines respectively, *diverges* from the areas to the north and west of these boundaries at *very high rates*.

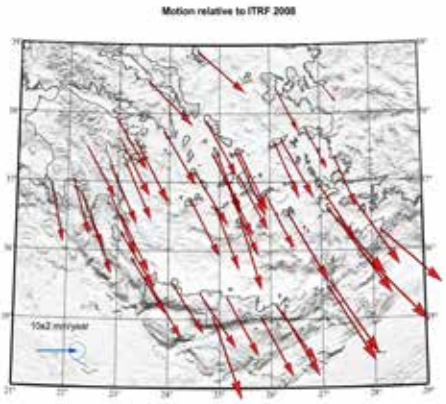

Figure 2. Horizontal velocities of the GNSS stations data in the ITRF2008 reference frame.

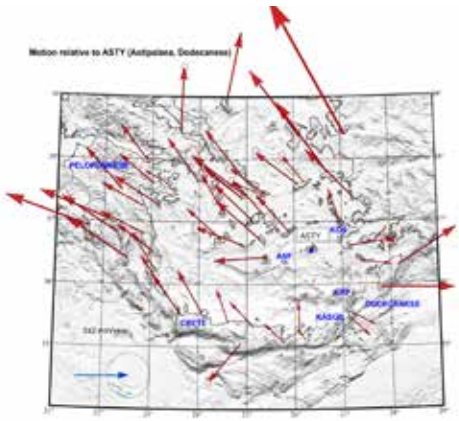

Figure 3. Horizontal velocities of the GNSS relative to the ASTY station.

Motion Relative to ANAV (23.91°E, 37.74°N) at Anavyssos, Attica (Figure 5): It is evident that in this local reference frame, the line Ikaria (IKAR) – Naxos (NAXO) – Paros (PARO) – Milos (MILO) defines a boundary so that: a) Stations to the north of the line and the west of longitude W of 24°E describe mainly NE-SW trajectories, approximately parallel to the south branches of the westward extension of the North Anatolian Fault into the Aegean; b) stations to the north of the line diverge northwards and, c) stations in the vicinity of this line describe NE-SW to E-W trajectories. Significantly, all stations south of the KOS-ASTY-ANF line and east of the ANF-KASOS lines, i.e. the Dodecanese, *diverge* rapidly in a South-Easterly direction. Because all stations located to the south of the Peloponnese and on western Crete are relatively stationary relative to ANAV, the trajectories of MILO, FOLE and SANT, as well as of all stations in eastern Crete indicate that the area within MILO, FOLE, SANT, western Crete, KASOS and ANF may undergo *counterclockwise rotation* which can only be effected by sinistral NW-SE and dextral NE-SW faulting along the KASOS-ANF line. Accordingly, it appears that the horizontal sense of NW-SE faulting changes from *dextral* north of the KALY-AMRG-SANT line to *sinistral* south of the KOS-ASTY-ANF line.

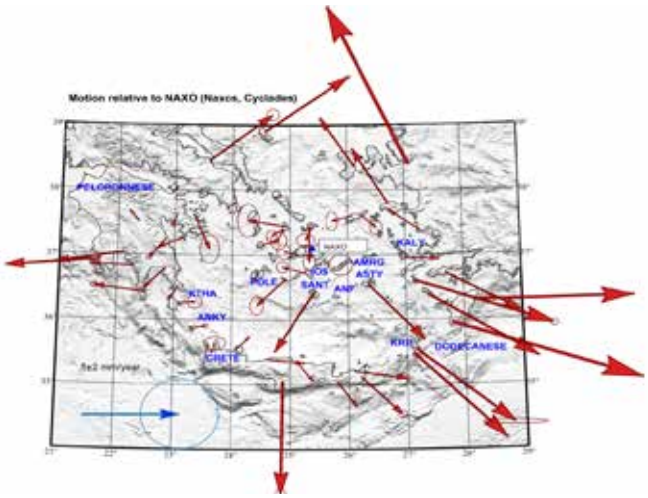

Figure 4. Horizontal velocities of the GNSS relative to the ASTY station.

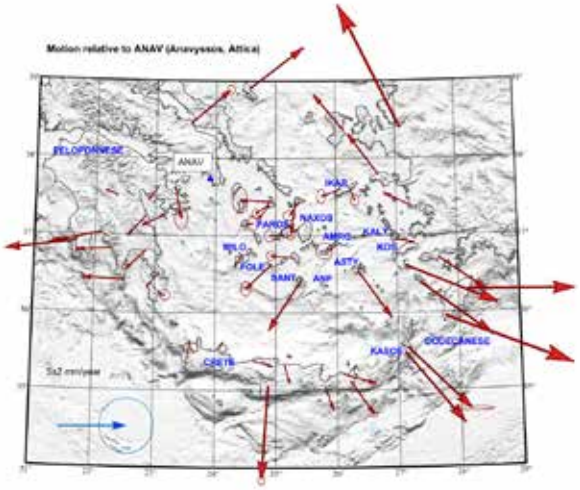

Figure 5. Horizontal velocities of the GNSS relative to the ANAV station.

Strain analysis and focal mechanisms: The calculated two-dimensional strain rate tensor is presented in Fig. 6. Extension (positive eigenvalues) is indicated with blue vectors and compression (negative eigenvalues) with red. The Cyclades Islands and the western coasts of Anatolia are characterized by an almost N-S extensional field, which rotates to NNW-SSE south of IKAR (Ikaria) – NAXO (Naxos) – Paros (PARO) – MILO (Milos) line discussed earlier. This counterclockwise rotation of the extensional field continues to the south and southeast, with the transition apparently associated with KOS (Kos) – ASTY (Astypalaea) – ANF (Anafi) line also discussed above. The Dodecanese Islands experience NW-SE to NNW-ESE extension. This changes to NE-SW compression in Crete. The transition appears to be almost abrupt and occurs just west of an (obvious in the focal mechanism distribution) NNE-SSW oriented extensional feature between the Kasos (KASOS)/ Karpathos (KPR) and Nisyros/Kos (KOS) islands, which we tentatively dub "the *Karpathos – Nisyros detachment*", as well as west of the Kasos – Anafi line which is hereby confirmed. Minor differentiations in the strain field are also evident near Santorini and Folegandros Islands, confirming their separation from the rest of the Cyclades bounded by a line through Santorini (SANT) and Ios/Folegandros (FOLE). Finally, Euboea and the eastern part of central Greece are characterized by NNE-SSW extension, while the south Peloponnese is dominated by E-W extension. Similar findings concerning the Peloponnese, the eastern part of the central Aegean and Euboea were also reported by Chousianitis *et al.* (2015). The results of our strain analysis agree remarkably well with the crustal stress field derived from the inversion of earthquake focal mechanisms, e.g. as reported by Kassaras *et al.* (2020).

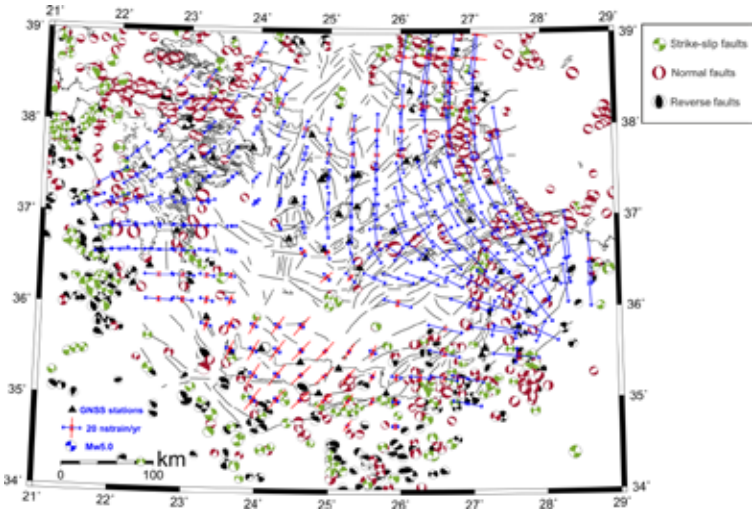

Figure 6. The strain field derived by inversion of the regional velocity field and focal mechanisms of crustal earthquakes with M≥4 over the period 1904-2022. The locations of the cGNSS stations are also indicated with black triangles.

Conclusions

The joint evaluation of all the above information confirms the distributed block deformation of the South Aegean and allows for the tentative identification of 7 major crustal blocks, of which block 1 is further partitioned into three sub-blocks. These are illustrated in Fig. 7 and are numbered from 1 to 7, with the sense of *horizontal* relative motion at their interfaces being as follows:

Block 1a: This includes the area to the north of the Ikaria – Paros/Naxos – Milos line and to the east of longitude 24°E. It is separated from Block 1b by a tentative, N-S oriented, apparently right-lateral discontinuity approximately extending along a line passing east of the Milos and Serifos islands and between the Euboea – Andros strait. It is also separated from Block 2 by a right-lateral and apparently aseismic discontinuity.

Block 1b: The Myrtoan Sea, separated from Block 1a by the Milos – Serifos – Andros line. The western boundary of this block exhibits null horizontal displacement as it comprises the NNW-SSE normal faults bounding the east coast of the Peloponnese. Moreover, the nature of its interface with Block 5 (Cretan Sea) remains undetermined.

Block 2: This comprises the southern Cyclades except for the island east of the Santorini – Ios line, Ikaria, Samos and others. It is separated from Block 1b by the Ikaria – Paros/Naxos – Milos line to the north, from Block 3 by the Kalymnos – Amorgos – Santorini line and from Block 4 by the Santorini – Ios line. The first interface has tentatively been identified as right lateral, the second appears to be normal with a left-lateral horizontal component and the third is tentatively identified as right lateral.

Block 3: The northern part of the Dodecanese. It is separated from Block 2 by the Kalymnos – Amorgos – Santorini line, to the east by the Kasos/Karpathos – Nisyros/Kos line and to the west by the Kasos Anafi line. The sense of horizontal motion here changes abruptly from left-lateral to practically null at the normal faults of the Kasos/Karpathos – Nisyros/Kos line (*Karpathos–Nisyros detachment*). The interface with Block 5 appears to be right lateral.

Block 4: Located at the southeast end of the Cyclades, it includes the islands Santorini, Sikinos, Folegandros. It is separated from Block 2 by the NNE-SSW right-lateral Santorini – Ios line, from Block 1a by the NW-SE right-lateral Paros/Naxos – Milos line and from Block 5 by the continental slope of the Cretan Sea, which is assumed to comprise normal faults with some right-lateral horizontal component. If this configuration is correct, Block appears to experience south-westward translation with simultaneous counterclockwise rotation.

Block 5 is the Cretan Sea. As indicated above, the eastern half of this block may undergo counterclockwise rotation effected by NW-SE left-lateral displacement and NE-SW right-lateral faulting.

Block 6 includes the southeast Dodecanese, Karpathos and Kasos. It is bounded to the southeast by the left lateral faulting of the Aegean – African plates interface and to the west by the normal faults of the Karpathos – Nisyros detachment.

Block 7 is the Karpathos – Nisyros detachment.

In a final comment, it is noted that this configuration and relative motion of crustal block amply explains the geographical configuration of the Cycladic islands.

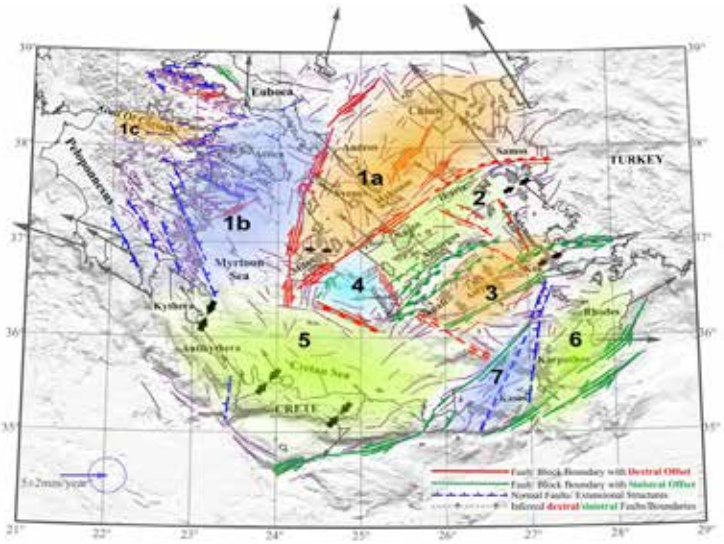

Figure 7. A model of contemporary distributed block deformation in the South Aegean.

Introduction

This study focuses on the identification of the boundaries of a landslide in a remote but inhabited area, laterally and in depth, as well as analyzing the characteristics of it using geoelectrical surveying methods. The landslade is located on the provincial road of Grevena - Vovousa (Fig. 1), limiting access to the country's main road network from remote areas. This study emphasizes on the importance of further investigetion, since the landslade often reactivates, damaging the road and posing a threat to the people of the area. The results showcase the geometry of the landslide's subsurface and the thickness of the layers comprising it.

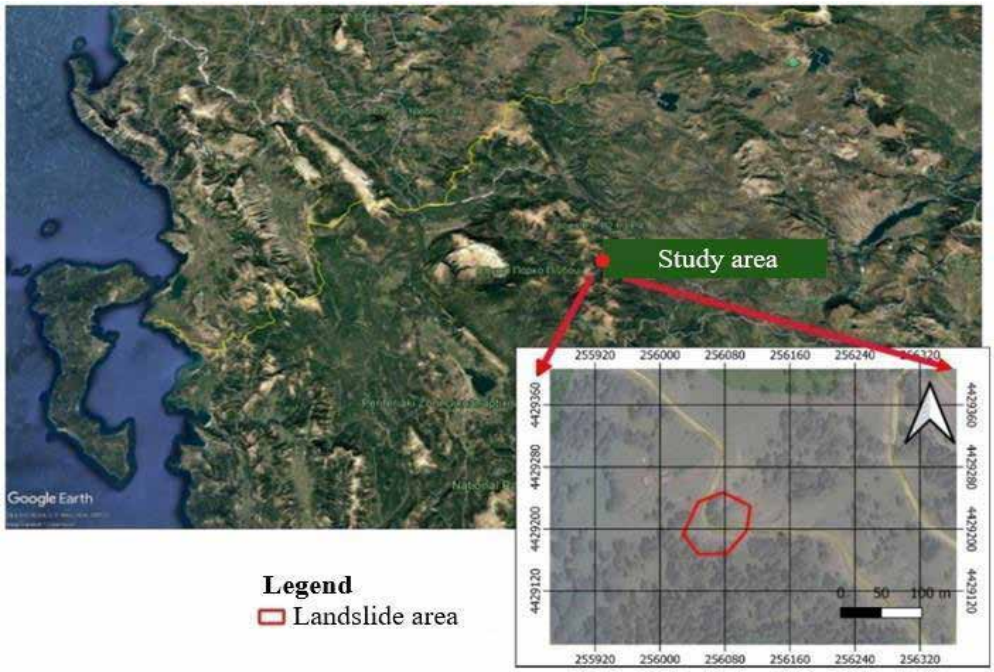

Figure 1: Location of the landslide (Google earth with modifications).

Geological Setting

The investigated area is part of the External Hellenides and more specifically it is located in the tectonostratigraphic zone of Pindos. The dominant formations of this zone are flysch, limestones and platy limestones. The Pindos flysch is divided into two layers, the 1st and 2nd flysch, both consisting of clastic sediments. The 1st is characterized by alterations of pebbles, sandstones and marls and was deposited during the Lower Cretaceous, while the 2nd has a calcareous-marl composition and was formed between the Danian and the Upper Eocene (Mountrakis, 2020). In the geologic map of Pentalofos (IGME, 1977) it can be seen that the landslide is entirely located in the area's flysch (Fig. 2), which overlies the limestone. The flysch in the area occurs with a chaotic structure, sandy and clayey composition and the limestones in the area are white (Mountrakis, 2020). The geological map also shows that the main formations include the undivided Pindos flysch (Danian-Eocene), which coexists with sandstone masses, marls and clay slates. In addition, Mesozoic limestones are found, either as platy/well-stratified ashy or reddish limestones, or as white limestone masses. Peridotites, serpentinites, dolerites and microlithic rocks also occur in the area, either individually or in combinations.

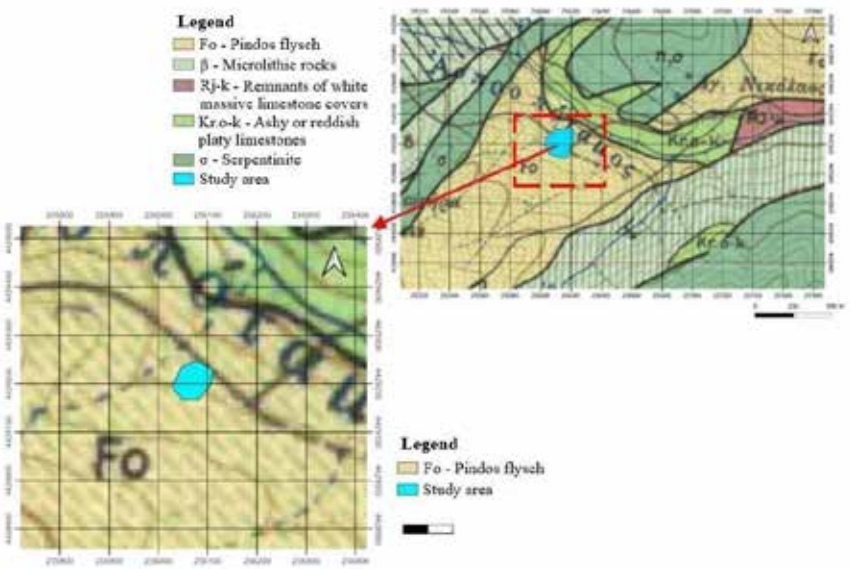

Figure 2: Geologic map of the area (IGME 1977, with modifications).

During the field research a stream was found acting as a natural boundary between the superficial geological formations (flysch and limestone). Flysch appears SE of the stream, while limestone predominates the NW side of it (fig. 3). This holds great importance, as it offers a clear view of the layers comprising the landslide. The subsurface consists of remnants of white limestone covers (Rj-k, Fig. 2), followed by a metabase layer. The upper layer/weathering mantle, which is the moving part of the landslide, consists of Pindos flysch. (Mountrakis D., 2020)

Figure 3: Stream as a natural boundary between the formations (Google earth with modifications).

Geotechnical characteristics

The flysch in the Perivoli area was geotechnically classified as category XI, characterized as strongly sheared siltstone or clayey shale with chaotic structure and clay pockets. It includes thin layers of sandstone that have been transformed into small fragments, making it particularly unstable and associated with landslide phenomena in areas of Western Greece. Its mechanical behaviour is characterised by great anisotropy, due to the degree of weathering, the orientation of discontinuities, high slope gradients and the presence of water. Furthermore, category XI flysch has increased clay content which creates impermeable and semi-permeable barriers, causing slope stability problems (Marinos *et al*., 2013). Limestone on the other hand, has high strength values due to its natural state. It is particularly

vulnerable to erosion due to the presence of water, which can lead to karstification and decrease its durability. The geotechnical characteristics of it depend on the degree of weathering, secondary relaxation and the presence of water. The weathering mantle occuring in the composition of the landslide, has a loose structure and the grain size of the material varies. Its mechanical strength values are lower than those of the original rock, while its limestone composition makes it permeable to groundwater, contributing to the occurrence of failures in the area.

Applied methodology

The geophysical method used in this study is electrical resistivity tomography (ERT). This offers a detailed depiction of the geological formations underground and provides insight on changes or possible movements in the landslide, helping to comprehend the phenomenon better. The arrangements used were the dipole-dipole, for the definition of the lateral boundaries, and the multi-gradient, for the definition of the landslide's depth. This combination provided a more complete depiction of the subsurface structure (Tsourlos P., 2021). A differential GPS (Trimble GNSS System) was used for the precise placement of the electrodes and the measurements were taken with the Syscal Pro instrument (IRIS Instruments). The first tomography (ERT1) was carried out along the movement axis of the landslide (Fig. 4). Its purpose was to determine the depth of the slip surface and the upper limit of the landslide. A limestone outcrop was observed in the southern part, which posed the question of whether it was the crown or just an eyebrow of the landslide. The tomography was 115 meters long and 23 electrodes were used (due to the road network) with 5 meters spacing in between. No increase in resistance was observed at a depth of 20 meters in ERT1, which affected the decisions regarding the length of the next two tomographies ERT2 & ERT3. The second tomography (ERT2) was carried out across the movement axis of the landslide (east to west) and a few meters north of the limestone outcrop mentioned earlier (Fig. 4). After a quick view of the preliminary results of ERT2, signs of clear increase in the resistivity were not identified, therefore this tomography was also 115 meters long in order to provide insight as deep as possible. As in the case of ERT1, 24 electrodes were used with 5 meters spacing in between. The third tomography (ERT3) was almost parallel with ERT2 at the landslide's foot area (Fig. 4). The tomography was 92 meters long and 24 electrodes were used with 4 meters spacing in between, providing slightly better resolution at expense of the maximum depth of investigation.

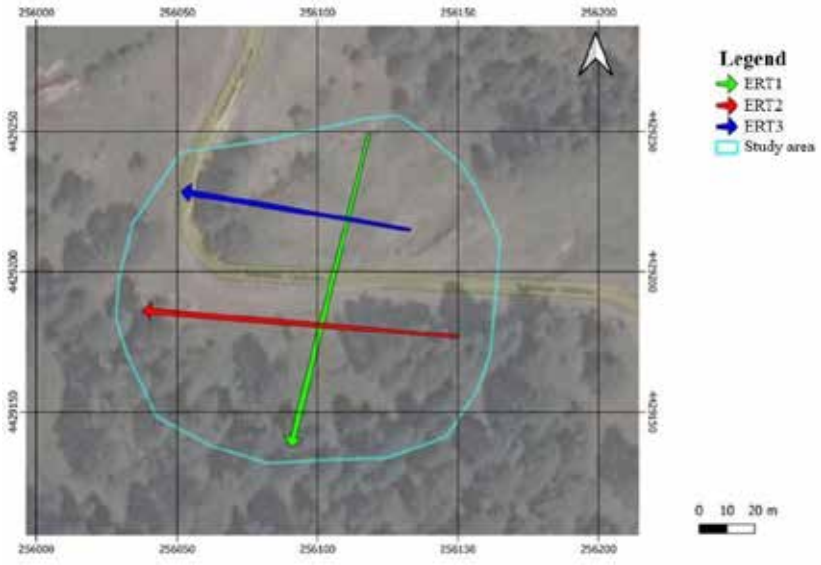

Figure 4: Orientation of the tomographies (Google earth with modifications).

Afterwards the results were subjected to mathematical inversion in the ResIPy open source software. Specifically, this software processed, filtered and finally modeled the geoelectrical data from the tomographies. The results of this process were easy to interpret images, depicting the layers' resistivity in representative colours.

Results

The inversion program ResIPy created two-dimensional models depicting the specific electrical resistivities of the subsurface (Fig. 5, 6, 7). The scale in the models ranges from dark blue for low resistivity values, to dark red for the highest resistivity values. In ERT1 (Fig. 5) 642 values were used by merging both the dipole-dipole and multi-gradient

arrangements and the final error (RMS) was 2.36%. The analysis of the results shows that the subsurface can be divided into three main layers. The first layer (Fig.5, blue area) had the lowest resistivity (20-45 Ohmm) and was about 10 meters thick throughout the entire tomography, except for the area between the 11th and 13th electrodes, where there was a lack of data due to the road network. The second layer (Fig. 5, green and yellow area) had a resistivity of 45-75 Ohm*m and was also 10 meters thick, which remained the same through the entire tomography, with the same anomaly on the road area.

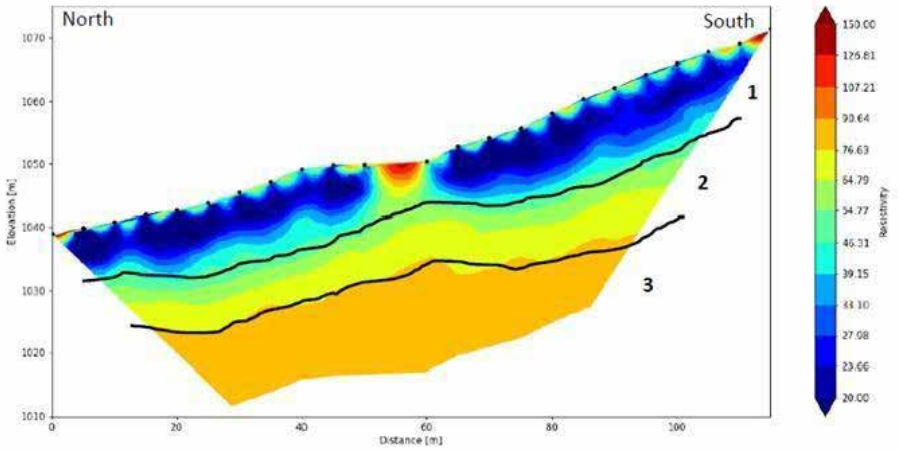

Figure 5: ERT1 resistivity distribution model.

In ERT2 (Fig. 6), 792 values were used by merging the dipole-dipole and multi-gradient arrangements and the final error (RMS) was 2.42%. The subsurface was divided into three main layers with different specific electrical resistivity. The first layer (Fig. 6, blue area), had the lower resistivity values (20-45 Ohmm) and was about 10 m thick. There were no obstacles, and all 24 electrodes were used this time. In this area, increased electrical resistivity values were observed at two points: eastern, between the 1st and 3rd electrode (90 – 105 Ohm*m) and between the 3rd and 4th electrode (45-75 Ohm*m) and western, between the 21st and 24th electrode (45-105 Ohm*m). In the central part of the section, between the 4th and 21st electrodes, the first layer dominates, which probably corresponds to the moving mass of the landslide. The second layer (Fig. 6, green and yellow area) had intermediate resistivity values (45-75 Ohm*m) and was also about 10 meters thick. In areas of increased resistivity, the second layer is locally thicker. Finally, at a depth of about 20 meters, a third layer appeared, which had higher resistivity values (75 to 90 Ohm*m) and was observed uniformly along the entire length of the tomography.

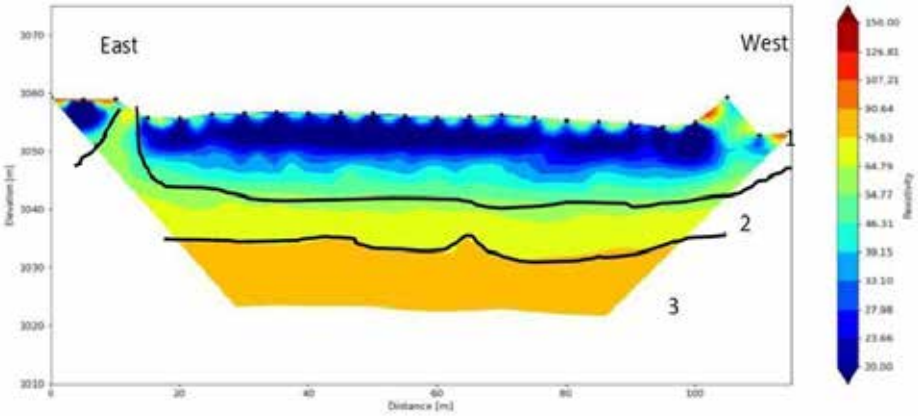

Figure 6: ERT2 resistivity distribution model.

In ERT3 (Fig. 7) 693 values were used by merging the dipole-dipole and multi-gradient arrangements and the final inversion error (RMS) was 2.92%. In this tomography only 23 electrodes were recording, due to the presence of the road network. As previously, three main layers are identified based on the specific electrical resistivities. The first layer is characterized by low resistivity values (20-45 Ohm*m), uniformly observed over most of the section, with the thickness being around 10

m. However, in the western part of the tomography, local variations are recorded, with increased resistivity values reaching 125 Ohmm between the 17th and 18th electrodes, and 45-90 Ohmm values in other areas. In the western part, where the tomography crosses the provincial road network, even higher resistance values were observed, reaching 150 Ohmm. The second layer, located at a depth of 10 meters, has intermediate resistivity values (45-75 Ohm*m), while its thickness reached 15 m locally, mainly in the area between the 6th and 10th electrode. Finally, the third layer appears at a depth of about 20 meters where higher resistivity values (75-90 Ohmm) are observed throughout the entire length of the tomography.

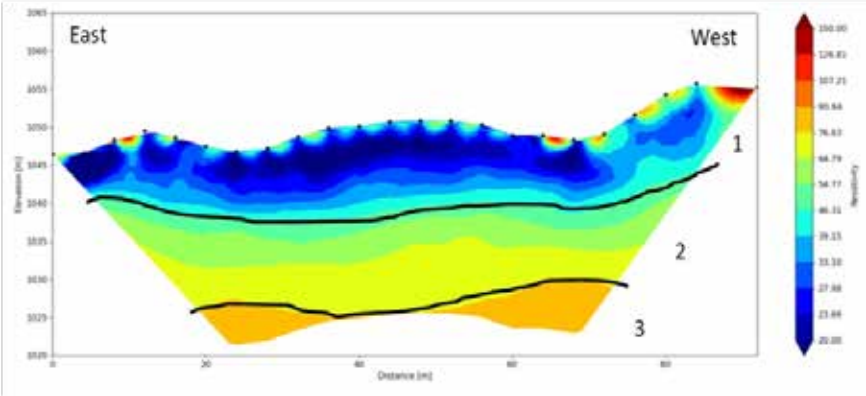

Figure 7: ERT3 resistivity distribution model.

The study of the area through three electrical tomographies (ERT1, ERT2, ERT3), revealed three main geoelectric layers corresponding to geological layers: the flysch (low resistivity values), the weathering mantle (intermediate resistivity values) and the limestone (high resistivity values). These geoelectric characteristics are directly related to the geotechnical properties of the formations, such as their strength, with limestone having the highest strength and flysch having the lowest. The analysis of ERT1 revealed ground subsidence, but it has not appeared as the main crown of the landslide. Instead, it is attributed to the heterogeneity of the flysch. Sections ERT1, ERT2 and ERT3 are cross each other at points used to confirm the validity of the results and to better understand the subsurface of the area. As the ERT1 was vertical to the other electrical tomographies (ERT2 & ERT3), there are two intersection points. The first one (Fig. 7), between ERT1 and ERT2, is located at the absolute altitude of 1.055 meters. On ERT1 this one is found between the 14th and 15th electrode and on the ERT2 it is found between the 9th and 10th electrode. For this common area were found both similar geoelectrical characteristics of the formations and thicknesses of them all, flysch was found 13 meters thick and weathering mantle 10 meters. The limestone basement is found at 23 meters depth.

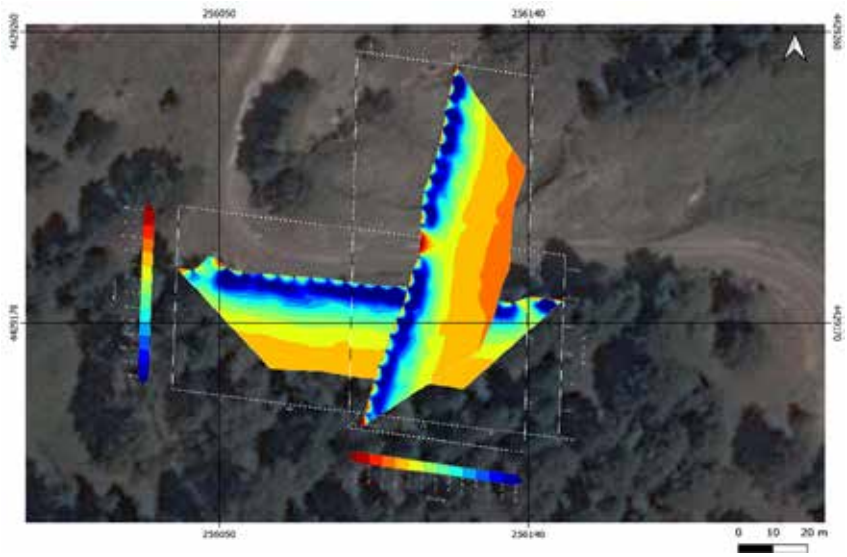

Figure7: Intersection point between ERT1 and ERT2

The second intersection point (Fig. 8), between ERT1 and ERT3, is located at the absolute altitude of 1.046 meters. This point is found between the 7th and 8th electrode on both first and third electrical tomography. At this intersection point the flysch appears with only 10 meters thickness and the weathering layer with 11 meters. The limestone basement is found at 21 meters depth.

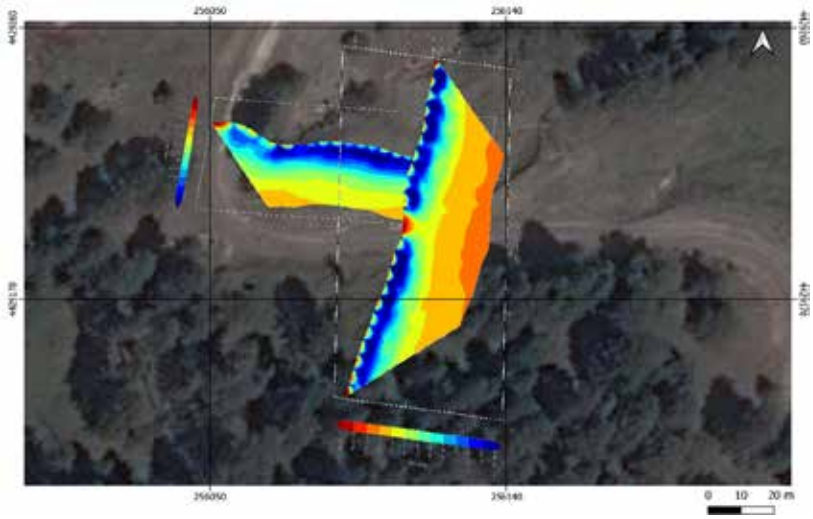

Figure 8: Intersection point between ERT1 and ERT3

Tomographies ERT2 & ERT3 were almost parallel and therefore provide data about the three formations on different elevations of the landslide. On ERT2 the subsurface flysch is found at 1046 meters altitude and on ERT3 at 1037 meters while the weathering layer is located at 1046 meters and 1037 meters and the base layer of limestone is located at 1035 meters altitude on ERT2 and at 1025 meters on ERT3. It becomes clear that the thickness of all the formations remain the same in the examined area even though the altitude decreases constantly, the distance between the two parallels is 37.5 meters.. According to these data, the altitude difference and the distance between the parallels, it follows the total slope of the landslide which is calculated as 13,5 degrees.

Introduction and background

The assumption of reference station conditions is an important one, yet is often taken for granted, especially at seismological stations or those presumably lying on rock. Stations are not always installed on true bedrock or in ideal free-field conditions, and –what is more– rock formations do not always exhibit negligible amplification, as assumed. In Greece, few site effects studies or field surveys have been conducted to characterise seismic networks in their entirety. Here, we first investigate broadband and accelerometric stations from the HL network, run by the National Observatory of Athens (NOA) throughout mainland and island Greece. We propose a solution that does not need significant nationwide resources (time and funding at a massive scale) such as would be required for in-situ geophysical campaigns. Instead of waiting for a time when funding and personmonths will be available at a massive scale to characterise all stations with measurements on site, we propose efficient desk studies that capitalize on the existing recordings collected so far, supplemented by additional desk work and existing knowledge that network operators have acquired from their site visits already. There are 60 such stations with publicly available data streams in the period 2012-2024 which are thought to lie on rock. We address the reference station question compiling a wide variety of parameters: waveform-derived (site-specific amplification characteristics), operator-derived (on-site observations from station visits and walk-overs), and external sources (geological maps and literature). We co-evaluate all these factors to propose a transparent scheme for assessing reference stations for the HL network. Finally, we propose the extension of this pilot study to include other networks, in the region of Macedonia and Thrace, as they can be of use in studying seismicity and seismic hazard in the Kavala-Prinos area, in the framework of EU project COREu.

Methodology

We follow the methodology set forth in detail in Ktenidou et al. (2024). We compile all types of information to create a comprehensive, systematic and holistic set of station metadata as follows.

1. We first compile all publicly available information from external sources. These include notes on geology and topography from the literature (e.g. the ESM ORFEUS website, (https://esm-db.eu/; Lanzano et al., 2021 & Luzi et al., 2016; the NOA/GEIN website, https://accelnet.gein.noa.gr/; Margaris et al., 2021 – M2021). We then collect and analyse geological maps to provide a consistent description of geological unit and geological age. We mostly use geological maps (1:50,000 scale) published by the Hellenic Survey of Geology and Mineral Exploration (HSGME). We then combine this with observations by the operators regarding the geology, topography, and the installation and housing conditions on site, which are attributed high accuracy and reliability owing to the site visits. These parameters are shown in Tables 1, 2 and 3. We acknowledge the limitations of using this kind of geological map, where the scale is more appropriate for nationwide studies than site-specific ones, where inconsistencies are likely between map sheets due to them having been compiles by different persons and even with several decades' time difference, and where simplifications are likely made in the presence of complexities. But there is no other readily available resource for deriving geological information homogeneously across the country, and in this sense the geological information we compile suffers from issues of granularity for the sake of some –relative- consistency and homogeneity.
2. The second and most demanding stage of this study is to create a strong-motion database to study amplification. We collect waveforms available from the past decade from events with M4 and above, and we perform a detailed analysis to estimate the local site response per station. To do this, the dataset first goes through quality control by visually inspecting and meticulously processing the data on a waveform-specific basis, both in the time and frequency domain. Single-station amplification functions are then estimated from the dataset using the horizontal-to-vertical spectral ratio (HVSR) technique of Lermo and Chavez-Garcia (1993). A good reference station should have low and flat amplification, as e.g. some of the Northern Greece stations shown in Figure 1. Moreover, it should exhibit no significant azimuthal variation, and to assess this we not only assess the features of the mean HVSR per station but also its directional sensitivity as per Ktenidou et al. (2016), which serves as a means to identify departure from the 1D assumption (Figure 2 shows the low sensitivity for two of those stations). We propose that three values of standard deviation at different frequency ranges (0.3-30 Hz, 1-10 Hz, and fo) can be used as approximate indicators of the azimuthal stability of site response. These parameters are shown in Table 4.

We evaluate each criterion independently and assess whether each station can be considered a reference station from the point of view of geology, topographic relief, installation conditions, Vs30, and the characteristics of the HVSR in terms of mean amplification level and shape as well as in terms of directional stability. These assessments are shown in the following tables for the three stations in Northern Greece, which ranked very high among the 60 Greek stations studied.
It is well known that the amplification (A_0, A_1 in table 4) is usually underestimated by HVSR, since the vertical component is of course amplified to an unknown degree yet assumed unaffected. We also attempt some preliminary corrections to the amplitude based on the methodology of Ito et al. (2020), which however was calibrated on regional data from Japan, and so may not reflect vertical amplification levels in Greece. Hence we show these results only in an indicative capacity. Figure 3 shows examples of the Ito correction of the mean HVSR shown in Figure 1, and Table 4 also includes characteristics of resonance (e.g. A0_corr) based on these corrections. Clustering was also performed based on corrected HVSRs and similar clusters were found (more details in Ktenidou et al., 2024).

Table 1. Parameters describing housing/installation conditions and Vs30 for 3 example stations.

Station code	Building type (GEIN)	Installation con-dition	Potential reference (Inst/on)?	EC8 (ESM)	Vs30 (ESM)	Vs30 geology (M2021)	Vs30 terrain (M2021)	Preferred Vs30 (M2021)	Potential reference site (Vs30)?

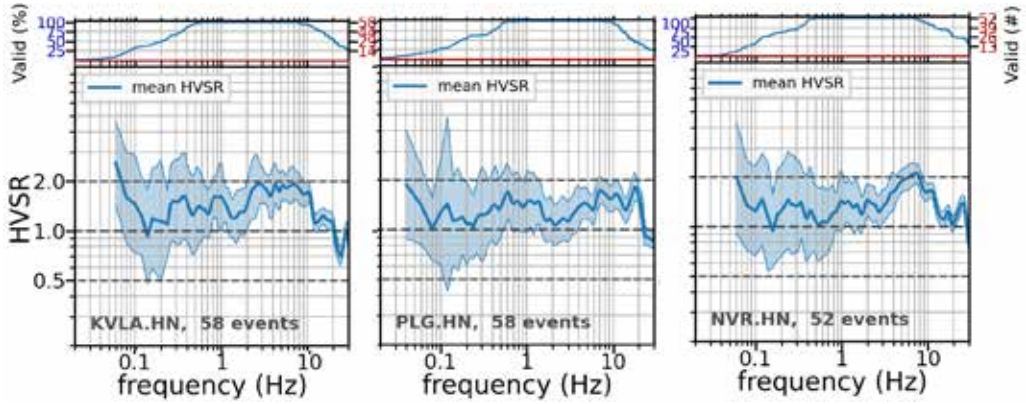

Figure 1. Mean HVSR ± 1 standard deviation for 2 stations in Northern Greece (left to right: HL.KVLA, HL.PLG and HL.NVR); inset on top indicates the number of available recordings per frequency.

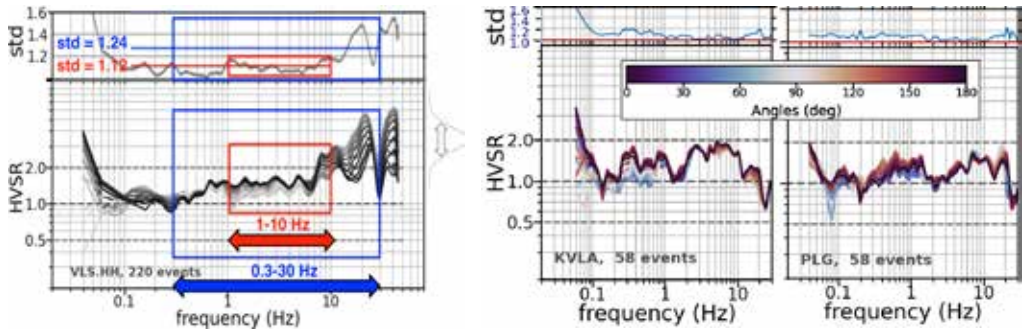

Figure 2. HVSR per component for 2 stations (left to right: HL.KVLA, HL.PLG), as those are rotated by 10º intervals from North to East; inset on top indicates the standard deviation (hence, directional sensitivity or variability) per frequency.

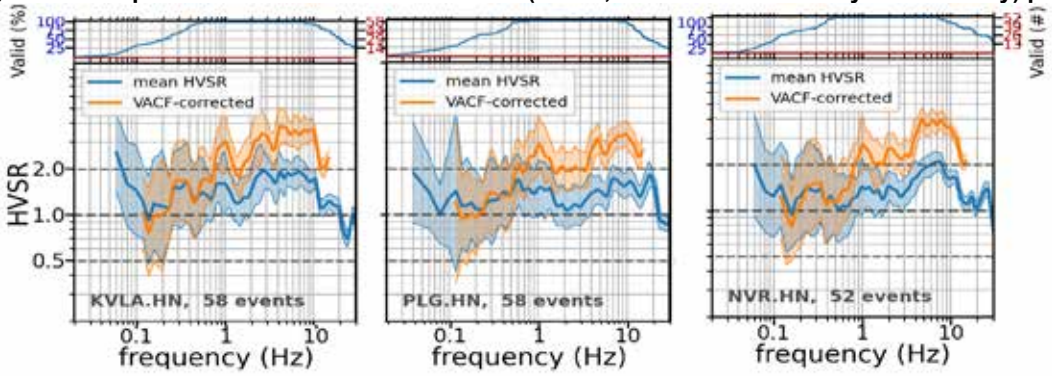

Figure 3. Mean HVSR±1 standard deviation (in blue) for 3 stations in Northern Greece (left to right: HL.KVLA, HL.PLG and HL.NVR) and corrected HVSR using Ito et al. (2020) correction function for the vertical component (in orange). The latter is only computed within the method's range of applicable frequencies and is offered in an indicative quality; inset on top indicates the number of available recordings per frequency.

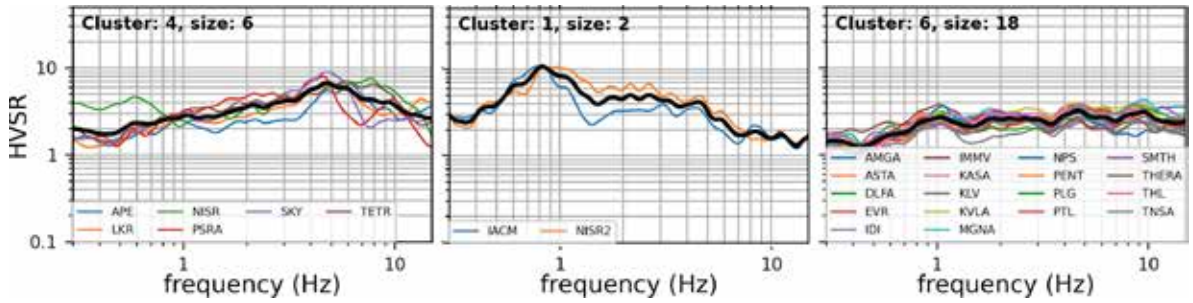

Figure 4. Example station clusters with different style of HVSR response.

Finally, we use clustering techniques to group stations with different response characteristics (Figure 4) and finally combine this data-derived characterization with the previously compiled metadata to evaluate the stations' overall capacity as reference sites.

Results and discussion

In this study, we compiled several descriptors from literature, geological maps and direct network operator observations from site visits and we also derived site-specific amplification characteristics from strong-motion data analysis. We brought everything together to co-evaluate the overall potential of our stations as reference stations. We proposed a solution that does not need significant nationwide resources (time and funding at a massive scale) such as would be required for in-situ geophysical campaigns. Instead of waiting for a time when funding and personmonths will be available at a massive scale to characterise all stations with measurements on site, we propose efficient desk studies that capitalize on the existing recordings collected so far, supplemented by additional desk work and existing knowledge that network operators have acquired from their site visits already. We acknowledge the limitations of HVSR, namely the underestimation of amplification level, and hence propose that our amplification results be regarded as potential lower-bounds. However we do stress that even with a full-blown budget for geophysical campaigns, the resulting Vs profiles would still suffer from that method's own drawbacks – they would be non-unique and any forward site response modeling using them would also heavily rely on the 1D assumption: this, HVSR does not – it actually reveals at least some of nature's departure from it.

This work has been completed for all HL network stations that lie on rock and is currently underway for stations from other networks in the regions of Macedonia and Thrace. The special focus on this region intends to add value and help decrease epistemic uncertainties for future applications that will take place within the European project COREU (https://coreu.eu/), which will involve seismic monitoring and hazard assessment in the Kavala-Prinos area in the framework of a CCS pilot study.

Acknowledgements

All waveforms and station metadata are freely accessible at https://eida.gein.noa.gr/, the regional node of EIDA hosted by the Institute of Geodynamics of the National Observatory of Athens (NOA). Event parameters come from the seismic catalogue of NOA, freely accessible here: https://eida.gein.noa.gr/fdsnws/availability/1. We gratefully acknowledge partial financial support from EU project COREU.

EXTENDED ABSTRACT 185

The Xerias Window near Argos (Peloponnesus)

Dipl.-Geol. Dr. Erwin Kunz, retired geologist, Bad Oeynhausen, Germany

Introduction and methodology

The area considered in this paper comprises a section of the mountains that separate the regions of Argolis and Arcadia. This mountain range is part of the Hellenides, and it is built up by the rock sequences of Tripolitza and Pindos Zone. Its tectonic architecture is deeply exposed in the Xerias Window (Jacobshagen 1986) (fig. 1). Key structures (Schwan 1964) are worked out for every lithological unit, for clarifying the large-scale architecture of the mountains.

Varying geodynamic stress fields

The nappe-shaped position of the Pindos Zone is obvious in the frame of the Xerias Window. The vergence of the key structures of the latter varies everywhere between W and SW, which proves a relative transport of the Pindos Zone as a whole in that direction.

In contrast, the Tripolitza Zone does not show evidence for such a transport. The folds and overthrusts within Tripolitza Carbonates and Flysch around Krya Vrysi trend resp. strike from WNW to ESE with their vergence to the NNE, which can be explained only by a compressional stress in this direction. Also, at the contact between Phyllite-Quartzite Series and Tripolitza Carbonates south of the Xerias valley, corresponding tectonic structures can be found.

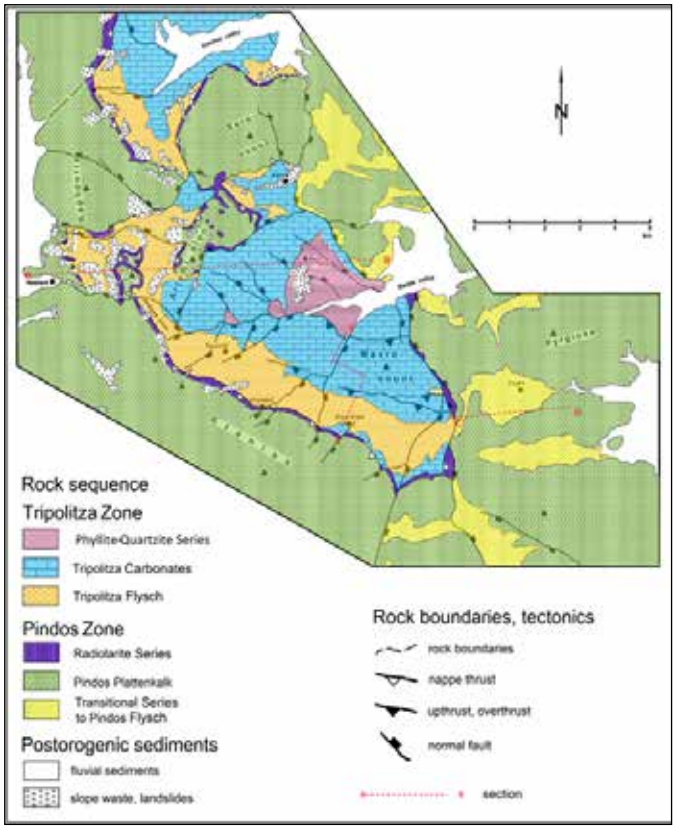

Fig. 1: Generalised geological map of the Xerias Window and its frame

Round about since Upper Miocene, the compressive stress was followed by young extensional tectonics, which continues until today. Its influence on the development of the Xerias Window and on the forming of its frame is described. The important faults created in this time (Xerias faults) show clear parallels to the Corinthian and the Argolic Gulf.

EXTENDED ABSTRACT 186

Mineralogy and Geochemistry of the Non-Sulfide Zinc-Lead Deposits, Thasos Island, North Aegean, Greece

Kyriakos A.[1], Sakellaris G.A.[1], Melfos V.[1], Stergiou C.L.[1,2], Papadopoulou L.[1], Kantiranis N.[1]
(1) School of Geology, Aristotle University of Thessaloniki, Greece, axkyriak@geo.auth.gr (2) Chemical Process & Energy Resources Institute (CPERI), Centre for Research and Technology Hellas (CERTH), 50200 Ptolemaida, Greece

Introduction

Thasos Island has long been recognized as an important mining center with its prehistoric ochre mines in the area of Tzines representing some of the earliest mining activities in Europe, dating back to 20,000 BCE (Koukouli *et al.,* 1988). The island was also renowned for its gold, silver, copper and lead production, referenced by Herodotus and Strabo. Due to its abundant Zn occurrences, and particularly calamine ore (smithsonite), Thasos witnessed significant mining activity in the early 20th century. On that time, calamine, a non-sulfide type of zinc ore, was the primary source of Zn worldwide. In 1902, the German company "Minengesellschaft Fr. Speidel" established a mining complex in the Limenaria town to exploit zinc and argentiferous lead ores. However, operations ceased in 1913 due to declining ore grades. In 1925, a subsidiary of the Belgian company "Société des Mines et Fonderies de Zinc de la Vieille Montagne" undertook the restoration and the expansion of the mining facilities. Despite these efforts, the global economic crisis of the 1930s along with the development of flotation and smelting processes for zinc sulfide ores (sphalerite), resulted in cease of the lead-zinc mining activity on the island (Epitropou, 2005). Further exploration on the island during the 1970s and 1980s failed to locate new significant resource of either non-sulfide or sulfide zinc mineralization.

Non-sulfide zinc deposits in Europe were used since Roman times for the production of brass (zinc-copper ± tin alloy). These ores are mostly secondary and form through supergene oxidation of primary sulfide deposits (Boni and Large, 2003). According to Large (2001), the non-sulfide zinc deposits are classified into three main groups based on their geologic characteristics: a) calamine-dominated deposits formed through supergene oxidation of primary sulfides in carbonate environments, often preserved as karst cavity infillings, with main minerals smithsonite ($ZnCO_3$), hydrozincite, and hemimorphite; b) willemite-dominated (Zn_2SiO_4) deposits of primary hydrothermal origin, associated with fault zones and brecciation, and; c) supergene zinc deposits formed by residual surface oxidation, hydromorphic dispersion, and precipitation in carbonate environments, with a complex mineralogy including smithsonite, sauconite, and hydrozincite.

This research work investigates the most important non-sulfide zinc-lead-silver deposits, as well as, the iron-manganese deposits of Thasos. Despite the extensive studies on the metamorphic lithologies and core complex structures of Thasos, these deposits have remained understudied, and no comprehensive data regarding the processes of formation and the characteristics of primary mineralization exist. The aim of this work is to classify the mineralization in respect to mineralogy, the metal concentrations, and the correlations between major and trace elements, contributing to a better understanding of their genesis and economic potential.

Geological Context

Thasos Island located in the northern Aegean Sea, Greece, is geologically part of the Rhodope Metamorphic Core Complex. This complex comprises Paleozoic to Mesozoic high-grade metamorphic rocks that were exhumed during the Late Oligocene to Miocene extension (Wawrzenitz & Krohe, 1998). The metamorphic complex of Thasos is divided into three units (Brun & Sokoutis, 2007): a) a lower unit of marbles (Profitis Ilias), and dolomitic marbles with intercalations of paragneisses and mica schists (Potamia series), which covers the eastern part of the island; b) an intermediate slab of orthogneisses with paragneisses, mica schists (Maries series), and marbles (Kastro), which dominates the western and central part and; c) an upper unit of Tertiary conglomerates and non-mylonitic metamorphic rocks, migmatites and pegmatoids, with minor amphibolites and marbles in southwestern Thasos (Figure 1). These tectonic units are separated by two major southwest-dipping, low-angle extensional fault systems. These low-angle faults were originally thrust faults that transported the migmatites and the overlying intermediate unit over the lower unit. However, during the Miocene, these faults were reactivated as detachment faults. Most of the zinc deposits are located in the western part of the island, within the intermediate marble-gneissic unit along the major detachment faults and can be characterized as stratabound.

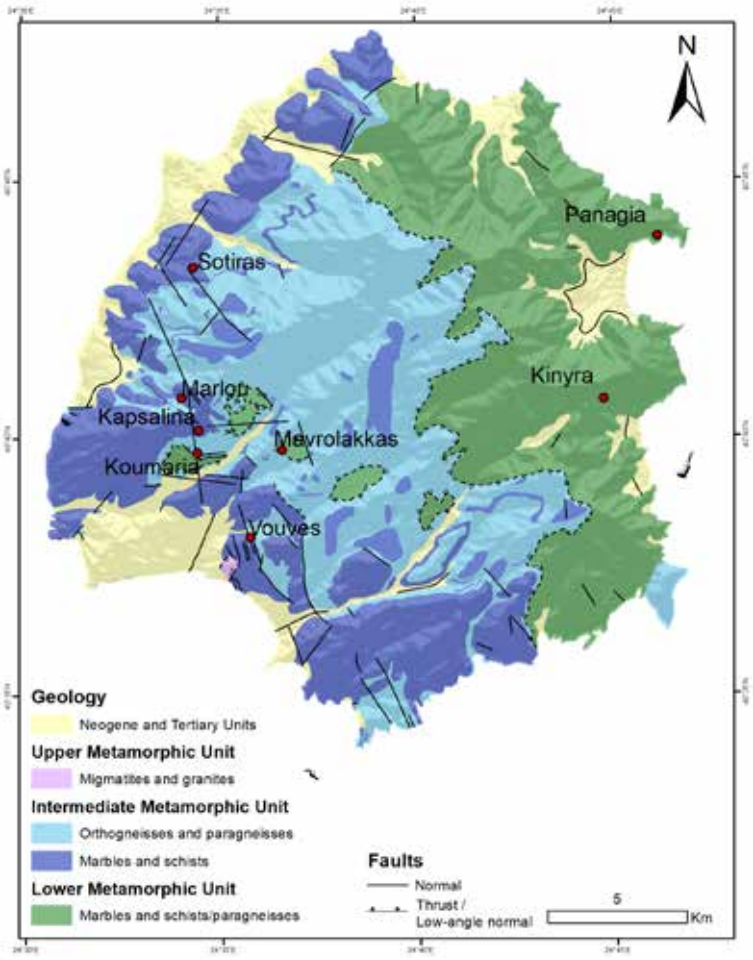

Figure 1. Geological map of Thasos illustrating the locations of the most significant zinc-lead and iron-manganese mines visited and sampled on the island, modified after Brun & Sokoutis (2007).

Samples and Methods

Representative hand specimens were collected from outcrops at the former (ancient and modern) mining sites of Sotiras, Koumaria, Kapsalina, Maries, and Vouves zinc-lead-silver deposits, as well as Mavrolakkas iron-manganese deposit during a two-day field work. Polished thin sections were prepared for microscopic examination using a Zeiss Axioscope 40 Pol, and by backscattered electron imaging (BSE) with a JEOL JSM- 6390LV scanning electron microscope (SEM) equipped with an OXFORD INCA 300 energy-dispersive X-ray spectroscopy (EDS). Powdered samples were proceeded for chemical analysis of major and trace elements, utilizing a wavelength-dispersive X-ray fluorescence (WD-XRF) spectrometry system. The instrument employs a Rhodium (Rh) X-ray tube with a Zirconium (Zr) filter, a three-crystal system (LiF(200), PET, RX25), and two detectors. The X-ray beam operated at high energy, with settings of 50 kV and 4 mA. The oxides measured include: Na_2O, MgO, Al_2O_3, SiO_2, P_2O_5, SO_3, K_2O, CaO, TiO_2, MnO, Fe_2O_3, and trace elements: Cl, Cu, Zn, Sr, Ag, Ba, and Pb (Table 1). All sample preparation and analytical procedures were carried out in the laboratory facilities of the Department of Mineralogy-Petrology-Economic Geology at the School of of Geology, Aristotle University of Thessaloniki.

Results

1. Structural setting

All visited zinc-lead-silver deposits are localized within certain layers of the marble units (Kastro) along major low-dipping detachment faults that bring the gneiss in contact to the marble (Figure 1). The geometry of deposits is highly dependent on the structural setting, with common morphologies including stratabound, stratiform, karst-hosted, lenticular, breccia-hosted, and tabular forms. The stratiform bodies are typically 1 to 3 meters thick extending for several 100s of meters to kilometers within the detachment zones (Figure 2).

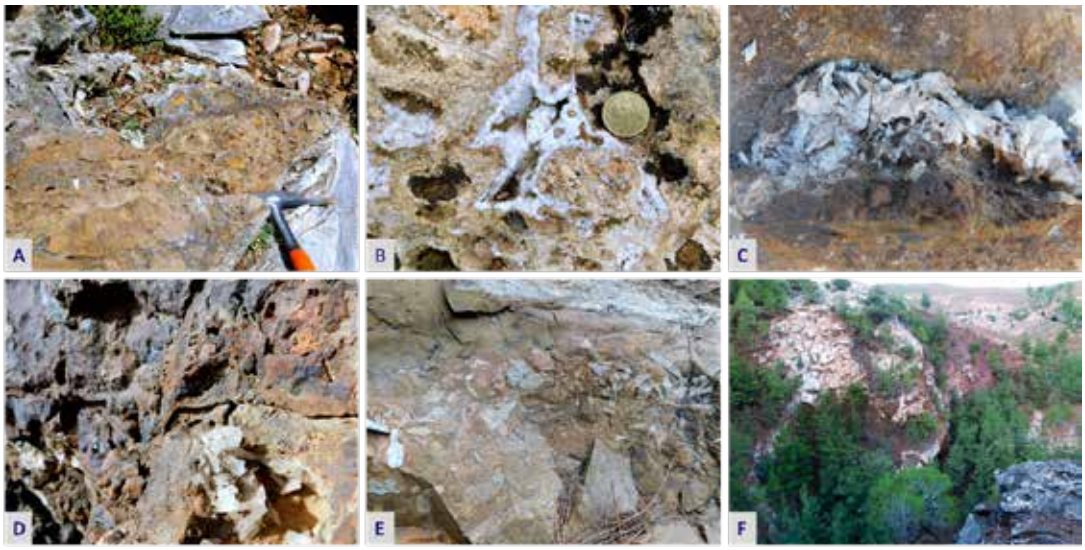

Figure 2. (A) Brecciated Zn-Pb mineralization within a low-angle detachment fault in marble at the contact with gneiss (Sotiras mine). (B) Zinc-rich aragonite filling fractures at the Sotiras mine. (C) Tabular barite crystal aggregates within Zn-Pb mineralization (Koumaria mine). (D) Well-formed barite crystals associated with massive stratiform Zn-Pb mineralization (Kapsalina outcrop). (E) Angular marble fragments within iron oxides-Zn-Pb breccia (Vouves mine). (F) Karst-hosted Fe-Mn (±Cu) mineralization within marbles (Mavrolakkas mine).

2. Mineralogy

The paragenesis of zinc-lead (±copper) minerals in all studied deposits consists predominately of the secondary carbonate minerals smithsonite ($ZnCO_3$) and cerussite ($PbCO_3$), and lesser lead-rich aragonite ($CaPbCO_3$), malachite ($Cu_2CO_3(OH)_2$), and azurite ($Cu_2(CO_3)_2(OH)_2$) (Figure 3). Notably, except Koumaria, where traces of sphalerite (ZnS) and galena were recognized, in none of the samples, primary sulfides were identified. Barite is a major gangue mineral constituent in most ore zones. More detailed:

Sotiras Zn-Pb mine:

The most abundant mineral phases in the ore samples are iron oxides enriched in Zn, smithsonite, and cerussite. Pure smithsonite or smithsonite with elevated Ca contents (up to 20%), is found as dispersed crystals in calcite-aragonite that replace dolomitic marble within breccia (Fig.2a,b and 3a,b).

Vouves Zn-Pb mine:

Mineralogical zoning within the ore breccia zones (Figure 2e) includes: a) a core zone with large euhedral crystals of barite, b) a botryoidal zone with Pb-rich calcite-aragonite, iron oxides enriched in lead, zinc, and occasionally in As and Si, as well as, calcite, c) an outer zone characterized by zinc-rich aragonite. Tiny flakes (less than 5 μm) of jarosite ($KFe_3(SO_4)_2(OH)_6$) and calcium-jarosite (jarosite with calcium impurities) are locally abundant within calcite, occurring between barite crystals. Additionally, concentric zoning in dolomite features iron-rich, Zn-rich and Pb-rich zones. An interesting mineral which occurs in botryoidal form is cesarolite, a rare secondary Pb-Mn oxide phase with the formula $PbMn_4O_6(OH)_2$ (Figure 3c, d).

Koumaria Zn-Pb mine:

Mineralization appears in breccia, consisting of cerussite, iron oxides, and Fe- and Zn-rich cesarolite, with frequent occurrences of barite veins (Figure 2c). The iron oxides are enriched in Pb, Zn, Si, and Mn, and, together with cesarolite, form euhedral structures related with the dissolution of primary mineral phases. Cesarolite appears as irregularly shaped and dispersed grains, suggesting its formation either as a secondary oxidation product or a replacement phase derived from earlier Pb-Mn-bearing minerals (Figure 3e,f). The iron oxides exhibit zoning and irregular morphologies, potentially indicating the oxidation of primary Fe-rich minerals. Their strong enrichment in Pb, Zn, Si, and Mn suggests remobilization and incorporation of these elements during post-depositional processes.

Mavrolakkas Fe-Mn mine:

The karst-filling mineralogy of this deposit within marble follows a distinct zoned pattern with an inner zone dominated by Mn-rich and Si-rich iron oxides, prismatic barite crystals, and quartz; and an outer zone composed of barren calcite/dolomite with minimal Fe and Mn enrichment (Figure 2f). The Fe oxides exhibit distinctive structures at the boundaries of what are likely primary crystals that have undergone oxidation. Additionally, apatite ($Ca_5(PO_4)_3(OH,F,Cl)$) crystals are occasionally observed among the Fe oxides.

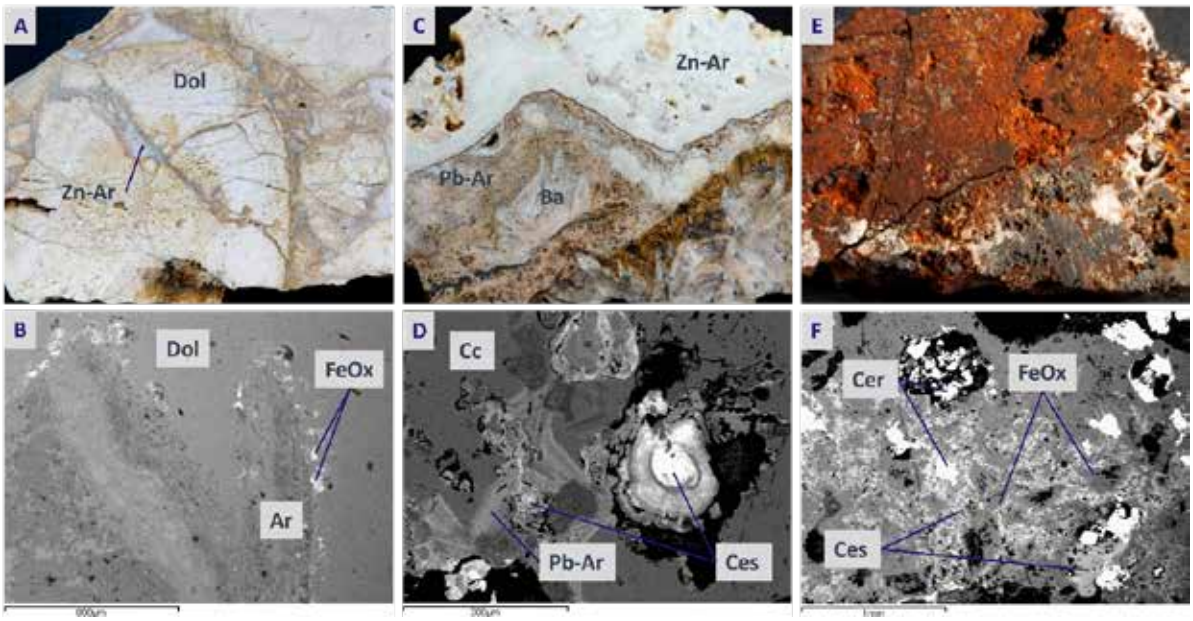

Figure 3. (A) Specimen from Sotiras showing Zn-rich aragonite veins within dolomite breccia. (B) BSE image from Sotiras depicting an aragonite vein within dolomite, with iron oxides forming along the contact zone. (C) Sample from Vouves displaying distinct mineralogical zonation. (D) Botryoidal cesarolite associated with Pb-rich aragonite. (E) Brecciated formation from Koumaria featuring a barite vein. (F) Typical Koumaria mineralization, characterized by cerussite, iron oxides, and cesarolite forming euhedral structures related to primary mineral phases. Mineral abbreviations: Cer: Cerussite, Ces: Cesarolite, Cc: Calcite, Ar: Aragonite, Pb-Ar: Pb-rich aragonite, Zn-Ar: Zn-rich aragonite, FeOx: Iron oxides, Dol: Dolomite.

3. Geochemistry

All samples from the Zn-Pb-Ag deposits exhibit several notable similarities, including consistently low bulk concentrations of Na, K, Al, Si, and Ti, while being enriched in Ca. This suggests a limited contribution from silicate phases and reinforces the strong association of the mineralization with carbonate-dominated host rocks.Sotiras Zn-Pb mine:

Elevated Mg and Ca concentrations are attributed to the presence of carbonates. Copper, Pb, and S exhibit the lowest amounts among all samples, with 0.002 wt.% Cu, 0.05 wt.% Pb, and 0.1 wt.% SO_3. Zinc is present at 0.48 wt.% Zn. Unlike all other samples, Ba was not detected, as its levels were below the detection limit. Iron and manganese concentrations are 1.37 wt.% Fe_2O_3 and 0.084 wt.% MnO, respectively.

Koumaria Zn-Pb mine:

The Koumaria samples are notable for the exceptionally high lead concentration, reaching 43 wt.% Pb, and the highest quantities of zinc (up to2.12 wt.% Zn) and manganese (up to 2.65 wt.% MnO), along with significant amounts of iron (up to 29 wt.% Fe_2O_3). Additionally, it contains notable silver (Ag) values up to 0,137 wt.% and the highest recorded copper (Cu) concentration of 0,104 wt.% among all analyzed samples. In contrast, calcium is the lowest among all samples at 1.05 wt.% Ca. Silicon and sulfur are present at similar levels, with 1.76 wt.% SiO_2 and 0.93 wt.% SO_2, respectively.

Vouves Zn-Pb mine:

The Vouves samples, similar to those from Sotiras, display high Ca and Mg concentrations (due to calcite-aragonite and dolomitic marble) along with notable amounts of zinc and lead. Zinc content ranges from 0.6 to 1.6 wt.%, while Pb varies from 0.25 to 0.64 wt.%. These samples also exhibit the highest recorded levels of barium and sulfur, reaching up to 16 wt.% Ba and 8 wt.% SO_3. Copper concentrations reach up to 0.049 wt.% Cu, while Fe and Mn are present in significant amounts, with values up to 4.12 wt.% Fe_2O_3 and 0.445 wt.% MnO.

Mavrolakkas Fe-Mn mine:

This site exhibits the highest iron and silicon quantities, exceeding 32.5 wt.% Fe_2O_3 and 11.1 wt.% SiO_2, respectively. Additionally, significant amounts of barium 10.5 wt.% Ba, sulfur 5.6 wt.% SO3 are observed, Manganese was measured at 1.8 wt.% MnO. In contrast, copper and zinc concentrations are relatively low at 0.007 wt.% Cu and 0.047 wt.% Zn, while lead is present at 0.36 wt.% Pb.

Table 1. Representative concentrations of major oxides and trace elements (wt.%), using X-ray fluorescence (WD-XRF).

* For the above samples, rounding was maintained to the third decimal place.

Discussion and conclusions

Most non-sulfide Zn-Pb deposits in Europe are classified as “calamine” ores, defined as concentrations of oxidized Zn and Pb minerals formed through deep weathering of carbonate-hosted primary sulfide ores (Large, 2001). These calamine-type ores are predominantly composed of smithsonite and hydrozincite, which result from the interaction of low-pH, Zn-rich groundwater with carbonate host rocks. Lead-bearing minerals, such as anglesite and cerussite, may also be present if the primary sulfide paragenesis contains galena (Hitzman et al., 2003).

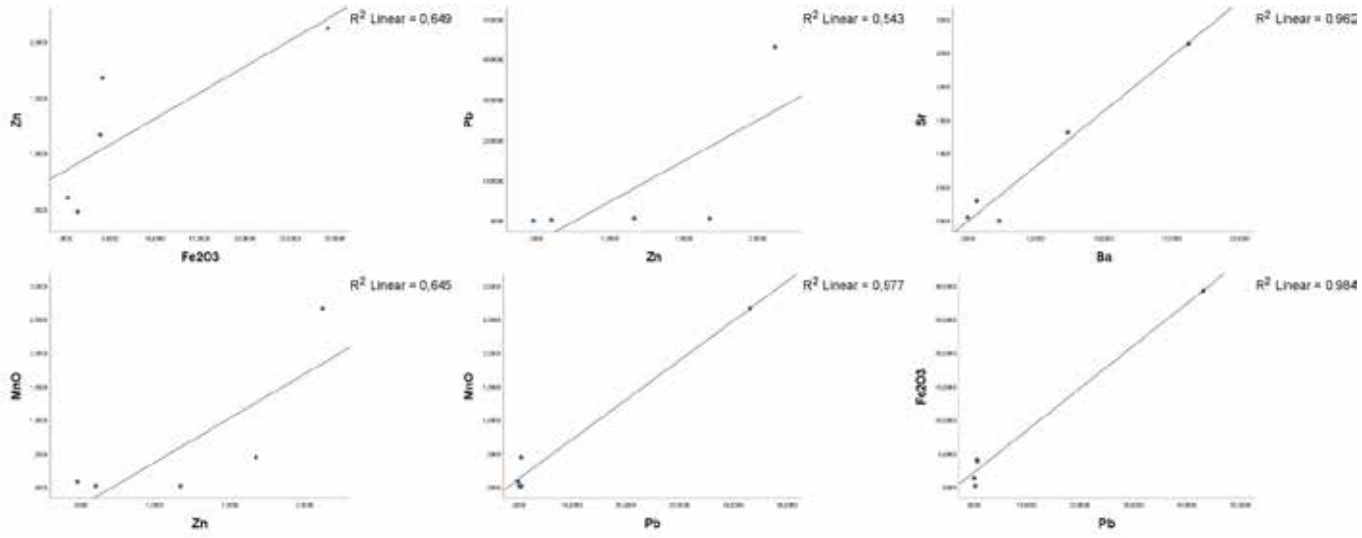

Figure 4. Positive correlation diagrams between major oxides and trace elements of the samples from Sotiras, Vouves and Koumaria.

The smithsonite and cerussite mineralization on Thasos Island is primarily hosted within breccia along large scale low-dipping (0–20°) detachment faults, which are likely of Middle Eocene to Early Miocene age, according to the studies of Brun and Sokoutis (2018) on the Kerdilion detachment fault. The ores are predominantly found within marbles at the contact zones with gneisses of the intermediate unit. The related Fe-oxides are enriched in Mn, Pb, and Zn, as well as As, Si. Other minerals include cesarolite, Pb-bearing aragonite-calcite, jarosite, and barite.
Chemical analyses reveal significant bulk concentrations of zinc and lead across the studied deposits, with Koumaria showing in addition to very high Zn and Pb content, notable enrichment in silver and copper (malachite, azurite). The correlation diagrams in Figure 4 provide insights into the geochemical relationships between different elements in the analyzed non-sulfide Zn-Pb deposits. The strong correlations of Pb with Fe and Mn oxides (Fe_2O_3 and MnO) suggest that lead was significantly remobilized (from oxidation of galena) and precipitated in oxidation zones either as cesarolite ($PbMn_4O_6(OH)_2$) and cerussite or was adsorbed onto Fe oxides/hydroxides. Moderate correlation of Zn with Fe and Mn oxides indicates that zinc liberated through oxidation from sphalerite and was partly incorporated into smithsonite and partly within the iron oxides (Fe-Zn-Si-As oxides). The moderate correlation between Pb and Zn indicates that these metals may have been liberated, transported and deposited together, although their geochemical behavior differs during formation of e.g., smithsonite vs. cerussite. The near-perfect correlation between Sr and Ba indicates the barite ($BaSO_4$) mineralization, with Sr substituting for Ba in the crystal lattice. In conclusion, the geochemistry supports a supergene enrichment model in which primary sulfides (galena, sphalerite) have undergone oxidation, leading to the formation of secondary carbonates (smithsonite, cerussite) and Pb-Mn oxides (cesarolite).
According to Hitzman *et al.* (2003), three main genetic models are considered as potential proto-ore types: Mississippi Valley Type (MVT), SEDEX, and Carbonate Replacement. Thasos deposits share almost all the typical characteristics of MVT Zn–Pb deposits. These include: a) carbonate sedimentary (dolomite) host rock, b) lead (Pb) and zinc (Zn) mineralization, with copper (Cu), silver (Ag), c) the presence of barite, d) stratiform morphology, and f) spatial relation with shale platform that contains hydrocarbon reservoir (Prinos oil district).
The development of the supergene mineralization may be attributed to the oxidation of the primary sphalerite-galena deposits which likely occurred through the infiltration of meteoric waters along post-Messinian normal faults. According to Boulvais *et al.* (2007) two distinct fluid flow events are associated with the normal faulting of Thasos: a) an early-stage, high-temperature fluid, likely of hydrothermal origin, and a later-stage, low-temperature fluid, possibly meteoric in nature, which appears to have driven the oxidative mineralization.

Introduction

The region of Kozani-Ptolemaida-Amynteo Basin hosts the largest lignite deposits in Greece. For decades, lignite has been extracted, stockpiled, and subsequently burned in the thermal power plants (TPPs) of the area. During combustion, many potentially trace elements, with some of them being harmful, are enriched in the fly ash dispersed into the broader region (Kassoli-Fournaraki et al., 1993; Sahanidis et al., 2001). Although previous research indicates that few elements from the region's fly ash exhibit a high degree of leaching, environmental concerns may arise due to the large volume of the fly ash produced (Georgakopoulos et al., 2002b).

The aim of this study was to investigate the geochemical distribution of uranium (U) and thorium (Th) in the soils of the Sarigkiol Basin, SE of Ptolemais town, as well as to evaluate their potential environmental impact. Additionally, an important environmental question addressed in this study is whether the origin of these two trace elements is lithogenic or anthropogenic.

Materials and Methods

For the purposes of this study, 24 soil samples were collected from the Sarigkiol Basin, Ptolemais. Eleven (11) of these samples were provided by Kantiranis et al. (2016) as part of research on assessing the origin of Cr(VI) in the groundwater supplying the municipal districts of Akrini, Agios Dimitrios, and Ryaki in the Municipality of Kozani. The data for these samples derived from the same study. The remaining thirteen (13) samples were collected in October 2023 for the purposes of this study. The sampling locations for each sample can be found in Table 1.

Table 1. Sampling locations for each sample (WGS 84, in decimal degrees).

The sampling area and the sample locations are presented in Figure 1. Sampling was conducted using an "Edelman" auger from the top, 10-cm-thick soil horizon. The samples were subsequently dried in an oven at 110°C for 24 hours, then grinded with a mechanical grinder, quartered with a mechanical splitter, and final grinded using an agate mortar.

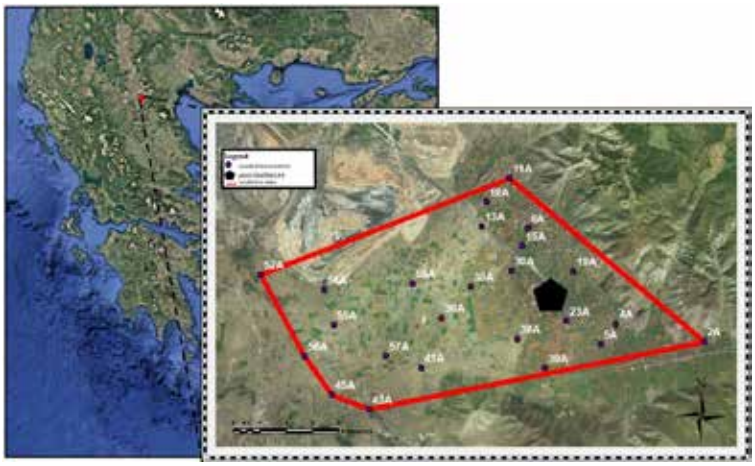

Figure 1. The sampling area and sampling sites (map taken from Google Earth).

The mineralogical analysis was performed using the X-ray diffraction (XRD) on randomly oriented powder preparations. A D8 ADVANCE diffractometer by BRUKER, housed in the Department of Mineralogy–Petrology–Economic Geology at the School of Geology, Aristotle University of Thessaloniki (AUTH), was used for this purpose. For the chemical analysis, the X-ray fluorescence (XRF) spectrometry was employed, using an S1 Titan 600 fluorometer by BRUKER, also located in the Department of Mineralogy–Petrology–Economic Geology at AUTH. The concentrations of the major oxides SiO_2, TiO_2, Al_2O_3, Fe_2O_3, MnO, MgO, CaO, K_2O, P_2O_5, SO_3, as well as the trace elements Cr, Ni, Cu, Zn, As, Rb, Sr, Y, Zr, Ba, Pb, Th and U were determined. Loss on ignition was determined as the percentage weight loss after heating 1 g of each sample at 1050/2h. The concentrations of the chemical elements were calculated using the Geoexploration reference curves integrated into the fluorosimeter. The accuracy of the values was ensured through the measurement of standard samples and the creation of calibration curves, with R^2 exceeding 0.9 in all cases.

The pre-existing measurements were conducted by the internationally certified and reliable Canadian Activation Laboratories LTD, located at 1336 Sandhill Drive, Ancaster, Ontario, Canada L9G 4V5 (http://www.actlabs.com). The following methods were applied: Inductively Coupled Plasma Optical Emission Spectrometry (ICP-OES) on fused pellets prepared with lithium metaborate ($LiBO_2$) and lithium tetraborate ($Li_2B_4O_7$) fusion; Inductively Coupled Plasma Mass Spectrometry (ICP-MS) on fused pellets prepared similarly; Instrumental Neutron Activation Analysis (INAA); and ICP after total digestion in a solution of $HClO_4$, HNO_3, HCl, and HF at 200°C (Kantiranis et al., 2016).

Due to the small number of samples, simple statistical processing was applied, and correlations of U and Th were performed with mineral phases, major oxides, and trace elements. Correlation diagrams were created, and the correlation coefficient R^2 was calculated. Finally, geochemical distribution maps were created in the ArcGIS 10.8.1 environment using the geostatistical Natural Neighbor (NN) method. Additionally, prediction models were generated using the deterministic Inverse Distance Weighted (IDW) method.

Results and Discussion

The mineralogical analysis of the soil samples identified the major mineral phases as calcite, quartz, dolomite, and feldspars. Chlorite, muscovite, amphiboles, serpentine, talc, pyroxenes, and clay minerals were also contained in the soils of the basin in minor amounts. A summary of their statistical distribution is provided in Table 2. The presence of these minerals is largely attributed to the lithology of the area, originating from the carbonate and ophiolitic rocks surrounding the mountainous regions of the basin (Kazakis et al., 2017, 2018), which enrich the detrital material in the study area, a region being now a drained mire (Pavlidis, 1985; Kazakis et al., 2018). Part of the calcite, quartz, feldspars, as well as pyroxenes and dolomite, is also attributed to lignite combustion (Filippidis and Georgakopoulos, 1992; Filippidis et al., 1996; Kolovos et al., 2002; Kostakis, 2009).

Tables 3 and 4 present the summary statistics of the chemical analyses of major oxides and trace elements, respectively. Additionally, the following trace elements were analyzed: Cr, Ni, Cu, Zn, As, Rb, Sr, Zr, Ba, and Pb. The presence of major oxides is attributed to the mineralogical composition of the soil. Nickel (Ni) exhibits a lithogenic origin, while arsenic (As), the third most enriched element, has a mixed origin (Nanos et al., 2015; Kantiranis et al. 2016). All other trace elements, including Cr, Cu, Zn, Rb, Sr, Y, Zr, Ba, Pb, Th, and U, have been identified in previous studies as being present in the region's lignites, as well as in the fly ash and bottom ash produced by the area's thermal power stations (Georgakopoulos et al., 1996; 2002a,b;c). For each major oxide and trace element, the pollution coefficient was calculated by comparing the results to the global average soil values (Hansford and Boerngen, 1984; Kabata-Pendias, 2011).

The pollution coefficients calculated for U and Th (Table 5) showed relatively low values. In the case of Th, most samples had pollution coefficient values below 1, classifying them as non-polluted. Additionally, six samples had values between 1 and 3, characterizing them as moderately polluted. Similarly, U exhibited pollution coefficient values <1 for the majority of the samples, classifying them as non-polluted. Two samples showed values between 1 and 3, indicating moderate pollution, while four samples had pollution coefficient values between 3 and 6, classifying them as significantly polluted for U.

The correlation of U and Th concentrations with mineral phases, major oxides, and trace elements revealed environmentally significant trends. Initially, U correlated with Th, yielding an R^2 value of 0.42, indicating a mild correlation and suggesting a partially common origin. Both radioactive elements showed positive correlations with quartz and feldspars but negative correlations with calcite and dolomite, with no correlation observed with other mineral phases.

For quartz, U had an R^2 value of 0.48 and Th an R^2 of 0.46 (mild correlations), while for feldspars, U showed R^2 = 0.46 and Th R^2 = 0.43 (mild correlations). Consequently, due to their positive correlations with quartz and feldspars, both elements also exhibited positive correlations with the major oxides SiO_2, Al_2O_3, and K_2O. For U, the R^2 values for these oxides were 0.50, 0.41, and 0.46 (mild correlations), respectively, while for Th, the R^2 values were 0.59, 0.60, and 0.63 (strong correlations), respectively. Positive correlations were also observed for Fe_2O_3 and TiO_2, although with lower correlation values. The other major oxides exhibited negative or negligible correlations with U and Th.

Regarding trace elements, U had the strongest correlation with Zr, Y, and Zn, with R^2 values of 0.75, 0.56, and 0.41, respectively (strong to mild correlations). Other trace elements showed weaker positive or negligible correlations. Th exhibited its highest correlation with Zn, Ba, Y, and Pb, with R^2 values of 0.72, 0.50, 0.48, and 0.44, respectively (strong to mild correlations). Figure 2 presents correlation diagrams for U and Th with various minerals, major oxides, and trace elements.

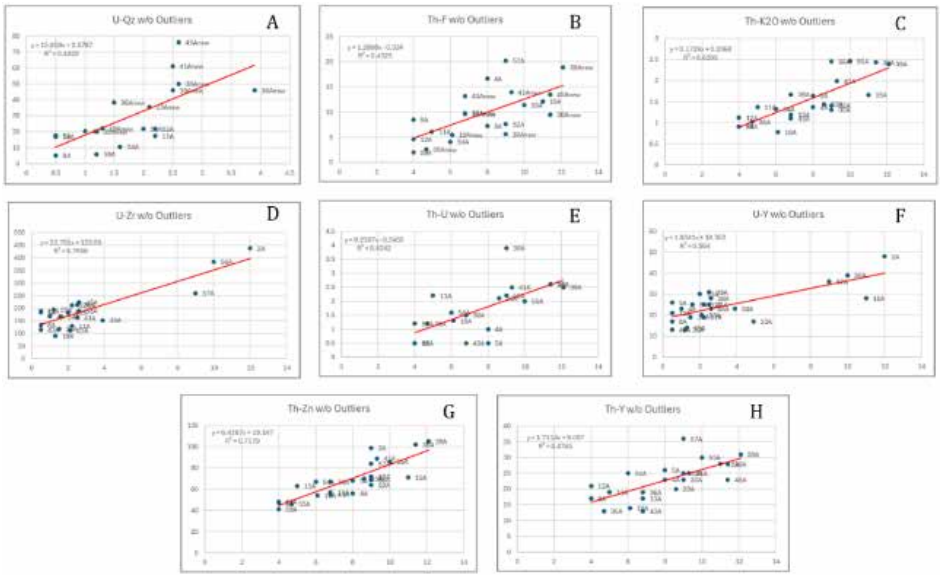

Figure 2. Correlation of U and Th. A) U with quartz, B) Th with feldspar, C) Th with K_2O, D) U with Zr, E) Th with U, F) U with Y, G) Th with Zn και H) Th with Y.

Finally, geochemical distribution maps were created for U, Th, and all other determined major oxides and trace elements. Alongside these distribution maps, predictive models were constructed for all chemical elements analyzed in the soils of the studied area.

The distribution maps for U and Th are presented in Figures 3 and 4, respectively. Additionally, the predictive model for K_2O is presented in Figure 5, which demonstrates very low errors (ME = -0.002 and RMSE = 0.6) based on the method applied.

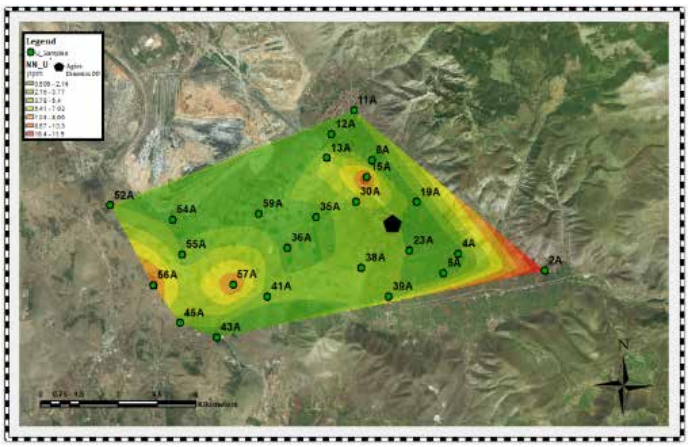

Figure 3. Geochemical distribution map of U using the NN method.

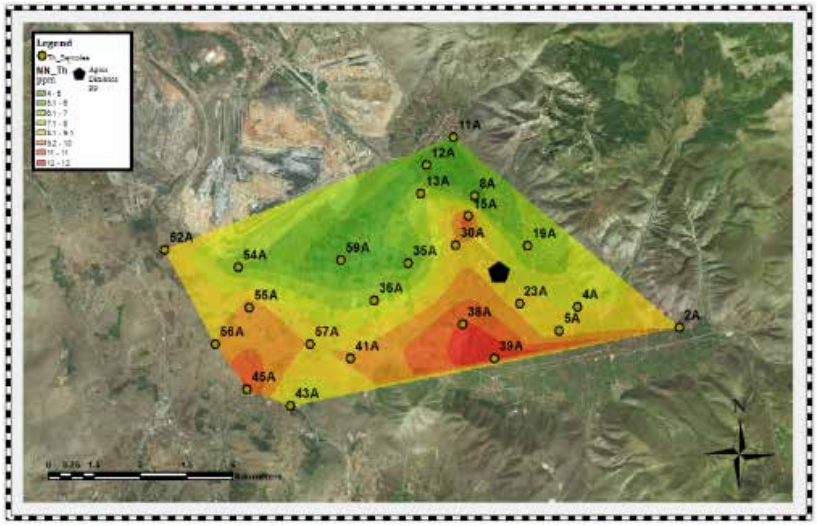

Figure 4. Geochemical distribution map of Th using the NN method.

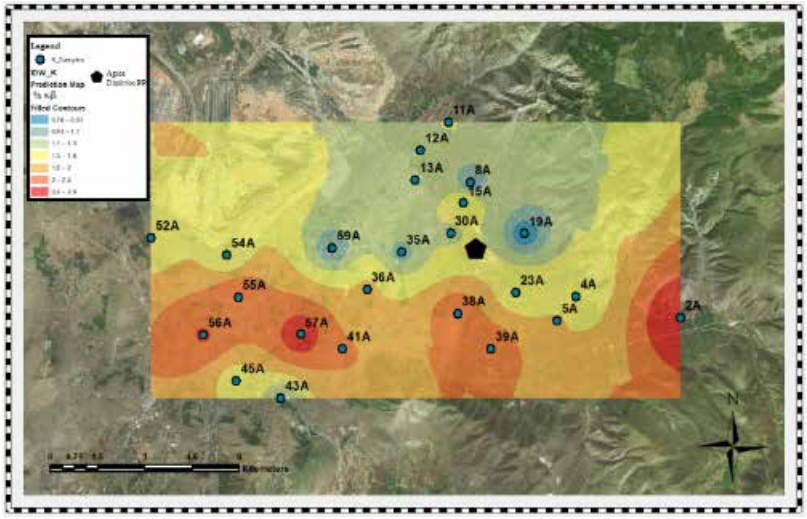

Figure 5. Geochemical distribution map of K_2O using the IDW method.

Conclusions

The results of this study present the geochemical distribution of U and Th in the soils of the Sarigiol Basin in the Ptolemais region, as well as their environmental significance. The main conclusions are as follows:

- Both radioactive elements, U and Th, are present in the basin's soils and show strong correlations with minerals such as quartz and feldspars, as well as with the oxides SiO_2, Al_2O_3, and K_2O.
- A strong correlation was observed between U and Th with the trace elements yttrium (Y), zirconium (Zr), zinc (Zn), and lead (Pb). These four trace elements exhibited a similar distribution pattern in the basin to this of U and Th and are primarily of anthropogenic origin, as they have been linked to industrial activities by previous studies, especially coal burning for energy production as they present high enrichment factors in fly ash.
- The high correlation values of these minerals, major oxides, and trace elements with U and Th, along with their geochemical distribution—showing higher concentrations near industrial activities—indicate anthropogenic activity, likely including lignite combustion and the dispersion of fly ash.
- According to the predictive models, K_2O could serve as a guiding element for identifying elevated concentrations of both radioactive elements.
- The concentrations of U and Th were considered relatively low based on the pollution index for each sample. However, their levels are not negligible, as both elements are radioactive and toxic at high concentrations, necessitating ongoing monitoring of their levels.

Introduction / Background

Natural disasters increasingly threaten human health, the environment, and the economy over time. The rise in frequency is attributed to two key factors: climate change and escalating human activity. Climate change intensifies natural phenomena, while human activity disrupts landscapes, leading to environmental imbalances. In 2023 alone, over 400 natural disasters were recorded globally, resulting in the deaths of 93 million people and damages amounting to
$498 billion USD. As shown in the accompanying image, from 1970 to 2024, the number of disasters has increased, with an average of 266.26 events per year (Burgueño Salas, 2024).

Dredge Spoils refers to the collection of solid and organic materials transported through water, which either flow in the watercourse and on the land surface or accumulate at the bottom of it. The accumulation of materials in aquatic environments is caused by factors such as urban development, agriculture, natural disasters, tidal effects, etc.

Flash floods carry a lot of dredged spoils due to the passage of water through vast areas, which then accumulate in floodplains, causing significant damage. They can roll boulders, cut trees, destroy buildings, and carry fabrics and metals. The resulting materials are transported to water channels and eventually to floodplains, leading to the contamination of the natural environment and acting as waste (Rao, 2017). Dredge materials are divided into two categories: Debris and Solid waste.

The flow of debris is one of the most destructive processes and can be defined as a rapid movement of mass composed of granular solids, water, and air (Varnes, 1978). The usual conditions for debris flow activity include steep slopes, loose materials, and wet conditions (Varnes, 1978). Debris flows can travel long distances and carry large amounts of debris along the way (Zimmermann & Haeberli, 1992). Moreover, in coastal environments, large volumes of debris are created and deposited after natural disasters such as tropical storms, floods, volcanic activity, earthquakes, fires, or explosions (Zimmermann & Haeberli, 1992).

Debris can sometimes be caused by human intervention due to uncontrolled land occupation and deforestation. For example, in Japan, most debris flows are created because of deforestation for building homes and temples. Acid rain could also be a factor, as seen in the Cubatáo area (Zimmermann & Haeberli, 1992).

The main types of debris are (Luther, 2006) (TCEQ Regulatory Guidance, 2017):

(a) Trees, shrubs, and other plant materials
(b) Building or demolition debris, such as construction materials, drywall, timber, treated wood, plastics, etc.
(c) Furniture and appliances such as carpets, furniture, mattresses, plumbing fixtures.
(d) Household hazardous waste such as cleaners, vehicle products, paints, oils, pesticides, solvents, etc.
(e) White goods like refrigerators, freezers, washing machines, dryers, stoves, water heaters, air conditioners
(f) Electronic waste such as computers, televisions, printers, stereos, DVD players, phones.

Other debris may include urban solid waste, including animal carcasses and trash that can cause unpleasant odors as they decompose.

Solid waste refers to any discarded material that is neither in a gaseous nor liquid phase. They can be defined as all discarded household, non-hazardous, industrial, and commercial waste. Additionally, construction waste, street garbage, agricultural waste, and all other non-hazardous, non-toxic waste are included. However, it does not include human excrement. They are produced by activities related to households, healthcare, agriculture, industry, commerce, and mineral extraction, and are piled on municipal streets and other public spaces (Goel, 2017).

Solid waste can generally be categorized as follows (Goel, 2017):

(a) Industrial and mining waste: Metal extraction and related industries represent significant factors for the economic development of many countries, and thus, mining waste represents most of the mining waste.
(b) Urban solid waste: City centers and commercial, institutional, residential, and municipal activities create this waste. This category is the most visible part, although it represents comparatively a small portion of the total solid waste produced.
(c) Hazardous waste: Refers to any waste considered toxic, reactive, radioactive, corrosive, flammable, or infectious. This category of waste also includes biomedical waste, plastics, and electronic waste. Hazardous waste is produced in relatively

small quantities compared to other categories of waste. This category has significant impacts on public health and the environment and is thus considered the most dangerous type of waste.

(d) Ash from thermal power plants: Thermal power plants that use coal are the primary source of electricity worldwide, although renewable energy sources are continuously increasing. Large amounts of ash are produced from coal combustion in thermal power plants. Thus, a significant solid waste management issue today is the management and disposal of this ash.

(e) Agricultural and related industries: Large amounts of agricultural waste are produced by these economic activities during harvesting and in food processing industries.

Other waste streams include oil waste, packaging waste, medical waste, scrap metal, and waste from tires and batteries. Cleaner manufacturing machinery can be developed to minimize waste at the point of production. Additionally, the environmental impact of solid waste can be reduced by sorting and processing waste before final disposal of the various components (Goel, 2017).

Disasters can generate enormous volumes of dredge spoils. During a debris flow, a liquefied mass of rocks, gravel, sand, soil, and other materials travel rapidly over long distances, causing severe destruction and intense erosion along its path. In most cases, the environmental consequences are significant. In terms of natural ecosystems, debris flows can devastate land and vegetation. Additionally, local populations may suffer fatalities, injuries, and displacement due to property loss (Kanji, 2001).

After a disaster, the removal of dredge spoils presents numerous challenges. The process often takes a long time, sometimes years—to complete. The most difficult aspect is finding effective management solutions. The dredge spoils management process should first address existing conditions and then gradually improve as follows ((ILO-OSH), 2001):

- Reduction of industrial, commercial, and household waste
- Increase in waste reuse and recycling
- Promotion of waste collection, processing, and disposal

Case Study

Between August 5 and 9, 2020, the storm “Thalia” struck Greece. This storm was caused by a cut-off low-pressure system in the mid and upper troposphere, located over the southern Adriatic and Ionian Seas. On August 8, the storm’s center was over the Ionian Sea before moving southeast toward the central Aegean on August 9.

By 19:00 UTC on August 8, thunderstorm clouds formed over Evia and organized into a severe storm within two hours. By 05:00 UTC, the storm began to weaken and soon dissipated. The main flooding event in Evia occurred on Sunday, August 9, with the Steni meteorological station recording 75 mm of rain from 23:20 to 02:40, 24 mm from 02:40 to 03:30, 200 mm from 03:30 to 07:30 and a total rainfall of 299 mm (Lekkas E., 2020).

The August 2020 flash floods primarily affected two riverbeds in the Politika area and the floodplain/coastal plains of the Lilandas and Messapios rivers. This study focuses on regions along the Lilandas River (Golubovic - Deligianni M., 2019), (Lekkas E., 2020).

According to the National Observatory of Athens, the storm resulted from a nearly stationary cut-off low-pressure system over the southern Adriatic and Ionian Seas. Early on August 8, 2020, the storm’s center was over the Ionian Sea, later moving southeast across mainland Greece. By the morning of August 9, 2020, the system’s center was detected over the central Aegean Sea (Lekkas E., 2020).

Methodology

The mapping of dredge spoils was based on field data collected by the research team from the Department of Dynamic, Tectonic, and Applied Geology at the University of Athens (NKUA). Immediately after the flood events, the team assessed the disaster’s impact. Data collection took place on August 9-10, 2020, using aerial imagery, videos, and ground-based photographs.

For aerial documentation, a Mavic 2 drone was deployed, flying at an altitude of 20-40 meters, depending on research needs, under sunny conditions.

The data collected was analyzed to identify and categorize dredge spoils in the study area. The categories observed included:

- Trees, shrubs, and other vegetation
- Construction and demolition debris
- Vehicles
- Mud, gravel, and boulders
- Waste
- Furniture and appliances

These categories slightly differ from those referenced in existing literature.

Google Earth was used to compare the aerial data with existing maps and determine the exact locations of the dredge spoils. Each identified deposit was outlined with a polygon to represent its occurrence. These polygons were then exported as Keyhole Markup Language (KML) files for use in Geographic Information Systems (GIS).

For final mapping and visualization, ArcGIS Pro was utilized. The KML file was imported into GIS and converted into a Feature Class, where descriptive data was processed, and each dredge spoil was classified based on its type and size.
Two separate layers were created, one illustrating sediment categories and another representing sediment sizes
To enhance visualization, the base map included Google Maps and a Digital Elevation Model (DEM), which provided elevation data for realistic terrain representation.

Results

The results present the mapping of dredge spoils through a series of maps, which illustrate the subregions within the study area to enhance the visualization of dredge spoils. These subregions, shown in figure 1, include Lilantas Delta, Lefkanti, Bourtzi, Vasiliko, Fylla, Afrati, Afrati/Pissonas, Pissonas, Pissonas/Pournos, and Pournos. For each subregion, two maps have been created, one categorizing the dredge spoils (a) and another representing their sizes (b).

From this study, the following conclusions can be drawn dredge spoils of various sizes are observed across different locations. In Lilandas Delta, small materials at the river delta increase in size upstream. The spoils are predominantly “Trees, Shrubs, and Other Vegetation”, along with “Construction or Demolition Debris”, “Mud, Gravel, and Boulders”, and “Vehicles”. In Lefkanti, small to medium-sized dredge spoils are mainly “Construction or Demolition Debris” and “Furniture and Appliances”, with some “Waste” and “Trees, Shrubs, and Other Vegetation”. In Bourtsi, dredge spoils of all sizes are mostly “Construction or Demolition Debris”, plus “Trees, Shrubs, and Other Vegetation”, “Mud, Gravel, and Boulders”, “Waste”, and “Vehicles”. In Vasiliko, dredge spoils of various sizes are mainly “Construction or Demolition Debris” and “Trees, Shrubs, and Other Vegetation”, with some “Mud, Gravel, and Boulders” and “Waste”. In Fylla, all sizes of dredge spoils are present, primarily “Construction or Demolition Debris” and “Trees, Shrubs, and Other Vegetation”, plus some “Mud, Gravel, and Boulders”. In Afrati, large-sized dredge spoils predominate, mainly “Construction or Demolition Debris” and “Trees, Shrubs, and Other Vegetation”, with some “Mud, Gravel, and Boulders”. In the Afrati/Pissonas area, medium and large dredge spoils are mostly “Mud, Gravel, and Boulders”, followed by “Construction or Demolition Debris” and “Trees, Shrubs, and Other Vegetation”. In Pissonas, medium and large spoils are mainly “Trees, Shrubs, and Other Vegetation” and “Mud, Gravel, and Boulders”. In the Pissonas/Pournos area, large amounts of medium and large “Construction or Demolition Debris” are observed. In Pournos, medium and large spoils are mainly “Mud, Gravel, and Boulders”, with “Trees, Shrubs, and Other Vegetation” and “Construction or Demolition Debris”.

Conclusions / Discussion

Dredge spoils of various sizes are observed across different locations, with materials ranging from small debris in river deltas to larger deposits upstream. The most observed categories include “Trees, Shrubs, and Other Vegetation,” “Construction or Demolition Debris,” and “Mud, Gravel, and Boulders.” In some areas, “Vehicles,” “Furniture and Appliances,” and “Waste” are also present. Larger spoils dominate locations like Afrati and Pissonas, while smaller to medium-sized materials are prevalent in places like Lefkanti and Vasiliko. Effective management and strategic land use planning are essential to mitigate risks associated with dredge spoil accumulation.

The state and relevant authorities must be aware of the extent of the destruction to reduce the likelihood of a similar future event. Identifying high-risk areas is crucial for implementing appropriate measures. Land use should be modified where necessary, such as prohibiting construction near riverbeds to prevent erosion risks. A rapid response is essential, including the removal of debris and financial recovery for affected environments. Protecting human life, health, safety, and the environment must be a priority. Public health risks should be minimized to ensure a swift return to normal activities. Additionally, securing basic needs and creating immediate short-term employment

opportunities will support recovery efforts. Enhancing governmental preparedness and establishing sustainable debris management systems are key to long-term resilience and disaster prevention.

Acknowledgements

I would like to express my sincere gratitude to all those who contributed to the completion of this research. First and foremost, I am deeply thankful to Professor Dr. Efthymios Lekkas and Nafsica-Ioanna Spyrou, for their invaluable guidance, support, and expertise throughout the course of this project. Their insights and encouragement have been instrumental in shaping the direction and quality of my work. A special thanks to the members of the scientific team, who gathered the primary data, as without their efforts none of this could have been possible.

Introduction / Background

Lesvos island, located on the Northeast Aegean region, Greece, is characterized by active tectonics associated with the evolution and deformation of the broader Northeast Aegean Sea.

The Northeast Aegean region is characterized by complex tectonics controlled by interplay of moving tectonic plates in the broader area. The area is affected by the dextral strike-slip movement of the North Anatolian fault, which ends in the Aegean basin and creates significant tectonic structures such as the North Aegean trough and the Skyros trough. The area is also affected by E-W trending normal faults.

Several studies show that the region of the Northeast Aegean region is characterized by complex transtensional stress pattern due to the influence of the NAF, which in combination with the N-S extension stress field of the Aegean micro-plate, creates several secondary faults. (Pavlides & Caputo, 1994; Bellier et al., 1997; Kiratzi, 2002; Flerit et al., 2004; McNeill et al., 2004; Chatzipetros et al., 2013; Konstantinou, 2017; Sakellariou et al., 2017). Except from the well-developed NE-SW faults, the reflection profiles also show the existence of E-W and NW-SE oriented faults which were interpreted as Riedel fractures resulting from the transtensional character of the stress field (Pavlides & Tranos, 1991; Chatzipetros et al., 2013; Konstantinou, 2017).

The tectonic structure of Lesvos Island, both offshore and onshore, is similar to the overall regional deformation of the North Aegean area, where the two main strands of the western prolongation of the North Anatolian Fault form the North Aegean and the Skyros basins. In the Northeast Aegean region there are several E-W trending normal faults due to the active N-S extension stress field, but also there are several other strike-slip faults which are compatible that created in combination of the North Anatolian Fault that pass very close to Lesvos Island. These strike-slip faults have primarily NE-SW orientation and secondarily a NW-SE orientation (Chatzipetros et al., 2013; Kiratzi, 2018; Nomikou et al., 2021).

Figure 1: Seismic and active faults map of the Lesvos Island (Zouros et al., 2008).

The neotectonic studies in Lesvos Island have identified and mapped the major active tectonic structures of the island which are both normal and strike-slip strike (Zouros et al., 2008, 2011; Chatzipetros et al., 2013, Mourouzidou, 2021). In Lesvos Island are represented three neotectonic stages from since the Miocene. A) The recent active stage since

the Pleistocene forms E-W trending normal faults (fig. 2&3), B) the second one took place in the Pliocene and formed normal faults of NW–SE strike, as well as strike–slip faults of NNE–SSW strike and finally, C) the earliest one of Upper Miocene age, based on its relation to synchronous volcanism and associated rocks, and formed strike–slip faults of E–W to ENE–WSW (fig. 4) strike (Chatzipetros et al., 2013).
In the area of west Lesvos there is a gap in tectonic data, due to the lithology which make difficult to identify fault traces. Since the relief is directly affected by erosional processes, among other factors, its intensity is associated with the age of faulting: younger activity generally produces steeper relief. Therefore, geomorphic structures associated with faulting are indicative of relatively recent age (Chatzipetros et al., 2013).
Intense volcanic activity appeared on Lesvos Island during Lower Miocene (23.5 to 16 million years ago) and the volcanic rocks are covering the 2/3 of the island's surface. Several volcanic rock units have been identified (Pe-Piper and Piper, 1993).
West Lesvos is covered mainly by pyroclastic material of the Sigri pyroclastic formation (Pe-Piper et al, 2019). Pyroclastic formations are easily eroded and thus the geomorphological indicators related with the recent tectonic activity are not well-preserved in the relief.

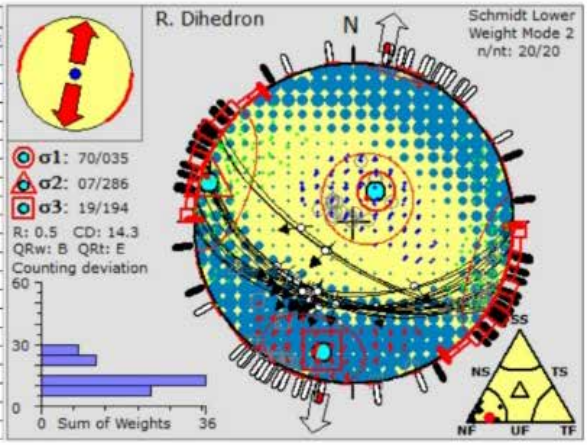

Figure 2: W – E to WNW – ESE trending normal faults affecting the Miocene lavas along the Voulgaris gorge.

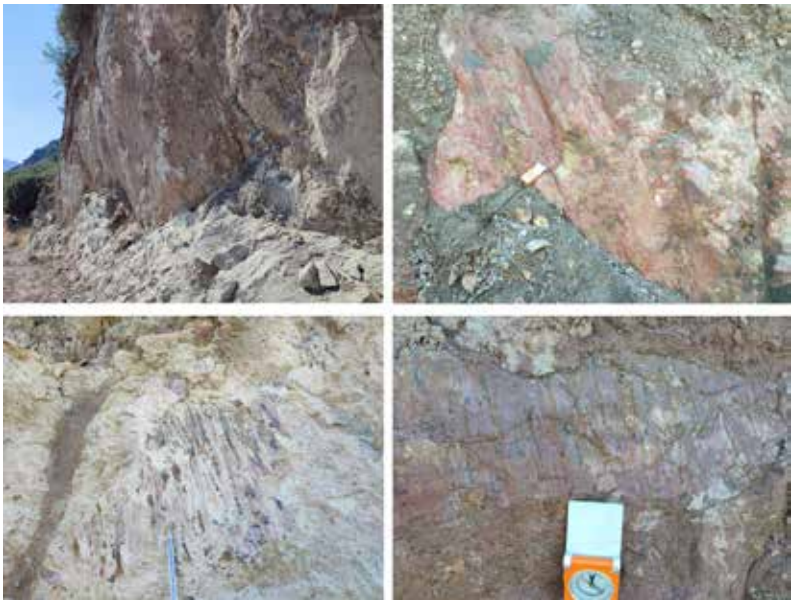

Extensive field work was carried out for the study of tectonic structures in order to identify the tectonic deformation in the broader area, according to the new data.
Our study was based on the observations of the fresh road cuts created due to public works for the reconstruction of the new Kalloni – Sigri road. Lots of new tectonic data in the area of West Lesvos, were revealed. The fault planes affecting the volcanic formations consist significant indicators for the tectonic deformation in the area.

Objectives and Methodology

The extensive field work and study on several new faults in the western peninsula of Lesvos Island gave us the opportunity to identify active tectonic structures in a broad area. The faults in the study area are variable in strike and character. Their activity level is determined based on their geological, geometrical and geomorphological characteristics.

The faults of West Lesvos affecting the volcanic rocks present various orientations and types of striking with very clear striations on their fault surfaces.

The tectonic analysis of field data was conducted using Win Tensor 5.9.0 software (Delvaux & Sperner, 2003) to determine the kinematic axes of the main stress pattern in the area. Developed by Damien Delvaux, this software defines stress fields based on geological data, including faults, fractures, and striations, as well as earthquake focal mechanisms.

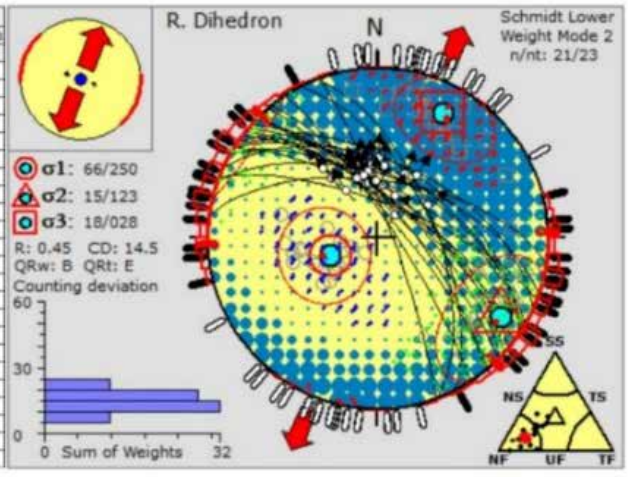

Figure 3: WNW – ESE to NW – SE trending normal faults affecting the Miocene lavas along the Voulgaris gorge.

Initially, tectonic data are entered into a worksheet, specifying the dip direction, dip angle, pitch angle and orientation. The fault type (normal, reverse, or strike-slip), certainty factor, and striation intensity are also assigned.

In the processing stage, the software generates rose diagrams, statistical summaries of fault surfaces, and applies the Right Dihedron method for stress analysis.

Also, Dextral Strike-Slip faults were also identified and measured with NE – SW orientation and less Sinistral Strike-Slip faults with NW – SE orientation (fig. 4 & 5).

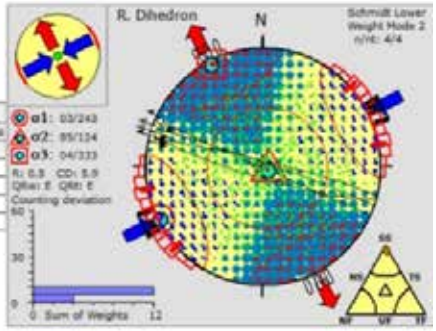

Figure 5: NW-SE trending strike-slip faults with sinistral component.

Results and Conclusions

The neotectonic evolution of Lesvos Island reflects the complex interplay of regional tectonic forces in the NE Aegean. The North Anatolian Fault (NAF), a major dextral strike-slip fault, exerts significant influence, generating numerous secondary strike-slip faults. Simultaneously, the general N-S extension of the Aegean microplate has led to the formation of large W-E trending normal faults (Chatzipetros et al., 2013). This interaction results in a transtensional stress field, producing a diverse array of tectonic structures.

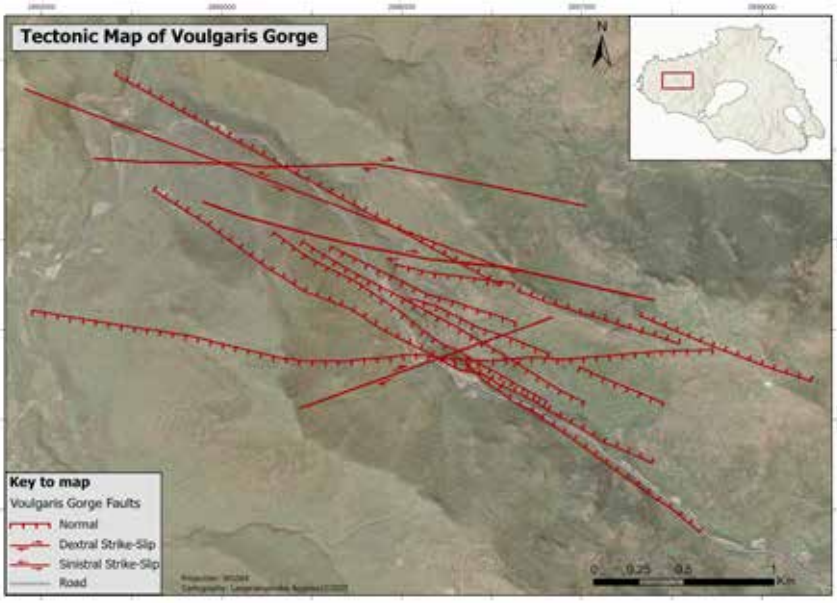

Figure 6: Tectonic map of Voulgaris Gorge area, where 3 different types of faults are presented. Can be observed E-W and NW-SE Normal faults, E-W and NE-SW Dextral Strike-Slip Faults, as well as NW-SE Sinistral Strike-Slip Fauts.

The transtensional field of NE Aegean region is formed by the dextral strike-slip fault of NAF and its stress pattern creates a variety of secondary tectonic structures (Fig. 6), such as secondary NW – SE strike-slip faults which are compatible with the active tectonics of the NE Aegean.

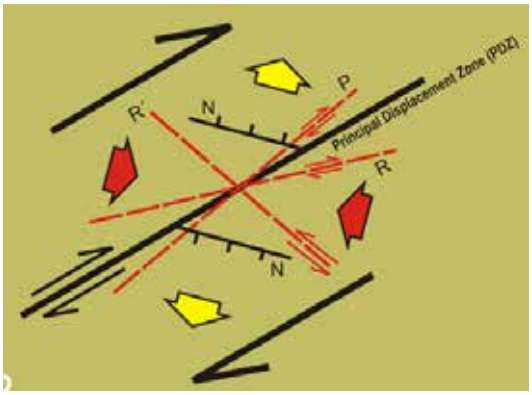

Figure 7: Schematic diagram showing the angular relationships between Riedel shears and the Principal Displacement Zone (PDZ) in a dextral strike–slip deformation zone R, R and P shears are strike slip faults, while N are normal faults perpendicular to the maximum extensional stress. This is a typical arrangement of faulting pattern in the close area of major strike–slip faults; not all types of faults however are always formed in such a setting (Chatzipetros et al., 2013).

In addition to W-E normal faults and NE-SW dextral strike-slip faults, a secondary set of sinistral strike-slip faults has been identified. These faults, which were previously underestimated, can now be considered potentially active structures within the broader stress regime. Their presence suggests a more intricate fault network than previously recognized, influencing seismic hazard assessments and regional tectonic models.

Findings from this study further indicate that the island's extensive tectonic activity has played a crucial role in shaping significant geological formations, such as Voulgaris Gorge. The gorge, along with similar landforms, is likely the result of long-term fault activation and progressive deformation under the prevailing transtensional stress field. These observations highlight the dynamic nature of Lesvos' neotectonic landscape and its ongoing structural evolution.

Research Highlights

This paper introduces a newly developed 55-hour educational program designed for higher education graduates to bridge knowledge gaps in speleology. The multidisciplinary course covered geosciences, biology, and archaeology, combining theoretical learning with practical fieldwork and advanced technologies. Emphasizing safety, data collection, and interdisciplinary methodologies, the program prepared participants for comprehensive cave research. Offering 4 ECTS credits and a specialized certificate, it significantly advanced speleological education while promoting sustainable research practices.

Introduction

Speleology, the scientific study of caves, requires a multidisciplinary approach to address the unique challenges of cave environments. This paper outlines a newly implemented educational program designed to bridge knowledge gaps and provide participants with practical and theoretical expertise. Based on the absence of dedicated training programs for cave studies highlights the need for such initiatives. This led to the development of a comprehensive curriculum that integrates various disciplines and ensures sustainability and safety in speleological research. Under the title “Field-Work Methods in Speleology”, a 55 instructional hours program, including synchronous and asynchronous components was created. The target audience consisted of graduates from higher education institutions who were interested in acquiring specialized skills in cave research.

Educational Framework

The program was structured around three key thematic units:

1. Geosciences: Covering cave morphology, stratigraphy, sampling and dating methods, paleoenvironmental reconstructions, and safety protocols along with topographic and geomorphological knowledge.
2. Biology: Focusing on terrestrial and aquatic cave ecosystems and organisms, sampling techniques, and data management.
3. Archaeology and Paleontology: Addressing excavation methodologies, anthropological artifact handling, and technological tools for research; cave clastic sediments and paleontological finds with emphasis on processes and taphonomy.

This educational package was developed in accordance with the Regulation of Studies of the Center of Education and Lifelong Learning of the Aristotle University of Thessaloniki (Greece). It underwent a peer-review evaluation process, which was approved to officially invite participants. The final program of the course provided 4 ECTS (European Credit Transfer System) and awarded a certificate of specialized training.

Methodology and outcomes

The program employed a blended learning approach that combined interactive lectures by leading experts with hands-on exercises in real-world cave settings. Participants actively engaged with advanced technologies to enhance their learning experience. By completing the program, they gained a comprehensive understanding of cave environments

and processes while developing practical skills in data collection, analysis, and, most importantly, interpretation. This preparation equipped the participants to confidently and expertly address complex research questions in speleology.

Field-work guide – the scientific approach

As a measure of the course's success, we developed an evaluation scheme designed to produce a field protocol for working in caves, based on the participants' understanding. By integrating the correct answers and addressing specific aspects, we created a comprehensive general guide outlined below.

1. Basic steps for preparing cave field research: Cave fieldwork preparation involves several steps to ensure safety and thorough data collection. Initially, the research objectives and the team involved should be determined. This includes gathering relevant background data from cave maps, previous studies and local knowledge (non-scientific). Equipment preparation is crucial, ensuring that suitable tools are available. Additionally, safety should be prioritized, including evaluating the cave's morphology, checking atmospheric conditions, and having proper first aid kits. Lastly, obtaining permits and considering logistical factors, like weather forecasts and cave access, should be addressed.
2. Determining cave mapping routes: Mapping cave routes accurately is essential for understanding the cave's internal structure. As caves often feature intricate branches and complex passageways, it is crucial to track changes in direction and elevation with precision. By using a laser meter and clinometer, surveyors can obtain accurate measurements of distances and angles. In addition, photogrammetry has revolutionized cave surveying, providing high-accuracy three-dimensional (3D) models of cave systems. Softwares like Polycam, allow precise spatial data collection. These 3D models are not only useful for research but also provide an interactive way for others to explore the cave virtually. This technology can save considerable time and effort while ensuring that the resulting data is accurate and comprehensive.
3. The role of geological research in cave exploration: Geological mapping in caves provides crucial data for understanding the processes that shape cave formation. By documenting sediment layers, mineral deposits, and other geological features, researchers gain insights into past environmental conditions and the processes that have shaped the cave's structure. They identify areas of particular interest for further study, such as areas with rare deposits or specific speleothems. The information gathered during geological research can also aid in conservation efforts. After data are collected, the next step is their analysis. This involves synthesizing measurements, observations, and geological data to create a comprehensive report. The report should include maps, diagrams, and photographs that illustrate the cave's features and structure. This report is an essential document for both scientific research and future cave evaluation from a conservation perspective, as it ensures that the cave's layout and characteristics are intact. For geological recording, several tools are necessary, such as measuring tools (e.g., clinometers, distance meters, compass), recording tools (e.g., gas detectors, data loggers), documentation tools (e.g., camera, notebook) and as technology progresses, apps such as FieldMove Clino assist in collecting and recording data, while LiDAR-based apps help in creating 3D models.
4. Assessing safety: Safety during cave exploration requires assessing weather conditions, especially in cases where rising water levels could be a risk. It is vital to monitor cave stability to avoid collapses, which could result in injury or entrapment. Atmospheric conditions should be regularly monitored using gas detectors for oxygen, carbon dioxide, hydrogen sulfide etc. In certain caves, radon meters may also be used. Descending and climbing in caves demands special training and equipment.
5. Importance of documenting the location and characteristics of deposits: Deposits in caves, including chemical, clastic, and biogenic, offer significant insights into the cave's geological and environmental history. Recording their location, size, shape, color etc. is vital for understanding various processes. For example, clastic deposits provide information about their origin and the conditions under which they accumulated. Speleothems, on the other hand, provide evidence about airflow, microbial activity, precipitation, paleoenvironment etc.
6. Data to record geomorphological features in caves: For geomorphological cave features, data should be collected on the size, shape, color, and location of features like dissolution forms, notches, and sediment deposits. The relationship of these features to other geological elements such as fault lines or water supply sources must be recorded. Information about mesomorphological features, such as passage shapes and their relationship to water levels, is also essential. When recording these data, it is crucial to take detailed measurements, considering the three-dimensional distribution.
7. Following a sampling protocol for geological studies: clear guidelines for selecting, collecting, and storing samples, with the aim of representing the geological diversity of the cave. Sampling should follow strict rules to avoid contamination or alteration. Data regarding the exact location, date, and conditions at the time of sampling must be recorded. Furthermore, documentation of the sampling site on cave maps and in photos with scales is needed.

8. Sampling protocol for excavation research: careful documentation of sample locations, with special attention to the sites of archaeological/paleontological finds. In particular, the stratigraphy of findings is essential for understanding historical periods and their chronological framework. Aadditionally, documentation of the type of findings (e.g., ceramics, tools, bones) and the method of storage, preservation, and analysis are important.
9. Use of maps and topographic measurements in cave studies: These are essential tools for understanding the structure of a cave. The use of topographic maps allows for precise representation of cave formations and the creation of 3D models that facilitate study.
10. Ensuring accuracy in cave observations requires precise measurement of geometric characteristics and the appropriate use of specialized instruments. Measuring instruments must be calibrated and regularly checked to avoid errors during research. Additionally, the use of GIS software for storing and analyzing data aids in recording and verifying observations based on geometric parameters and geological models.
11. Key data in cave studies and their management: In cave studies, the data typically recorded include geological parameters (such as rock types and formations), geometric characteristics (width, height, depth), and ecological data (abiotic factors and cave biological communities). Managing this data requires the use of digital tools and databases for categorizing, storing, and extracting it for analysis, as well as fostering collaboration among scientists.
12. Key features and requirements of biological research in caves: Biological research in caves requires documentation of species inhabiting the caves, the assessment of ecological conditions, and evaluating the conservation needs. Key features include the utilization of specialized instruments and techniques for abiotic data acquisition, biological sampling, sample preservation, and subsequent laboratory procedures for species identification and analysis.

Interdisciplinary relationships – a synthesis

Multiple questions were tested during and at the end of course; a summary of which is given in the following section by providing a relevance scale of scientific fields to cave research (Table 1) along with a key table about the utilization of research fields in multidisciplinary studies (Table 2).

The relevance scale was created to assess and compare the significance of various scientific fields in the study of cave environments. It is based on seven key criteria, each designed to evaluate the contribution of each field to understanding different aspects of caves. These criteria are: 1) Contribution to understanding the processes that created and influenced the evolution of the cave; 2) Contribution to describing the structures and forms found within the cave; 3) Contribution to reconstructing the paleoenvironment and broader geophysical environment that influenced the cave; 4) Understanding the conditions (e.g., pH, temperature, nutrient levels) prevailing in the cave; 5) Contribution to developing a protection plan for caves as natural and cultural landscapes; 6) Understanding the impact of humans on the evolution of caves; and 7) Provision of technologies, methods, and data that facilitate cave study. For each field of study (Geology, Geomorphology, Mineralogy-Geochemistry, Paleontology, Biology, Topography, and Archaeology), scores were assigned based on how well the field meets these criteria. The scale provides a clear, comparative analysis of the relevance of each discipline in cave research. It serves as a guide for prioritizing which aspects of cave studies are most central to specific research objectives (such as geological, geomorphological, or biological studies), but it should not be interpreted as suggesting that fields with lower scores are unimportant. Each field plays an integral role in providing a comprehensive understanding of caves and their significance, both scientifically and culturally.

In this relevance scale, the “total” represents the average score for each scientific field in relation to the criteria established. Higher values indicate a strong relevance of a field to the corresponding criteria, while lower values indicate weaker relevance.

Table 1. Relevance scale for scientific fields to speleology.

Scientific fields	Criterion 1	Criterion 2	Criterion 3	Criterion 4	Criterion 5	Criterion 6	Criterion 7	Total
Geology	5	5	4	4	5	4	5	4.6
Geomorphology	5	5	4	5	5	3	5	4.6
Mineralogy-Geochemistry	4	5	5	5	3	5	5	4.6
Paleontology	3	4	5	5	3	4	4	4.1
Biology	4	4	4	4	5	3	4	4.0
Topography	3	5	3	2	4	1	5	3.3
Archaeology	2	3	4	2	5	5	1	3.1

Cave studies are a prime example of interdisciplinary research, where various scientific fields converge to offer a more

comprehensive understanding of cave environments, their formation, evolution, and their preservation. Research from different disciplines contribute their unique methods, knowledge, and insights, allowing for the exploration of caves from multiple perspectives. Table 2 demonstrates the interaction among scientific disciplines and their contributions to cave research, showcasing how one field's tools or methods can yield valuable outcomes for another. Fields such as geology, biology, archaeology, and paleontology, play crucial roles in addressing different scientific questions and broader environmental, historical, and ecological contexts.

Table 2. Interdisciplinary connections between scientific fields and their contribution to cave research, highlighting how tools and insights from one discipline enhance the understanding and study of caves.

Utilization of	Applied on	Result
Geology	Geomorphology	Understanding the structural, petrographic and hydrologic conditions that led to the formation of specific landforms.
Geology	Archaeology	Use of stratigraphy for the relative dating of cultural artifacts; understanding processes; interpreting formation of spaces and deposition of sediments.
Geomorphology	Biology	Correlation of geomorphological structures and microhabitats with the distribution of various species inside the cave.
Mineralogy – Geochemistry	Archaeology	Determining the origin of raw materials used in artifacts and their processing techniques. This study provides information about human activities (e.g., presence of organic remains); identifying human use of fire, spaces, materials etc.
Archaeology	Geology	Study of the impact of human activity on cave formation and dating of classic sediments through archaeological findings.
Topography	Geology	Cave mapping to understand the creation and evolution of the cave; cave morphometrics; marking sample site.
Topography	Geomorphology	3D representation and survey of caves, landforms and dissolution and depositional features.
Paleontology	Archaeology	Study of fossils can provide information about the relationship between humans, animals and the environment (e.g., hunters, gatherers, domestication of animals) and their dietary habits.
Paleontology	Biology	Comparative study of anatomical structures and ancient DNA (aDNA) to draw conclusions about the evolution and adaptations of organisms in the cave environment and through time.
Biology	Archaeology	Study of the corrosive effect of microorganisms on archaeological finds.
Biology	Geomorphology	Influence of various biological factors on the formation of geological cave structures (e.g., guano-related minerals; biologically mediated deposits, dissolution structures).

Conclusive remarks

This program marks a significant advancement in speleological education, equipping participants with the essential tools and knowledge to thrive in this specialized field. Future iterations will focus on enhancing international collaborations and incorporating emerging technologies.

The program's multidisciplinary approach ensures participants to be prepared for diverse applications, from scientific research to heritage conservation. It also emphasizes sustainable practices to protect fragile cave ecosystems.

The relevance scale serves as a practical tool to prioritize efforts in cave-related research, with the importance of each scientific discipline varying based on the context and specific research goals.

The interdisciplinary nature of cave studies is clearly demonstrated, with various scientific fields working together to provide valuable insights that enrich and support one another. This highlights how methods and tools from one discipline can yield crucial outcomes for other areas, fostering a more integrated understanding of cave environments.

Research Highlights

This study undertakes a comprehensive assessment of karst landforms within the Grevena-Kozani UNESCO Global Geopark, focusing on scoring and analyzing the area's speleological features. By applying six evaluation criteria—scientific, ecological, cultural, aesthetic, economic, and potential utilization—previously used in Crete's Psiloritis and Lasithi Mountains (Fasoulas et al., 2011), the study employs a multidisciplinary methodology to explore management prospects for these unique landforms. It also aims to promote sustainable use and geoconservation of the geopark's caves, aligning with principles advocated by the European Geoparks and the International Union for Conservation of Nature (IUCN).

Introduction

There is a growing global interest in sustainable and alternative tourism that leverages natural and cultural resources. This trend has emerged as a reaction to the challenges of urban lifestyle. The term "Geotourism" refers to a type of alternative tourism that highlights the geological heritage of a location, offering visitors educational and nature-focused experiences. It addresses to individuals interested in geology and the geological processes that created landforms such as caves, gorges valleys, fossil sites and more. Importantly, the study of geosites extends beyond geological interest, contributing to a broader understanding of the environmental conditions in these areas. These conditions have significantly influenced historical human events as well as the evolution of other species and habitats (Rassios & Grieco, 2021).

Caves hold substantial importance within the tourism industry and have historically been the primary geological features of interest to tourists and they continue to be among the most popular geological sites. Cave tourism gained significant popularity in Europe during the 18th century, and today, caves worldwide attract hundreds of thousands of visitors annually (Theodosiadis, 2020). Greece is rich in carbonate rocks, the majority of which have undergone karstification, leading to the formation of thousands of caves across the country. Landforms of karst are of interest not only for natural and geological sciences, but also in other multidisciplinary fields. From a geological perspective caves provide invaluable insights into the conditions that led to their formation, their impressive internal features and their unique microclimate (Mammola et al., 2019). Biologists study caves as habitats, focusing on biodiversity and the ecosystems they sustain (Culver & Pipan, 2019). Fundamental is also the relationship of caves with anthropocentric sciences such as archaeology since caves are considered the earliest human habitation, while from a religious standpoint, caves remain significant as sites of worship and spiritual reverence (Trimmis, 2015).

UNESCO Global Geopark Grevena-Kozani geological settings

The Grevena-Kozani Geopark has been assigned as the UNESCO Global Geopark since 2021. Spanning an area of 2,486 km2 across five regional units in the geographic region of Western Macedonia,the geopark is renowned for its significant geological phenomena related to the formation processes of the Hellenic Orogeny. The area features Greece's oldest rocks, dated at 1 billion years, located in the Deskati region. These formations reveal the geological history and rifting processes that marked the formation of the Tethyan Ocean and the emergence of Europe as a distinct continental landmass. Oceanic crust rocks of the Tethys Ocean are found in Mount Vourinos, alongside sedimentary rocks of the Mesohellenic Trough.

The study area consists of rocks of the Pelagonian and Sub-Pelagonian geological zones (Mountrakis, 1985). The Pelagonian zone comprises Alpine and pre-Alpine rocks, originating from the Paleozoic, Mesozoic and Tertiary periods, which form the bedrock of the region. Overlying these bedrock formations are post-alpine formations, including the molassic sediments of the Mesohellenic Trough and the Plio-Pleistocene terrestrial deposits found in the Kozani-Servia and Grevena basins. These formations are the most recent deposits, consisting primarily of alluvial fans and younger river sediments.

The carbonate rocks of the area were formed during the main sedimentation that took place during the Triassic-Jurassic period. In the Vourinos area, these rocks are represented by crystalline, thickly layered, and tectonized limestones with interbedded layers of dolomites and dolomitic limestones. They form the carbonate cover on which the ophiolites were deposited. Upper Jurassic limestones which were formed in relatively shallow environments, are not distinctly separated from the overlying Cretaceous limestones and are typically mapped as a single unit. These massive carbonate formations are found in contact with the underlying ophiolithic rocks and the overlying Cretaceous limestones (Batsi, 2011).

Data and Methods

The methodological approach employed in this study combined fieldwork, bibliographic research and the application of the evaluation criteria proposed by Fassoulas et al. (2011). Karstic landforms in the area were studied in situ and documented. In specific cases, such as the Crystal Cave, which exhibits vertical development, specialized rope equipment was required for descent and documentation. A detailed catalog of all caves in the area was created, providing an extensive overview of the locations and landforms within Geopark. Precise cave mapping was performed using a Light Detection and Ranging (LiDAR) sensor Numerous 3D models of previously scanned caves, are available on the project website "Virtual speleological field trip in Greece" (Fig. 1).

According to Fassoulas et al. (2011), a systematic methodology for evaluating and assessing geotopes was developed to standardize scoring and minimize subjectivity in geological heritage management. This method categorizes evaluation criteria into six primary groups: scientific, ecological, cultural, aesthetic, economic, and potential for use. Each group is further subdivided into specific criteria that assess attributes such as geological history, ecological impact, cultural significance, landscape visibility, visitor appeal and future use potential. Scores are assigned on a scale from 1 to 10, incorporating qualitative and quantitative factors to account for intangible heritage elements.

This scoring system (Table 1) identifies geotopes of national and international significance, aligning with previous assessments (Grandgirard 1995; Rivas et al. 1997; Pralong, 2005; Zouros, 2007; Reynard et al., 2007). Based on the scores from different groups of criteria, three value indices were developed (Fassoulas et al, 2011): touristic value (Vtour), educational value (Vedu), and protection-need value (Vprot). Each index uses weighted coefficients to reflect the importance of different criteria. For example, Vedu prioritizes scientific value, while Vtour emphasizes aesthetic appeal, reflecting their respective focuses in education and tourism. The Vprot index incorporates scientific scores, integrity, and ecological risk factor, balancing ecological impact with protection status to assess conservation priorities.

- V_{tour}=0.4 Aesthetic + 0.2 Cultural + 0.2 Potential of Use + 0.2 Economic
- V_{edu}=0.4 Scientific + 0.2 Cultural + 0.2 Aesthetic + 0.2 Ecological
- V_{prot}= {Scientific + F_{ecol} + (11-Integrity)}/3

This methodology advances geotope evaluation by incorporating weighting coefficients, enabling a nuanced understanding of geotopes' multifaceted values. It supports sustainable tourism, education, and geoconservation, offering a replicable framework for assessing geological heritage in diverse contexts.

An inventory of caves in the area was compiled based on an unpublished archive of public documents provided by the late speleologist Konstantinos Ataktidis to Georgios Lazaridis. A total of 53 caves were reported, 10 of which are located within the municipality of Siatista, with the majority being potholes. The predominant rock in the broader region where the caves are located is limestone from the Pelagonian zone. The caves exhibit a variety of characteristics, including vertical and horizontal formations, as well as a range of sizes from small to large caves, with some featuring notable speleothems. However, many of these caves remain unexplored or insufficiently studied. This study focuses on analyzing four of these caves: Keli Kalogrias, Kalogria Cave, Orliakas Cave, and Vainaki Cave in the vicinity of the Geopark. These caves were selected for their unique and significant features, as well as the fact that they have been more thoroughly studied compared to others in the region.

Keli Kalogrias

Keli Kalogrias is a rock shelter formed in the limestone of the western banks of the Venetikos River, situated within the Portitsa Canyon. The shelter is located in close proximity to the historic village of "Spilaio" and derives its name, "Keli Kalogrias" (Nun's Cell), from a local legend suggesting that a nun once lived there. This characteristic enhances the cultural value of the landform. The cave is adorned with various speleothems, adding to its scientific and aesthetic significance.

Kalogrias Cave

This cave is located in the slopes of Orliakas Mt. It is small, a few meters long with an ascending branch that exits to a small opening. It is mainly fracture guided and displays a few common speleothems. It is also a cave of significant cultural and religious importance, deeply rooted in the local traditions of the area.

Table 1. Explanation of criteria and scoring system used in the evaluation framework for geosites as proposed in Fassoulas et al (2011).

Criteria	Explanation	Score 1	Score 10
1.1 Geologic history	Diversity of geological history represented at the site.	Simple type history	Tells the whole local story
1.2 Representativeness	How well the site exemplifies typical geological processes or features.	No representativeness	Very high representativeness
1.3 Geodiversity	Proportion of geological elements present.	<5%	>75%

1.4 Rarity	Frequency of similar features in the region or globally.	>7 (least rare)	Unique (most rare)
1.5 Integrity	Preservation state of the geosite	Almost destroyed	Intact
2.1 Ecological impact	Ecological significance of the geosite	No impact	Very high impact
2.2 Protection status	Level of ecological protection measures in place.	No protection	Complete protection
3.1 Ethics	Ethical value of the site.	No ethical significance	Very high significance
3.2 History	Historical importance of the site.	No historical relevance	Very high relevance
3.3 Religious	Spiritual or religious significance of the site.	No religious significance	Very high significance
3.4 Art and culture	Artistic and cultural relevance of the site.	No significance	Very high relevance
4.1 Viewpoints	Number of viewpoints the site offers.	None	>4
4.2 Landscape difference	Degree of visual contrast in the landscape.	No difference	Very high diversity
5.1 Visitors	Annual visitor number	<5,000	>75,000
5.2 Attraction	Site's appeal to visitors	No attraction	International recognition
5.3 Official protection	Level of official protection	International protection	No official protection
6.1 Intensity of use	Extent of site usage and potential overuse.	Very intense	No use
6.2 Impacts	Degree of human-induced impacts.	Very high impact	No impact
6.3 Fragility	Susceptibility to damage	No fragility	Very high fragility
6.4 Accessibility	Proximity to infrastructure	Close to hiking trail	Close to highway or town
6.5 Acceptable changes	Tolerance of the site to change.	No acceptable change	Very high tolerance

Orliakas Cave

The Orliakas Pothole (Fig.1), also known as the Cave of Crystals, is located to the west of the col of Mount Orliakas and reaches a depth of about 15 meters. Its entrance comprises two openings at nearly the same elevation, both of similar size and elliptical in shape. Transparent scalenohedral calcite crystals are adorn the walls and the ceiling of the cave. These crystals are remarkable in size, exceeding 30 cm in length. The cave is formed within Upper Cretaceous reef limestones, which unconformably overlain by sediments from the Mesohellenic Trough (Lazaridis, 2024).

Vainaki

Vainaki cave (Fig.1) comprises a phreatic passage now located several tens of meters above the current water table of the region. It is partially eroded and features two entrances, one at each end. The side walls retain well-defined scallops (Fig.1), offering valuable insights into the paleoflow and specifically the velocity and the flow direction that led the formation of the scallops within the passage.

Figure 1. 3D models of caves: Left – Orliakas Cave, Right – Vainaki Cave, Below – Close-up view of the Vainaki Cave 3D model showcasing well-defined scallop formations. (Source: https://speleology8.wordpress.com).

Results

Results According to the methodology outlined by Fasoulas et al. (2011), the corresponding scoring values for these geosites are presented in Table 2. As shown, the highest educational values are attributed to Orliakas Cave, due to its rarity and uniqueness in the area, its distinct morphology and its high integrity. Remarkably high ecological impact of Orliakas Cave reflects the geotope's role in supporting the development of specific ecotopes or the presence of endemic species in the region. Orliakas cave also receives the highest score for protection-need value because of its significant ecological impact, and its low actual protection status and preservation. The greatest potential for tourism development is attributed to Kalogrias Cave, which is known as a religious site. Its connection with local traditions and historical events in the region is of considerable importance.

Table 2. Evaluation results of geosites in the Grevena-Kozani UNESCO Global Geopark using the Fassoulas et al. (2011) method.

Cave Name	Keli Kalogrias	Kalogrias Cave	Orliakas Cave	Vainaki
1. Scientific score	2.9	2.9	7	5.5
1.1 Geological history	2.5	2.5	7.5	5
1.2 Representativeness	2.5	2.5	5	5
1.3 Geodiversity	1	1	5	2.5
1.4 Rarity	1	1	10	7.5
1.5 Intergrity	7.5	7.5	7.5	7.5
2. Ecological score	4.25	4.25	5.5	4.25
2.1 Ecological impact	7.5	7.5	10	7.5
2.2 Protection status	1	1	1	1
3. Cultural score	7.5	7.5	1.75	4.63
3.1 Ethics	10	10	2.5	10
3.2 History	7.5	7.5	2.5	5
3.3 Religious	10	10	1	1
3.4 Art and culture	2.5	2.5	1	2.5
4. Aesthetic score	5.5	5.5	5.5	6.25
4.1 Viewpoints	1	1	1	2.5
4.2 Landscape difference	10	10	10	10
5. Economic score	2	2	2	2
5.1 Visitors	1	1	1	1
5.2 Attraction	2.5	2.5	2.5	2.5
5.3 Official protection	2.5	2.5	2.5	2.5
6. Potential use score	5.7	6.5	4.7	6.5
6.1 Intensity of use	7.5	7.5	7.5	7.5
6.2 Impacts	7.5	7.5	2.5	7.5
6.3 Fragility	10	10	10	10
6.4 Accessibility	1	5	1	5
6.5 Acceptable changes	2.5	2.5	2.5	2.5
Fecol[1]	7.5	7.5	10	7.5
Vedu[2]	4.61	4.61	5.35	5.23
Vprot[3]	4.63	4.63	6.83	5.5
Vtour[4]	5.24	5.4	3.89	5.13

[1]Fecol: ecological factor, [2]Vedu: educational value, [3]Vprot: protection-need value, [4]Vtour: touristic value

Discussion

The evaluation was conducted on 8% of the caves within the geopark territory. Observing the analysis results, it appears that the economic, aesthetic, and ecological scores exhibit the greatest uniformity in their values. Specifically, the low ecological score is attributed to the limited tourist visitation, as these caves are considered local destinations, are not widely known, and some of them are difficult to access. Regarding the aesthetic score, there are small variations in values, with the average score across all caves exceeding 5. This indicates moderate landscape contrast, which evaluates differences in shape, color, or morphology between the geotope and its surroundings. Additionally, limited viewpoints are considered, focusing on visibility from roads or trails a few meters apart. The ecological score generally displays moderate to low values due to the high ecological impact and low protection status, as these caves are categorized as having no protection.

The most significant variations are observed in the cultural score. The Kalogrias Cave and Keli Kalogrias are religious sites of historical importance, and together with the Vainaki cave, they highlight the traditions and customs of the region. In contrast, no sufficient evidence has been found for Orliakas Cave to provide information supporting such an evaluation.

Previous work by Fasoulas et al. (2011) has provided information and analysis from caves in the Cretan region, allowing us to compare our results and form a more comprehensive picture. Especially at Psiloritis Geopark, the main tourist attractions in the area and the most suitable geotopes for educational activities are Idaion Andro and Sfentoni caves. These sites are already used for various educational programs and initiatives organized by the Geopark and

local educational centers. It is important to note that the low tourist value score attributed to the aforementioned geotopes, is either due to restrictions on visitor numbers, or due to the site's fragility (Sfentoni cave) or ongoing excavations (Idaion Andro Cave). Compared to the touristic score values of Grevena-Kozani Geopark, similarly low value scores are observed, as they are limited to the local level.

At Lassithi Mountain most of the studied geosites lack proper protection or are inadequately managed due to the absence of centralized oversight. As a result, they face significant risks and threats. Many of these geotopes are deeply tied to the history and culture of Crete, such as the renowned Diktaion Andro, mythologically known as the birthplace of Zeus, and hold importance for both educational and tourism purposes. Notably, Dikation Andro, the area's most popular attraction with approximately 70.000 visitors annually, receives a tourism value score of only 4.8. This low score is primarily due to severe discoloration of stalagmites and stalactites caused by decades of improper lighting.

Conclusions

The application of evaluation frameworks is an invaluable tool for geopark management authorities, facilitating informed decision-making, sustainable exploitation, and the effective protection of natural resources and landforms. While criteria such as Scientific, Cultural, and Aesthetic scores largely depend on the natural characteristics of the geosite and its surroundings, Ecological, Economic, and Potential of Use criteria are significantly influenced by management practices and the applicable regional legislation. This distinction emphasizes dual dependency on both natural features and human interventions in the evaluation process.

The uniqueness of the Scientific criterion lies in its potential for enhancement, as it is directly tied to the extent and quality of interdisciplinary research conducted on the geosite. For example, incorporating advanced studies in geology, biology, and cultural heritage can elevate its scientific value. Similarly, the viewpoints of a geosite have a profound impact on its Aesthetic score. Although this factor is an inherent part of the landscape, it can be significantly improved through targeted management initiatives, such as the development of well-planned trails and the installation of strategically positioned viewpoints. These efforts not only enhance the visual appeal but also improve Accessibility scores, ultimately contributing to the geosite's Potential of Use.

The karstic geosites within the Grevena-Kozani UNESCO Global Geopark demonstrate strong performance in Cultural, Aesthetic, and Potential of Use categories. These promising results provide a solid foundation for more detailed investigations into the geosites, aimed at further promoting and showcasing their unique features. A comparative analysis of parameter values between the Grevena-Kozani Geopark and other geoparks reveals that these caves possess significant potential to be recognized as key geotopes within the geopark. Their inclusion would undoubtedly contribute to the geopark's enrichment and global significance.

Upon closer analysis of the applied criteria, it becomes clear that more specialized metrics are necessary for the comprehensive evaluation of karstic landforms, particularly karstic caves. Essential criteria include the accessible length of the cave, the level of technical expertise required for entry, and the suitability of its atmosphere for safe exploration. These parameters are critical for determining the potential for sustainable utilization while ensuring the protection of these fragile environments.

In conclusion, the evaluation frameworks not only serve as a cornerstone for effective geosite management but also underscore the necessity of refining assessment tools to address the specific needs of karstic caves. This step-by-step approach will enable more accurate evaluations, fostering both conservation and sustainable tourism development, and ultimately contributing to the long-term success of geoparks.

Acknowledgements

The authors would like to express their sincere gratitude to Iraklis Kalogeropoulos and Antonis Kleisiaris for their valuable contributions to the fieldwork. 3D cave scans conducted as part of the 'Virtual Speleological Field Trip in Greece' project, formally supported by the International Union of Speleology (UIS).

Research Highlights

Recent research within the Vikos-Aoos UNESCO Global Geopark and neighboring Albania has highlighted the significance of sulfuric acid speleogenesis (SAS) caves, drawing the attention of explorers and researchers alike. Collaborative efforts by the Geopark and the School of Geology at Aristotle University of Thessaloniki focus on mapping these caves and investigating their unique processes. Their presence in a Greek Geopark underscores their scientific importance and potential for fostering awareness and sustainable tourism. However, the challenges posed by toxic atmospheres and fragile ecosystems necessitate strict protection measures, advocating for innovative approaches such as Information and Communication Technologies (ICT) to ensure responsible geosite development.

The Geopark

The Vikos-Aoos Geopark, located in Epirus, Greece, spans 1,200 sq. km across the municipalities of Zagori and Konitsa and includes 62 villages whose residents primarily engage in tourism, agriculture, livestock farming, forestry, and small-scale manufacturing. Dominated by the Vikos and Aoos Gorges, the towering mountains of Northern Pindos, and rivers like Aoos, Voidomatis, and Sarantaporos, the geopark showcases a geologically diverse history starting 200 million years ago. Comprising sedimentary, metamorphic, and igneous rocks, including ophiolitic formations from the Tethys Ocean, the area reflects tectonic processes of the Alpine Orogeny and extensive faulting during the Quaternary, which shaped its rugged karstic landscape (Telbisz et al., 2019). Recognized as a UNESCO Global Geopark since 2010, it supports conservation, education, and sustainable development while protecting unique ecosystems and fostering public engagement through its exceptional geological and natural heritage.

The diverse geological processes in the Vikos-Aoos Geopark are reflected in its landforms and geomorphology, offering unique insights into the geological evolution of Greece. The park features 51 geosites classified into seven categories: springs, tectonic structures (faults and folds), river terraces, rock shelters, panoramic viewpoints, karstic formations, and glacial landforms. These sites showcase significant geological interest, rarity, and beauty.

Classic caves, such as the vertical shafts of “Vulture’s Hole” (Geosite 39, -584m depth, 650m length), and “Chasm of Epos” (Geosite 40, -455m depth), and Gailotrypa (Geosite 44, -155 m deep), exemplify the dissolution of limestone along fractures and faults. Additionally, smaller rock shelters like Boila (Geosite 25), Kleidi (Geosite 24), and Megalakkos served as Paleolithic refuges for hunter-gatherers

While classic caves are well-recognized geosites within the park, SAS caves do not form a distinct category, emphasizing the broad diversity and representation of geological phenomena in the Geopark, and suggesting future actions on geoheritage recognition and preservation.

The SAS geosites of the Geopark

Landforms associated with sulfuric acid dissolution within the geopark include notable caves and springs (Fig.1 & Fig.2). Among them is the Skordyli Cave, situated on the northern bank of the Sarantaporos River, close to the Albanian border and approximately 2.5 km west-southwest of the Kavasila thermal springs. The cave entrance serves as the outlet for an underground sulfuric river that traverses a series of large chambers connected by smaller passages. Extending about half a kilometer from the underground spring to the outlet, the cave’s sidewalls are coated with gypsum and native sulfur. Its ecosystem is remarkable for the presence of chemoautotrophic microorganisms and a high level of endemism (Sarbu et al., 2024).

Pixaria Cave, located east-northeast of the Kavasila thermal springs in a limestone outcrop, is similarly influenced by sulfur springs near its entrance, which lies close to the Sarantaporos River. The cave features fracture-guided passages forming

a maze-like pattern, with a slightly inclined floor and median feeders. The walls of the passages are covered with gypsum, reflecting its speleogenetic processes.

Neles Cave is found near the Neles spring in Kleidonia Village, at the escarpment of the Konitsa Fault that borders Papigo Mountain to the west. The cave entrance is aligned along a fault plane, leading to a vertically developed passage. At its deepest point, 13 meters below the entrance, a horizontally oriented passage carries a stream of sulfuric water. The atmosphere is rich in hydrogen sulfide, and gypsum coats the walls and boulders. Although the cave and the spring appear interconnected, a direct link has yet to be confirmed.

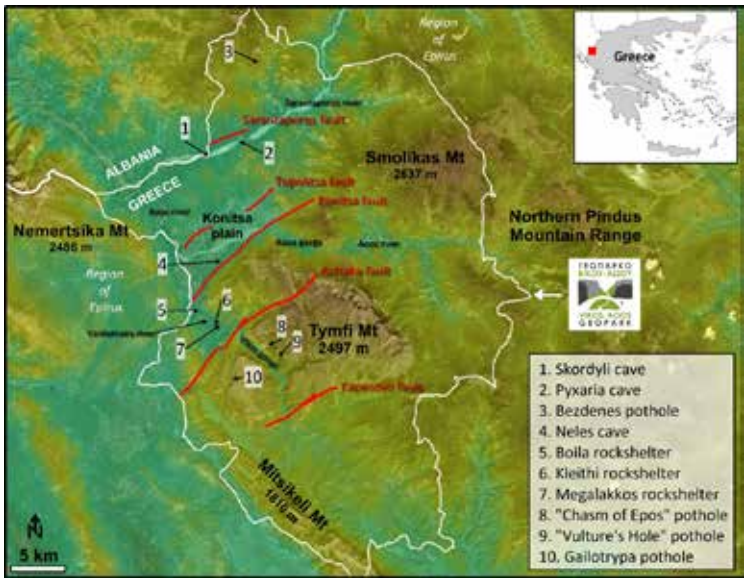

Figure 1. A map of the Vikos-Aoos Geopark showing the locations of the major caves, faults, mountains and rivers of the region (modified after Chatzipetros et al., 2024).

Lastly, Bezdenes Pothole, near the Amarantos thermal springs, is preliminarily included due to gypsum-like deposits found in its deeper sections. This impressive vertical void has a reported depth of 268 meters. Ongoing research aims to confirm its sulfuric acid dissolution origin and further clarify its speleogenetic context.

Figure 2. Entrances of Sulfuric Acid Speleogenesis caves in the Vikos-Aoos UNESCO Global Geopark: A. Skordyli sulfur Cave; B. Pixaria Cave; C., Neles Cave; D., Neles Spring; E. Bezdenes Pothole.

Application of Information and Communication Technologies

Information and Communication Technologies (ICT) have been utilized to support the study and promotion of sulfuric acid speleogenesis (SAS) geosites. Tools such as multimedia, data management systems, and virtual reality (VR) facilitate map creation, data analysis, and immersive public experiences. Their application varies across SAS geosites, addressing site-specific challenges while prioritizing safety.

In the field, a flexible suite of tools—primarily mobile-based applications—has been utilized. These tools facilitate the capture of georeferenced photographs of cave entrances, springs, and related features, as well as 3D scans of the caves. These scans form the foundation for VR or augmented reality (AR) experiences. Notable applications include FieldMove Clino by Midland Valley (specialized in petroleum engineering and structural geology software) for structural data collection and Polycam for 3D scanning. Polycam utilizes LiDAR (Light Detection and Ranging) technology, which works by emitting laser pulses and calculating the time taken for the light to bounce back, generating a precise 3D map of the cave. Advanced machine learning algorithms refine the scans, while AI plays a crucial role in enhancing 3D models by cleaning them, optimizing textures, and filling in missing data. The combined use of these applications, already validated in scientific cave research (Lazaridis et al., 2024), produces cave maps that meet the highest standards as defined by mapping grades (Häuselmann, 2011).

In the Vikos-Aoos Geopark, various 3D models have been developed to document the key features of SAS geosites. At the Neles location, two models were created to capture the spring and the cave, offering ground plans and depth measurements of the vertically developed cave. Similarly, at Pixaria Cave m (Fig.3), three models were produced: one documenting the entrance area with distinct dissolution forms, another capturing a passage characterized by a median sulfuric feeder, and a partial scan of the cave's initial section, highlighting its maze-like pattern of passages with consistent size and morphology.

Some of these scans are featured on the webpage "Virtual Speleological Field Trip in Greece" (https://speleology8.wordpress.com/pixaria-cave/) and are linked to related publications (e.g., Lazaridis et al., 2024). This makes these significant landforms accessible to a broad audience, including researchers, cavers, and the general public.

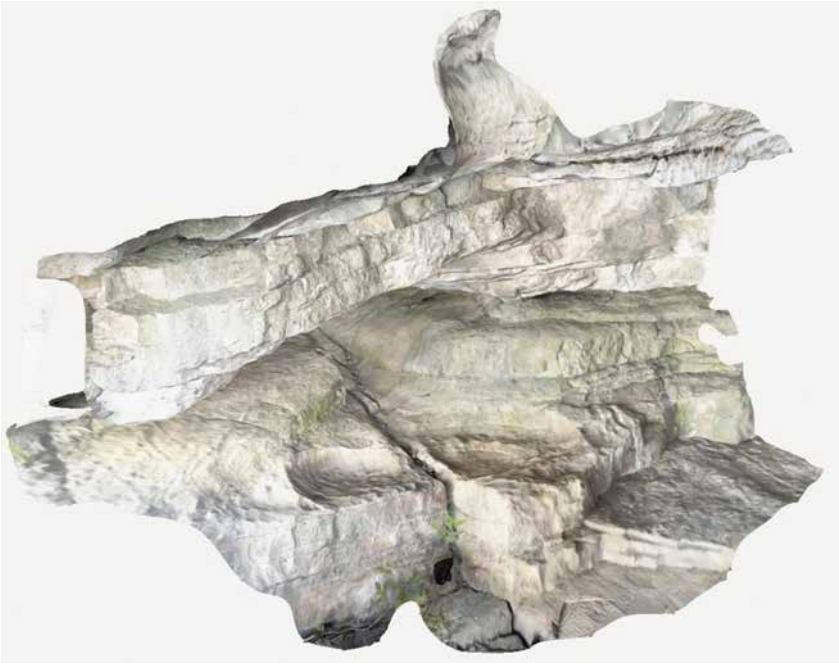

Figure 3. Example of a 3D-model from the entrance area of Pixaria Cave in Kavasila thermal springs of the Vikos-Aoos UNESCO Global Geopark.

Discussion

During the initial phase of this project, several challenges were encountered in applying ICT for geosite development. The primary concerns were identifying a time-efficient, safe, and cost-effective method capable of providing accurate data. To address these concerns, well-trained field participants were involved, equipped with real-time gas detectors and data loggers for monitoring radon levels. The use of smartphone-based tools proved to be an effective solution,

helping minimize factors such as equipment costs and the time required for data acquisition. While this approach sometimes results in lower resolution or precision—such as in the point cloud data from 3D scans—it is a necessary trade-off, as safely entering these caves with highly specialized instruments is virtually impossible.

The fieldwork techniques employed in this study enabled the efficient collection of data and the development of a solid methodology that can be adapted for use in other karst geosites. The combination of ICT tools allowed the team to gather data quickly, facilitating the creation of comprehensive datasets while maintaining a rigorous approach to scientific research.

The implementation of ICT offers several advantages for overcoming speleological challenges and addressing preservation needs, while simultaneously promoting public engagement. In particular, the toxicity of hydrogen sulfide in the cave atmosphere and the elevated radon levels present significant obstacles for fieldwork, increasing the need for safety equipment and monitoring, especially for non-trained visitors. Furthermore, caves with vertical extents, such as Bezdenes Pothole and Neles Cave, pose accessibility challenges for both researchers and the public.

ICTs provide a way for the authorities of the Vikos-Aoos Geopark to offer virtual access to these geosites, enabling the public to explore them remotely while ensuring their protection. Moreover, these technologies support the creation of a management plan that safeguards both the caves and the sensitive ecosystems they contain, which are home to unique species with high levels of endemism. In addition to enhancing visitor safety, the geopark fulfills its role in the conservation and protection of these valuable geological sites.

The integration of ICT in geosite development not only advances scientific research but also provides a sustainable method for preserving these delicate ecosystems. By offering virtual access to otherwise inaccessible caves, such as Bezdenes Pothole and Neles Cave, the Vikos-Aoos Geopark can engage a wider public without compromising safety or the integrity of the sites (e.g. Evelpidou et al., 2021). This virtual experience, coupled with 3D scanning and augmented reality tools, allows visitors to explore these caves remotely, fostering greater awareness and interest in their preservation. The successful application of ICT in this context could serve as a model for other geosites, demonstrating the potential for technological advancements to enhance both public engagement and conservation efforts. Looking ahead, the continued use and advancement of these technologies will help ensure the long-term protection of these valuable natural resources, while also supporting local communities through increased tourism and educational opportunities (see for example Lazaridis et al., 2023).

The sulfuric acid caves in the Vikos-Aoos Geopark are the only known examples of this type of speleogenesis in Greece that are located in the area of an UNESCO Global Geopark, adding critical value to the promotion of these landforms. Their unique morphology also makes them ideal for educational purposes.

Finally, this work aligns with UNESCO's policies by fostering sustainable development, education, and cultural heritage preservation. By utilizing ICT to provide virtual access to inaccessible geosites, we promote inclusivity, enabling broader public engagement while protecting fragile ecosystems. The project supports education through innovative tools like 3D scanning and augmented reality, which enhance understanding of unique geological features. Additionally, our efforts contribute to local communities by encouraging geotourism and raising awareness about the importance of conserving these natural and cultural assets, reflecting UNESCO's goals of balancing accessibility, education, and preservation.

Conclusions

The use of ICT in the Vikos-Aoos Geopark has proven effective in overcoming challenges like toxic cave environments and limited accessibility. Smartphone-based tools and virtual technologies allowed for efficient data collection while keeping costs and time in check. These technologies not only helped gather accurate data but also enabled virtual access to caves, ensuring public safety while promoting awareness of these unique geological sites.

By offering virtual experiences, the Geopark can engage the public without compromising preservation efforts. This approach, using 3D scanning and augmented reality, sets a good example for other geosites looking to balance access and protection. Continued use of ICT will help safeguard these fragile ecosystems, support local tourism, and provide educational opportunities. The sulfuric acid caves in the geopark are particularly valuable for educational purposes and conservation, offering a unique opportunity for both research and public engagement.

This work supports UNESCO's policies by promoting sustainable geosite management, enhancing public engagement through virtual access, and fostering education and conservation of unique geological and cultural heritage.

Acknowledgements

Cave visits for this work have been approved by the Greek Ministry of Culture – Ephorate of Paleoanthropology and Speleology. Special thanks to the cavers who participated in the various expeditions for research in the area. 3D cave scans conducted as part of the 'Virtual Speleological Field Trip in Greece' project, formally supported by the International Union of Speleology (UIS).

EXTENDED ABSTRACT 193

Management of solid wastes from offshore oil drilling, based on their geochemical properties: A case study from the Prinos facilities in the Northern Aegean Sea.

Lianou Vasiliki[1], Tsakiridis Petros[2]
(1) National and Kapodistrian University of Athens, Athens, Greece, vlianou@geol.uoa.gr (2) National Technical University of Athens, Athens, Greece

Introduction

The increasing growth of the oil and gas industry has resulted in the generation of huge amounts of waste, most of which is produced during the drilling of wells for the exploration, extraction and production of hydrocarbons. The solid phase of drilling waste, also known as drill cuttings or DCs, is a major concern for oil companies, mainly due to the organic and inorganic contaminants it contains (Onwukwe & Nwakaudu, 2012). Increasing regulations and environmental concerns require the proper treatment and disposal of this waste (EU, 2013). However, the complexity, slow pace, and high cost of traditional debris remediation methods have, in recent years, shifted research focus toward its use as a raw material for manufacturing various products. The reuse of drilling waste in various applications, particularly in the construction sector, aligns with the principles of the circular economy and serves as a key solution for sustainable development (Asim *et al*., 2021). Research has already presented various proposals for the use of DCs, but choosing the appropriate solution is not an easy task. Each case is unique and demands a thorough understanding of the waste material's physical and chemical properties.

In Greece, the management of drill cuttings from hydrocarbon extraction has not been thoroughly studied. A significant challenge in exploring alternative management solutions is the lack of data on the composition and microstructure of this debris. Addressing this gap, this paper takes an initial step in analyzing and characterizing the geochemical properties of solid drilling cuttings from the country's sole hydrocarbon production facility.

Materials and Methods

A series of laboratory tests were carried out on a sample of DCs from Prinos facilities (fig. 1), using advanced X-ray (XRF and XRD) and scanning electron microscope (SEM) analysis methods to investigate its physical/mechanical properties, measure its hydrocarbon content (as these are its major contaminants) and determine its geochemical composition.

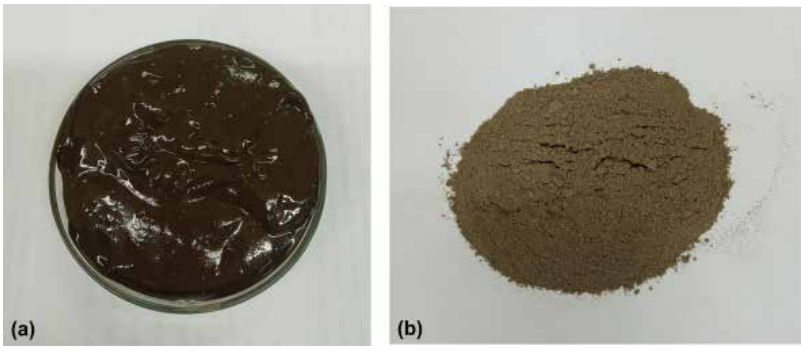

Figure 1. Sample of the study material: (a) coated with drilling mud, and (b) after drying at 110 °C for 24 hours.

Results

The results showed that the physical properties as well as the chemical and mineralogical composition of the DCs from Prinos depend on the rocks of the mining area, mainly on the calcium sources and the residual drilling mud. The debris material was characterized as silt, with the main oxides in its composition being BaO (21.98%), CaO (16.1%), SiO2 (14.21%) and SO3 (8.54%). The sample had a high loss on ignition (LOI ≈25.83% w/w) and contained organic material at 10.04% w/w and total petroleum hydrocarbons (TPH with C>12) at 7.34% w/w (fig. 3). It was also contaminated with polyaromatic hydrocarbons (PAHs: ≈180 mg/kg) (fig. 2). In terms of mineralogical composition, it contained: quartz (SiO2), calcite (CaCO3), dolomite [CaMg(CO3)2], anhydrite (CaSO4), barite (BaSO4) and alite (NaCl), with the dominant phase being quartz (excluding barite).

Molecular weight (gr/mol)	Polycyclic aromatic hydrocarbon (PAH)	Quantity (mg/kg)	Group of rings	Composition (%)
128	Naphtalene	122	2-rings	67,9
166	Accenaphthalene	2,33	3-rings	6,2
	Acenaphtene	6,18		
	Fluorene	0,095		
178	Phenanthrene	0,86		
	Anthracene	1,67		
202	Fluoranthene	3,04	4-rings	2,2
	Pyrene	0,65		
228	Benzo (a) anthracene	0,044		
	Chrysene	0,152		
252	Benzo (b) fluoranthene	0,122	5-rings	0,4
	Benzo (k) fluoranthene	0,089		
	Benzo (a) pyrene	0,033		
278	Dibenzoanthracene	0,522		
276	Benzo (g,h,i) perylene	26,2	6-rings	23,28
	Indeno (1,2,3-c,d) pyrene	15,6		
	Total	179,59		100

Figure 2. PAHs concentrations and percentage distribution of their fractions based on their ring group, in the sample.

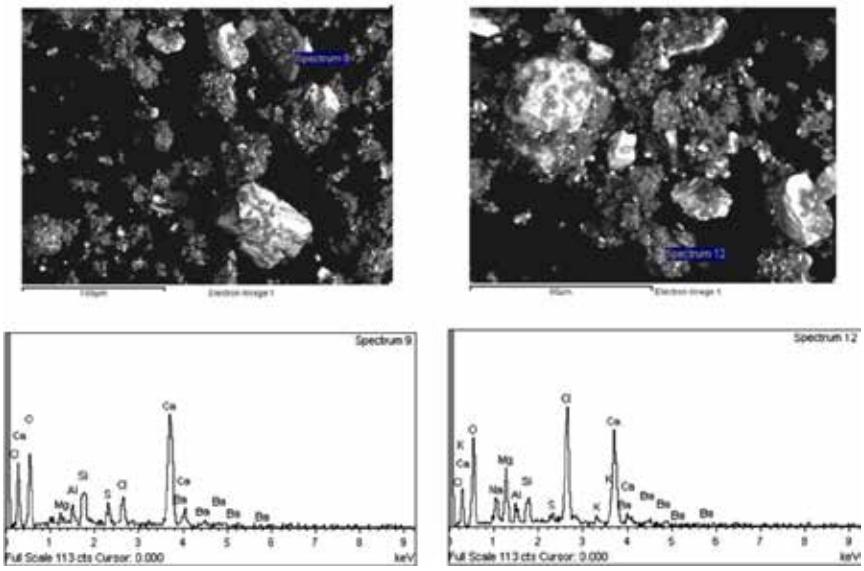

Figure 3. Characteristic mineral phases of the DCs sample from Prinos.

Conclusions

The main conclusions from the study of the results are summarized as follows: (a) the inorganic phases identified indicate that the material under consideration is of evaporite origin, (b) the very high percentage of Ba indicates the presence of drilling mud residues in the sample, (c) the contents of the remaining elements can be attributed mainly to the rocks of the mining area, and (d) the concentrations of trace elements in the DCs are probably controlled by the composition of the individual grains, with the exception of strontium, which is probably associated with the barite in the drilling mud.

Finally, to support the reuse and recycling of DCS, this study also explored three potential scenarios for utilizing Prinos drill cuttings. While the analysis was theoretical, the findings indicate promising opportunities for incorporating this type of solid waste into various products, demonstrating viable alternatives for its management.

Acknowledgements

I extend my gratitude to ENERGEAN OIL & GAS – ENERGIAKI AEGEAN S.A., with special thanks to Mr. V. Tsetoglou and Mr. P. Kokkini for supplying the material necessary for this study.

EXTENDED ABSTRACT 194

Palaeobotanical study of the Vrisaki flora from the Lesvos Petrified Forest

Eleni M. Liapi[1,2], George Iliopoulos[3], Nikolaos Zouros[1,2]

(1) Natural History Museum of the Lesvos Petrified Forest, Sigri/Lesvos, Greece, geod22002@aegean.gr (2) Department of Geography, University of the Aegean, Mytilene/Lesvos, Greece (3) Department of Geology, University of Patras, Rio/Patras, Greece

Research highlights

New insights into the plant palaeoassemblages from the Petrified Forest of Lesvos Island are revealed through the documentation and taxonomic determination of the leaf macro-remains from Vrisaki fossiliferous locality.

Background

The Petrified Forest, located at the western peninsula of the Lesvos Island, Greece, and recognized as a UNESCO Global Geopark, plays a pivotal role in preserving and showcasing the natural heritage of the Lesvos Island through efforts in scientific research, geo-conservation, geo-education and geo-tourism.

The recent construction of the new Kalloni-Sigri road, crossing the protected area of the Lesvos Petrified Forest in Western Lesvos, has exposed a remarkable wealth of plant fossil sites (Fig. 1). Especially, twelve fossiliferous localities were identified and excavated along the road, carefully protected, and studied to ensure their preservation and to advance knowledge. The findings include a wide variety of fallen and in situ fossilized tree trunks along with mass occurrences of leaf macro-remains revealing the great palaeobotanical richness of the region (Zouros, 2021).

The unearthed fossil material surpasses all prior expectations establishing the Lesvos Petrified Forest as one of the most significant areas for scientific investigations worldwide. Recent studies on both wood anatomy and leaf macro-morphology have provided new insights into the preserved volcanic flora of the broader protected area of the Petrified Forest (Velitzelos et al., 2019; Iamandei et al., 2022, 2024; Kafetzidou et al., 2022; Tsitsou et al., 2022; Liapi et al., 2022, 2023, 2024; Zhu et al. 2024).

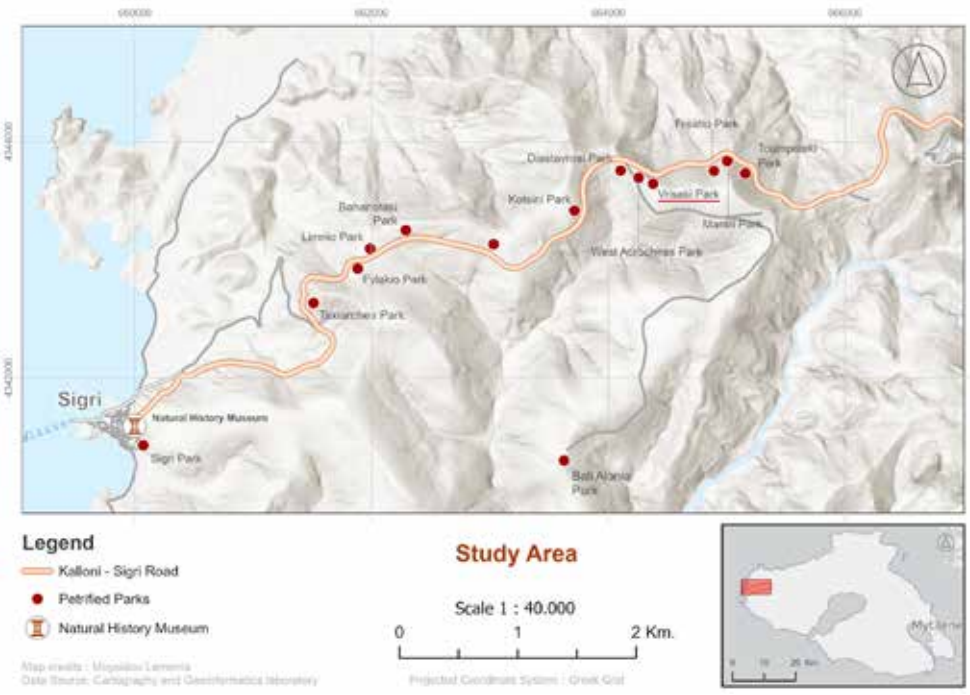

Figure 1. Location map of Western Lesvos where several new fossiliferous localities have been unearthed in the broader area of the Akroheiras hill range along Kalloni-Sigri road. The studied fossil material originates from Vrisaki Park (underlined on the map).

Objectives

The primary objective of this work is to enhance the study of the palaeobotanical record of the Petrified Forest through the documentation and taxonomic determination of leaf macro-remains from the new fossil sites along the Kalloni-Sigri road which traverses the Akrocheiras hill range (Fig. 1). In this context, several leaf macro-remains from Vrisaki

fossiliferous locality have been examined, described and determined. Additionally, the palaeoecological signals of the plant taxa have been assessed to reconstruct the environmental conditions that prevailed during the Early Miocene.

Material and Methods

The studied material consists 500 fossiliferous slabs comprising over 6930 leaves and a small number of reproductive organs. These remains have been preserved within different fine- to coarse-grained tuff layers, occurring both as leaf litter accumulated in the fine tuff layers, and as scattered leaves intermixed with pyroclastic material. The slabs were collected, conserved and cataloged by the research and technical team of the Natural History Museum of the Lesvos Petrified Forest (Zouros et al., 2022). The fossils were evaluated, with the majority of the material examined under an OPTIKA SLX-5 stereomicroscope. The taxonomic determination was conducted following the manual of leaf architecture with a focus on the key macro-morphological features of the fossils, including margin type, apex and base shapes, as well as venation architecture (Ellis et al., 2009).

Preliminary Results

To date, the palaeoflora of Vrisaki consists of at least one bryophyte, three ferns and more than 50 different angiosperm taxa, 21 of which are determined at a high taxonomic rank (family, genus and/or species). The determined taxa based on foliage include Bryophyta gen. et sp. indet., Thelypteridaceae gen. et sp. indet., aff. *Rumohra recentior* (Unger) Barthel, *Daphnogene polymorpha* (A. Braun) Ettingshausen, *Laurophyllum* sp. 1, *Laurophyllum* sp. 2, *Smilax weberi* P.Wessel, *Phoenicites* sp., *Calamus* sp., Zingiberaceae gen. et sp. indet., aff. Zingiberales, Fagaceae gen. et sp. indet. 1, Fagaceae gen. et sp. indet. 2, Juglandaceae gen. et sp. indet., *Alnus* vel *Rubus*, *Rubus* sp., aff. *Celtis japeti* Unger, *Populus* sp., *Nerium* sp., *Myrtophyllum* sp., and *Pungiphyllum cruciatum* (A. Braun) Frankenhäuser & V. Wilde. Additionally, the leaf material has been grouped into several distinct morphotypes, each requiring further investigation for a more detailed classification (Fig. 4, 4.4–4.7). Based on reproductive organs, the flora includes a solely infructescence of *Alnus* ?*kefersteinii* (Göppert) Unger, winged fruits of *Acer* sp. and cf. *Acer* sp., and a few buds probably of lauraceous affinity. Different representative plant taxa of the studied area are illustrated in Figures 2–4, underscoring the floral diversity of Vrisaki.

Discussion

The enormous quantities of leaf macro-remains and the numerous petrified tree trunks preserved in various fossiliferous localities within the pyroclastic rocks of the Lesvos Petrified Forest provides a great opportunity to decipher the Early Miocene subtropical history of the island. This ongoing research focuses on the documentation and systematic taxonomy of the abundant leaf material from the fossiliferous locality of Vrisaki. So far, more than 54 plant taxa have been documented and analyzed based on their macro-morphological characteristics. The palaeoflora of the Vrisaki fossiliferous locality represents a diverse array of vegetation types, ranging from riparian habitats to lowland and upland mesophytic forest regions. The determined taxa are linked to one or more vegetation units, reflecting the ecological diversity and complexity of the palaeoenvironment. Evidence of a riparian plant association is suggested by taxa such as aff. *Rumohra recentior*, *Daphnogene polymorpha*, *Phoenicites* sp., *Alnus* ?*kefersteinii*, *Alnus* vel *Rubus*, *Populus* sp. and possibly *Pungiphyllum cruciatum*. The occurrence of members of the Lauraceae and Fagaceae families, Juglandaceae gen. et sp. indet., aff. *Celtis japeti* and *Nerium* sp. is indicative of well-drained forests. Herbaceous monocots, including members of Zingiberales, were likely adapted to the shaded understory beneath the forest canopy of the riparian or well-drained forests. In addition, lianas such as *Smilax weberi* and *Calamus* sp. may have been part of riparian or well-drained forests, suggesting a forest structure with multiple layers. The preliminary results from the systematic taxonomy of the Vrisaki fossiliferous locality reveal sufficient floristic similarities with the West Akrocheiras fossiliferous locality from the Akrocheiras hill (Kafetzidou et al., 2022; Tsitsou et al., 2022; Liapi et al., 2022, 2023). Both palaeofloras share plant taxa such as Thelypteridaceae gen. et sp. indet., *Daphnogene polymorpha*, *Laurophyllum* sp. 1, *Smilax weberi, Phoenicites* sp., *Calamus* sp., Zingiberaceae gen. et sp. indet., Fagaceae gen. et sp. indet. 1, *Rubus* sp., aff. *Celtis japeti*, *Populus* sp., *Acer* sp., *Nerium* sp., *Myrtophyllum* sp., and *Pungiphyllum cruciatum*. Notably, the Vrisaki palaeoflora appears to exhibit a greater diversity based on fruit remains, including *Alnus* ?*kefersteinii*, *Acer* sp. and cf. *Acer*.

Despite the progress that has been made in recent years, further investigation is required as several morphotypes still remain under study. The systematic taxonomy of the plant macro-remains from Akrocheiras hill poses challenges due to the extensive abundance of collected specimens and the overlapping morphological features exhibited by certain leaf types. Completing the systematic classification in the future will provide a more comprehensive floristic knowledge and offer valuable insights into the palaeoenvironmental history of the Early Miocene of Lesvos.

Recent seismic activity in the Santorini region has attracted global attention and raised concerns about ongoing volcanic hazards. Santorini, a large volcanic caldera featuring the central islets of Nea Kameni and Palea Kameni, has a complex eruptive history spanning approximately 650,000 years, including the catastrophic eruption (~1560 B.C.) linked to the decline of the Minoan civilization. Since 27 January 2025, the region has experienced a major seismic crisis, with over 2,000 earthquakes recorded, including 14 events with magnitudes ≥5.0 and a maximum magnitude of 5.3. Seismicity has been concentrated approximately 25 km northeast of Santorini and 25 km southwest of Amorgos.

We present the results of two geochemical surveys conducted between March and April 2025, involving water sampling from 10 wells, measurements of soil CO□ fluxes and d^{13}C-CO□ values in Santorini and Nea Kameni, as well as sampling of fumarolic gases at Nea Kameni and bubbling gases at Palea Kameni. These data provide a preliminary assessment of the current degassing dynamics of the area. Comparison and integration with existing literature indicate that the post-seismic volcanic phase following the January–February 2025 seismic crisis is marked by an increased degassing rate in the Nea Kameni region. However, the chemical and isotopic compositions of the gases (^{3}He/^{4}He and d^{13}C values) exhibit only minor variations relative to pre-crisis measurements reported in previous studies.

Although preliminary, these findings underscore the critical need for continuous monitoring of the Santorini volcanic system, in order to deliver timely and reliable information to the local community and to support effective volcanic risk mitigation strategies.

EXTENDED ABSTRACT 196

Automated Seismic signals' identification: A statistical criterion for decreasing the false alarm rate; Implementation on synthetic data.

Lois A.[1], Giannopoulos D.[1], Sokos E.[1]

(1) University of Patras, Department of Geology, Patras, Greece, lois@upatras.gr

Abstract

Algorithms dealing with the problem of the identification of micro-earthquakes constitute a topic of ongoing research. The development of methodologies dealing with the specific problem has gained considerable attention during the last decades in the context of research, appearing at the same time to be the central issue in various application areas. The extraction and efficient analysis of the useful information from continuous recordings are of great importance, since it is a prerequisite for reliable interpretations. Nevertheless, such processes usually suffer from a number of false alarms, which tends to be significantly increased in extremely noisy environments. In this paper, we propose a "decision-making" scenario to be applied on the extracted intervals, for the purpose of decreasing the probability of false alarms. The specific statistical criterion can be implemented regardless of the detection algorithm that has been applied for the identification of the seismic events and its efficiency is confirmed by its application on a series of experiments on synthetic data.

Introduction

The most widely used algorithms, mainly due to their simplicity and the low computational resources that they demand, are the energy-based algorithms, which are also referred to in the literature as STA/LTA detectors. In its simplest form, the STA/LTA algorithm processes the initial recordings, or some characteristic function derived from raw data, using two moving windows and compares their absolute values' ratio to a user-defined threshold value, to declare a seismic event. This idea was firstly adopted by Allen (1978), who applied energy criteria on the characteristic function that resulted from the signal's positive envelope. Baer & Kradolfer (1987) proposed a modified and improved version of Allen's method, aiming in overcoming specific drawbacks that characterize the latter, which are mainly associated to the user-defined parameters of the technique, such as the selection of the appropriate characteristic function, as well as the threshold value, in order to increase the detection rate. Another class of techniques that are commonly used for the solution of the seismic event detection problem, as well as the picking of phase arrivals are the methodologies which utilize autoregressive modeling along with the Akaike Information Criterion (AIC) (Leonard & Kennett 1999). The basic assumption constituting the base of these algorithms is that the seismic recordings can be segmented into locally stationary parts, which can be described by autoregressive models of different orders. This property can be used as a diagnostic tool to discriminate useful information from the background noise. Moreover, several methodologies based on classical statistical concepts, such as the maximum likelihood, hypothesis testing scenarios, higher order statistics etc., were introduced as possible solutions for the signal identification problem. Since the statistical properties of seismic noise are not easily predictable, as it is widely reported (Arrowsmith et al. 2008) Lois et al. (2013, 2019) proposed the solution of the problem under examination, using a thresholding type technique, which is applied under a non–strict hypothesis testing framework. Higher order statistics (HOS) also constitute an important tool that has been exploited by geoscientists, during the last two decades, for the purpose of solving the event detection problem, as well as the accurate estimation of the phase arrival times (Saragiotis et al. 2002). Apart from the above-mentioned techniques, which mainly rely on classical seismic signal analysis applied on either 1C or 3C data, there are also more sophisticated approaches that are referred to in the literature, using artificial neural networks (Mousavi et al. 2018), machine learning (Chen 2018), fuzzy logic theory (Chu & Mendel 1994), etc. Nevertheless, it is obvious that the above-listed methodologies are affected by several factors, such as the source type, the instrument response, the noise level of the study area, the epicentral distance of the recorded events etc. Thus, the development of robust algorithms that provide stable results for general situations is of vital importance. In this study we propose a statistical criterion serving as an "outcome control" process, adopted to refine the initial outcome acquired by any detection algorithm.

Methodology

Once the extraction of the segments of the seismic record is achieved (using any of the well-known detection algorithms), the main effort of the proposed methodology is focused in performing the implementation of a mechanism capable to control the results by retaining the useful, for our analysis, information and eliminating the intervals corresponding to false alarms. In that scope, pure seismic noise is initially isolated, using energy criteria, and, thereafter, we introduce

a “decision-making” criterion, based on the comparison among autoregressive models estimated on the isolated seismic noise, as well as the detected segments resulting from the application of the detection algorithm.

Let us consider that $\mathfrak{B}$ is a set containing *I* blocks $\boldsymbol{b}_i$of length *L* that have been drawn independently and with replacement from the initial stationary record $\mathbf{z}_n$, corresponding to the vertical component, that is:

$$\mathfrak{B} = \{\boldsymbol{b}_1, \boldsymbol{b}_2, \dots, \boldsymbol{b}_I\},\ \boldsymbol{b}_i = [z_i, z_{i+1}, \dots, z_{i+L-1}], i \in [1, N-L+1]. \quad (1)$$

It is clear that the *i*–th element $\boldsymbol{b}_i$of the set $\mathfrak{B}$ is a block of length *L* consisting of consecutive samples, with its starting index *i* being a uniformly distributed discrete random variable ensuring equiprobable selection of each *L*-length block from the available $N-L+1$ that are contained in the initial record $\mathbf{z}_n$ (Lois et al 2013). Apparently, $\mathfrak{B}$ can also be formulated as a $I \times L$ matrix, having in its *i*–th row the block $\boldsymbol{b}_i$.

Having formed the set $\mathfrak{B}$ by applying the previously mentioned sampling procedure, the goal now is to identify blocks consisting solely of noise samples. This constitutes a clustering problem that can be addressed using various approaches. For instance, Lois et al. (2013) proposed the application of a modified “k-median” algorithm that exploits as input autoregressive models estimated on blocks $\boldsymbol{b}_i$, instead of the blocks themselves, in order to reduce the dimensionality of the problem. Following the specific approach, a robust separation among “noise” and “signal” models is achieved, but in general high computational resources are demanded, due to the modeling procedures that have to be applied on each block that is selected during the sampling process. In this work, a simple energy-based procedure is applied in order to establish the desirable isolation of the noise blocks. In general, given a stationary recording, samples forming a noise block are expected to be characterized by insignificant fluctuations in amplitude, thus resulting in low values of the block’s variation. On the other hand, the presence of a seismic signal or part of it in a block causes an increase in the block’s variation, due to high fluctuations among the samples within the block. Therefore, the selection of the desirable intervals is based on the comparison of their standard deviations to a predefined value.

More particularly, assuming that $\boldsymbol{\mathcal{S}}$ is a set including the standard deviations of the blocks $\boldsymbol{b}_i\boldsymbol{b}_i$:

$$\boldsymbol{\mathcal{S}} = \{\sigma(\boldsymbol{b}_i)\}_{i\in[1,I]} = [\sigma(\boldsymbol{b}_1), \sigma(\boldsymbol{b}_2), \dots, \sigma(\boldsymbol{b}_I)], \quad (2)$$

the desirable set $\mathfrak{B}_{noise} \subseteq \mathfrak{B}$, containing the noise blocks is selected using the following relation:

$$\mathfrak{B}_{noise} = \{\boldsymbol{b}_i \in \mathfrak{B}; \sigma(\boldsymbol{b}_i) \leq median(\boldsymbol{\mathcal{S}})\} \quad (3)$$

It is apparent that since the median value of the set $\boldsymbol{\mathcal{S}}$ constitutes the “middle observation” of its sorted values, the latter can equally be formulated as an $\frac{I}{2} \times L$ or $\left(\frac{I}{2}+1\right) \times L$ matrix, depending on whether *L* is an odd or an even number. What we need now is to calculate a time series, representative of the noise characteristics of the given recording, in order to use it as a “reference vector” for the next step of our analysis. In that scope, we calculate and denote as $\bar{\boldsymbol{b}}_n\bar{\boldsymbol{b}}_n$ the average of the noise blocks, calculated column-wise, such as:

$$\bar{\boldsymbol{b}}_n = \left[\frac{1}{r}\sum_{j=1}^{r}\mathfrak{B}^j_{noise}(1), \frac{1}{r}\sum_{j=1}^{r}\mathfrak{B}^j_{noise}(2), \dots, \frac{1}{r}\sum_{j=1}^{r}\mathfrak{B}^j_{noise}(L)\right] \quad (3)$$

where the first element of the reference vector is the average of the first column of matrix $\mathfrak{B}_{noise}$, the second element is the average of the second one etc. and *r* equals to $\frac{I}{2} \times L$ or $\left(\frac{I}{2}+1\right) \times L$, depending on whether *L* is an odd or an even number, as it has already been mentioned. Index jj refers to each selected noise block that fulfils eq. (2).

Since the “average” noise block has been isolated using the above-mentioned energy-based procedure, our goal is to estimate the stochastic models that best describe both the noise and the “candidate” seismic signals. These models will be the tools that will permit the elimination of any “false” information that may have been included in the initial results. To this end, we apply autoregressive (AR) modeling procedures to the specific time series, selecting the optimal model orders by using the corrected Akaike Information Criterion (*AICc*). In general, the *AICc* for finite sample sizes and for a model order *P* is defined as follows:

$$AICc = 2P - 2\ln\{l(\theta^*)\} + \frac{2P(P+1)}{L-P-1} \quad (4)$$

where $l(\theta^*)l(\theta^*)$ is the achieved maximum of the likelihood function $l(\theta)$ and θ^* is the maximum likelihood parameter estimator of length *P*, resulting from the solution of the following optimization problem:

$$\theta^* = arg\max_{\theta}\{l(\theta)\} \quad (5)$$

Moreover, it is known that *AIC* (so *AICc*) provides a means of model selection by estimating the amount of information that is lost by a given model. Hence, the less information a model loses, the higher the quality of that model is. Therefore, given a set of models, the optimum model is the one corresponding to the minimum value of the *AICc*, so if $P_i, P_i \in \mathbb{P} \subseteq \mathbb{N}$ are the candidate AR model orders, then the optimum order *P* is estimated by:

$$P = arg\min_{P_i \in \mathbb{P}}\{AICc(P_i)\} \quad (6)$$

Now, we can formulate the average PP-order noise model $\bar{m}_n\bar{m}_n$ which is described as follows:

$$\bar{x}_t = c + \sum_{j=1}^{p}\varphi_j\,\bar{x}_{t-j} + \varepsilon_t,\ \ \varepsilon_t \sim N(0,\sigma_\varepsilon^2) \quad (7)$$

where c is a constant value, φ_j are the parameters of the model and ε_t is white noise with zero mean value and variation equal to σ_ε^2.

Furthermore, assuming that the algorithm has detected *k* segments in the initial recording, we derive in the same way *k* AR(Q_i) models, where the *i*-th model m_i of order Q_i is given by:

$$x_t^i = c^i + \sum_{j=1}^{Q_i}\theta_j^i\,x_{t-j}^i + \varepsilon_t^i,\ \ \varepsilon_t^i \sim N\left(0,\sigma_{\varepsilon^i}^2\right) \quad (8)$$

where c^i is a constant value, θ_j^i are the parameters of each model m_i and ε_t^i is again a process of white noise with zero mean and variation equal to $\sigma_{\varepsilon^i}^2$. Apparently, the model orders Q_i are also computed using the *AICc*. The remaining step, in order to complete the presentation of the proposed algorithm, is a "Decision-Making" criterion which will allow controlling the outcome of detection algorithm, thus ensuring the best possible final result. The general idea lies on the fact that, given the AR models describing the average noise block, as well as the detected intervals from the initial record, we can conclude on the "nature" of each candidate segment by examining whether it converges to the estimated noise model or not. Here, the concept of convergence implies the notion of the distance among these models. In other words, in an ideal case, a model describing a detected segment, which is close to the estimated noise model, is more likely to correspond to a false detection, than to a seismic signal. Alternatively, a model that deviates sufficiently from the noise model probably corresponds to a microseismic event or to any other signal with dynamical characteristics that differ from the characteristics of the background noise. The main question arising from the proposed approach concerns the measure of similarity or the appropriate criterion that must be adopted in order to conclude to secure results. For example, Picolo (2010) proposed the autoregressive metric for comparing time series models, by introducing the Euclidean distance between the coefficients of their AR formulations. Even though the specific distance is a well-defined measure of structural dissimilarity between two stochastic models, its implementation to models associated with passive seismic data leads to unstable conclusions, especially in extremely noisy environments.

Taking into consideration the fact that changes in both the order and the values of the AR coefficients are diagnostic of the differences between noise and signal (Leonard & Kennett 1999), we propose the following scenario in order to decide about the "nature" of the detected intervals under investigation:

$$(P \le Q_i) \cap \left(\sigma(|\boldsymbol{\varphi}|) < \sigma\left(\left|\boldsymbol{\theta}^i\right|\right)\right), \forall\, i\epsilon[1,k], k\epsilon\mathbb{Z} \quad (9)$$

where $\sigma(.)$ refers to the standard deviation of the quantities $\boldsymbol{\varphi} = [\varphi_1, \varphi_2, \ldots, \varphi_P]$, which is the vector containing the coefficients of the noise model, and $\boldsymbol{\theta}^i = [\theta_1^i, \theta_2^i, \ldots, \theta_{Q_i}^i]$ is the respective vector corresponding to the *i*–th detected interval.

Experimental Results

The simulations with synthetic data were performed using two different noise process scenarios. To this end, two first-order AR processes were utilized (denoted by AR1 and AR2 respectively) with poles of different magnitude, in order to simulate, as realistically as possible, a "normal" case (pole magnitude = 0.73), as well as an extreme case (pole magnitude = 0.9), where the assumption of stationarity almost fails. For each of the two noise process scenarios, 500 records of synthetic seismic data were constructed (each having a duration of 10 min and a sampling rate of 100 Hz), containing a total number of 2500 events. More specifically, to construct each data record, we initially created the noise process, using the above-mentioned AR processes, and then 5 synthetic seismic events, with the desired SNR in the range [-5, 5] dB, were superimposed. The SNR was estimated using a window of 100 samples (1s) in the vicinity of the first arrival of each seismic event. Moreover, the seismic events were created according to Lois et al. (2013). Initially, a window of white Gaussian noise was low-pass filtered and the resulting sequence was multiplied by a half-Gaussian window of the same length, for the purpose of simulating the exponential decay (attenuation) of the signal's amplitude. Then, the vector representing the seismic signal was multiplied by a constant gain, in order to control the SNR in the desirable range. The detected segments were acquired using an improved 3C version of the well-known STA/LTA algorithm (STA/LTA_{3C}). According to the classical approach (STA/LTA), the ratio between a short-term average (STA) and a long-term average (LTA) window is usually calculated using data from the vertical component. In our experiments (STA/LTA_{3C}), in order to increase the SNR of the ratio function and, consequently, its capability to detect small-magnitude events, we exploit information from all three components of the recorded signal, using their L_2–norm, that is:

$$f_i^{sl} = \sum_{i=1}^{N}\left(\sqrt{z_i^2 + x_i^2 + y_i^2}\right) \quad (10)$$

where z_i corresponds to the vertical component, while x_i and y_i to the East-West and North-South horizontal components, respectively. The results regarding the false alarm rate prior and after the application of the proposed statistical criterion is presented in table 1.

Table 1. False alarm rate prior and after the application of the proposed statistical criterion on synthetic data

False Alarm Rate	AR[1]		AR[2]	
SNR (dB)	Prior (%)	After (%)	Prior (%)	After (%)
-5	33.87	14.47	66	37.33
-2	15.13	8.07	52.63	28.97
0	7.92	1.96	25.15	16.79
2	4.03	0.86	13.35	7.38
5	0.39	0	6.74	2.03

1: Results from the application of the proposed "Decision Making" criterion on the two different noise process scenarios.

By inspecting the results presented in table 1, associated with both noise scenarios it becomes evident that the implementation of the proposed criterion significantly reduces the false alarm rate of the initial outcome derived by (any) detection algorithm. Regarding the first noise scenario and for noise levels down to 2 dB the results are acceptable even without the application of the "decision – making" scenario. But for extreme noise levels, corresponding to negative values of SNR the proposed technique provides a reduction of almost 50% to false detections. Moreover, for the second noise scenario where the useful information is buried to strongly correlated synthetic seismic noise, the attempt is focused on testing the performance of the method in cases where basic assumptions, such as the stationarity, almost fail. Nevertheless, and by considering the extremely noisy environment (-2 and -5 dB), the rate of false signal identifications reduced significantly, approaching again a reduction of 50%.

Conclusions

In this study, we introduce a statistical criterion which can be applied on the initial outcome obtained by the implementation of each well-known detection algorithm on seismic data. This "Decision-Making" scheme relies on stochastic modeling applied on both the detected intervals and a signal representative to the recorded seismic noise. Comparisons among the calculated models provide us an indication about the nature of the "candidate" seismic signals. The advantages of the proposed approach were confirmed through a series of experiments, using synthetic seismic data, providing a significant reduction of the false alarm rate even in extremely noise environments.

Introduction / Background

The area offshore the central Ionian Islands (Cephalonia, Lefkada, Zakynthos, and Ithaca), western Greece (Fig. 1A; 1B), is within the Mediterranean regions one with the highest seismic activity and tsunamigenic potential (Fig. 1C). Here, the Hellenic frontal thrust system stops against the right-lateral Cephalonia Transform Fault, a fault more than 100 km-long (Louvari et al. 1999), to step back towards Corfu (Sachpazi et al., 2000). In recent decades, this area experienced several destructive events, such as the 1953 Cephalonia earthquakes (three M6+ events) and the more recent the Mw 6.8 Zakynthos event occurred the 28 October 2018 (Ganas et al., 2020) and the swarm of moderate size events ranging from 5.3 to 5.7 occurred in 2006 (Papadimitriou et al. 2012). Although this area has a high exposure to geological risk, offshore remains little explored. In order to improve the knowledge on shallow deformation, fault geometry and on the hazard potential of tsunamigenic faults, we carried out two oceanographic cruises, in May 2022 (aboard of the R/V G. Dallaporta supported by the Italian National Research Council - CNR) and in June 2023 (aboard of the R/V L. Bassi from the National Institute of Oceanography and Applied Geophysics - OGS in the frame of the POSEIDON project supported by the Eurofleet+ Program). During these two cruises we collected a multidisciplinary and multiscale dataset composed of geophysical (e.g., bathymetry, multichannel seismic data, magnetometry) and geological data (gravity cores).

Results

The newly collected high-resolution multichannel seismic data (Fig. 1B), integrated with high-resolution swath bathymetry, allowed us to define the sediment deformation patterns at the intersection between the Cephalonia Fault and the thrust fronts of the Hellenic Arc. To south of Cephalonia, the high-resolution multichannel seismic profile highlights a series of small bulges with internal discontinuities close to small drops of the seafloor (Fig. 2) interpreted as reverse faults bounding positive flower structures dipping toward southeast. Amongst two well-imaged flower structures, a shallow layer of sediments is dislocated by E-verging thrusts forming reverse structures. More eastward, the Argostoli Ridge is bounded on its west side by a strike-slip fault with inverse component, interpreted as a west-verging transpressive fault. The ridge internally is affected by a series of minor compressive faults, as revealed by the dislocations of sedimentary layers L1 and L2, and by a series of minor normal faults related to gas escape that have generated a Giant Pockmark. Further south, the Cephalonia Fault still shows this transpressive character and the Argostoli Ridge looks bounded even on its east side by a strike-slip fault with inverse component (Fig. 3).

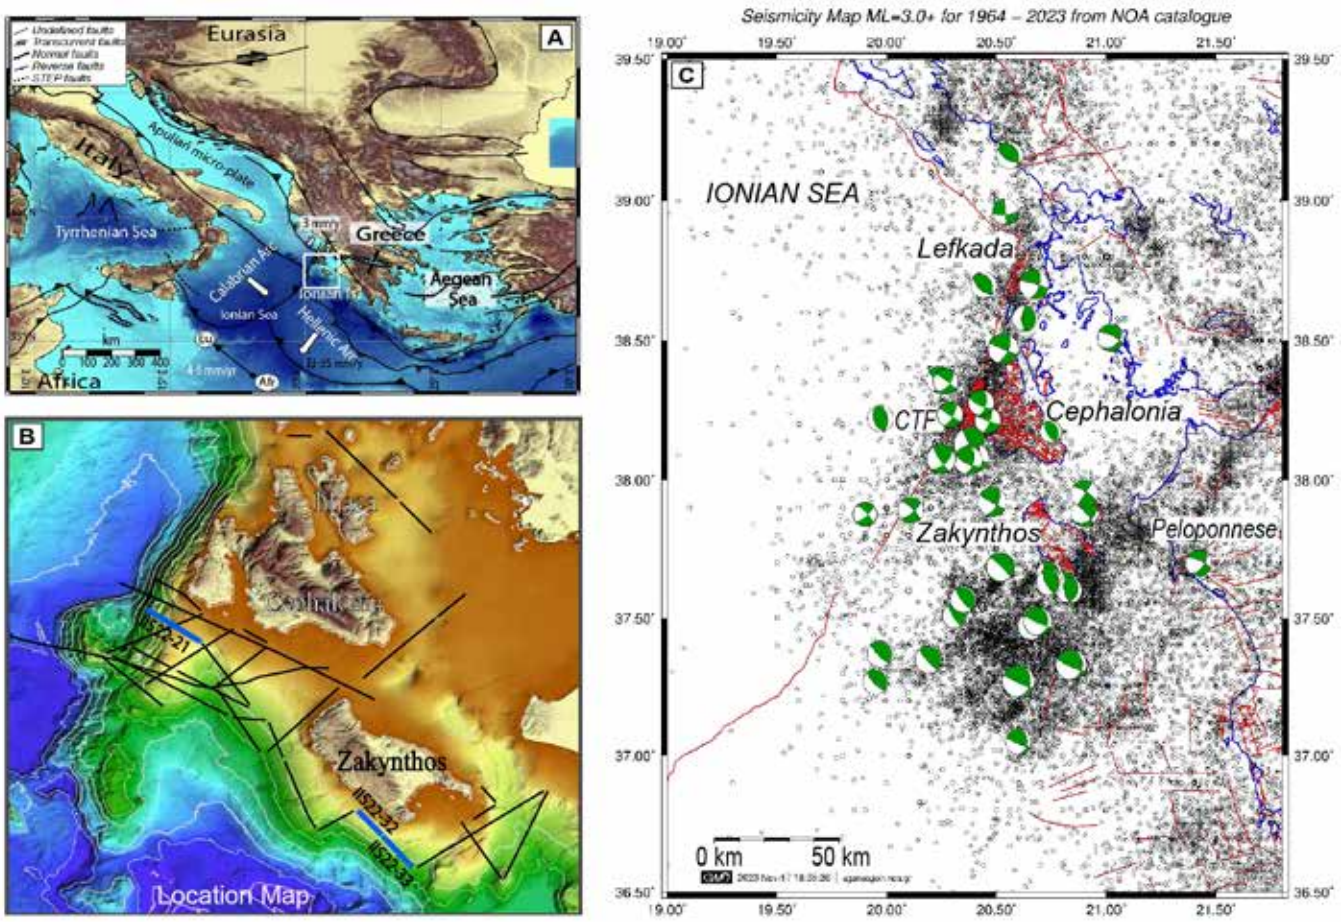

Figure 1. A) Tectonic map of the central Mediterranean showing location of the study area (white box). Mediterranean structural sketch modified after an online Tectonic Map (Woudloper - Own work, CC BY-SA 1.0) and by Loreto et al., (2021). B) Relief map of the study area. It shows the dataset collected during the IONIANS2022 survey. The multichannel seismic profiles shown in this abstract are pointed out with thick blue lines. Bathymetry data were downloaded from EMODnet portal (https://emodnet.ec.europa.eu/en/bathymetry#bathymetry-approach) and gridded using GMT software (Wessel et al., 2019). Inset (upper right): GPS velocity vectors map from https://www.unavco.org/. C) Map showing the distribution of the instrumental seismicity (black dots) with focal mechanisms (beachballs; events with 5.5 ≤ M ≤ 6.8; period 1959 - 2022). Green beachballs are focal mechanisms downloaded from the Global Centroid Moment Tensor database (www.globalcmt.org). Seismicity data collected from 1964 to 2023 by the NOA Institute of Geodynamics (only events with local magnitude M≥3 are shown; https://www.gein.noa.gr/en/services-products/earthquake-catalogs/). Faults are after Ganas et al. (2013, 2018). Map projection is geographic, Datum WGS84.

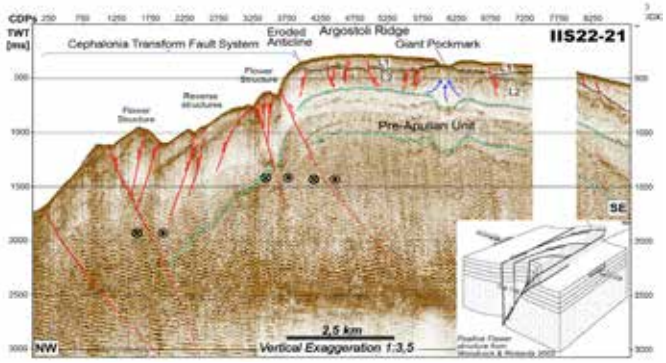

Figure 2. High-resolution multichannel seismic profiles crossing IIS22-21 the Cephalonia Transform Fault system. Faults are marked with red lines, while the kinematics (normal, reverse) are inferred by arrows direction. Blue lines mark the multiple signals. Black lines bound two sedimentary units. A sketch of a strike-slip fault with compressive component modified by Woodcock & Rickards (2003) has been included.

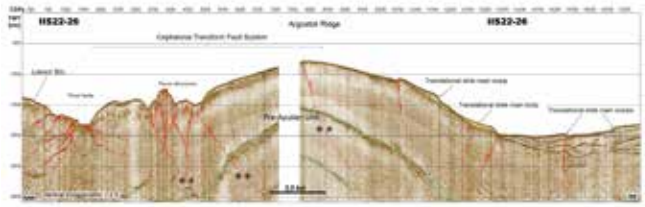

Figure 3. High-resolution multichannel seismic profiles crossing IIS22-26 the Cephalonia Transform Fault system further south of Cephalonia Isl. Faults are marked with red lines, while the kinematics is inferred by arrows direction. Light blue lines mark multiple signals.

South of Zakynthos, the deformation setting changes with respect to the CTF system zone. Here a well-stratified shallow unit, likely of Plio-Quaternary age, overlies a unit internally low reflective facies; we interpreted belonging to the Pre-Apulian unit (Fig. 4). The sedimentary unit is cut by widespread SE and NW dipping faults with extensional kinematics. Some of these faults affect the stratified unit and part of the underlaying Pre-Apulian Unit. These faults frequently reach the seafloor forming small steps. A series of sedimentary unconformities and a deep graben filled by sediments have been mapped in the surroundings of this gentle anticline. This complex setting suggests that there is a strong interplay between tectonics and sedimentary processes.

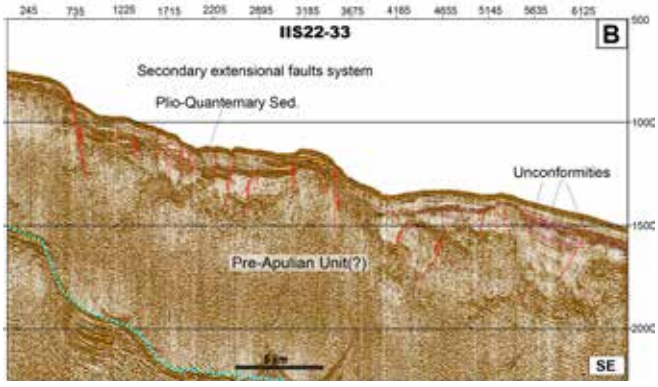

Figure 4. High-resolution multichannel seismic profiles IIS22-33 crossing the slope offshore Zakynthos. Faults are marked with red lines, while the kinematics is inferred by arrows direction. Light blue lines mark the multiple signals.

Discussion

The morphotectonic setting of the CTF fault system results show more complexity than previously mapped (Fig. 2, 3 4). Shallow sediment deformation in the central sector of the CTF system is controlled by a series of strike-slip faults with a compressive component, locally expressed by positive flower structures, generally E-dipping. The Cephalonia fault system splays into several branches, similar to a compressive strike-slip duplex (Woodcock and Fischer, 1986), and changes size passing from ~6 km (Fig. 1B), to west of Cephalonia Is., to 25 km-wide in the southern part. Our new findings completely change the previous published interpretation of the geometry of CTF system, inferred only from seismological data and modelling (Louvari et al., 1999; Papadimitriou et al., 2021). Given that the single fault "widens" into a fault system, the overall slip rate (~17 mm/yr; Tsironi et al. 2024) is partitioned, which might decrease the earthquake magnitude over several active faults and increases the distribution of events over a large area, as inferred from recorded seismicity (Fig. 2 and Fig. 4 in Kassaras et al., 2016). This new fault anatomy, with a multi-segment geometry, should have an effect over the seismological models proposed in the future for the CTF system. Southwest of Zakynthos, a series of normal faults dissecting the shallow marine sediments SE-ward (Fig. 4) indicate that this area is dominated by extensional stress. However, this area has been struck during last decades by several earthquakes, most of which with thrust mechanisms (Figs. 1c and 2a; Kassaras et al., 2016). Combining MCS data (Fig. 4) with swath bathymetry (fig. 1B) and seismological data (Fig. 1C) and considering the orientation of faults with respect to the morphologic features of the area (Fig. 4), we interpret these extensional structures as a secondary system that is able also to trigger earthquakes. This idea is also supported by some focal mechanisms with extensional kinematics recorded on-land (see Figs. 4 and 7 in Kassaras et al., 2016). This extensional secondary system may accommodate deformation induced by a deep compressive fault system, whose orientation remains still to be determined, or may result by a local extensional stress field controlled by gravitational instability, suggested by the large slump and morphological steps along the slope (Figs. 1B, 3 and 4).

Conclusions

The new geophysical data, including high-resolution and high-penetration multichannel seismic data and high-resolution swath bathymetry, allowed us to map the anatomy of the Cephalonia Transform Fault system in its southern sector and deformation affecting the slope to south of Zakynthos. We studied the sediment deformation patterns at the intersection between the Cephalonia strike-slip fault and the thrust fronts of the Hellenic System revealing a larger system and more complex structure than anticipated from previous works. The main outcome of the present work is a new morpho-structural map of Cephalonia and Zakynthos offshore. South of Cephalonia Island, the CTF "widens" to a 25 km-wide system of splays composed of elongated sigmoidal, positive-flower structures, possibly merging at depth into a single strike-slip fault. To west of Cephalonia Island, CTF narrows into a 6 km-wide strike-slip structure. Our data supports a dominant strike-slip kinematics with compressive component of the CTF. South of Zakynthos, the tectonic regime in the shallow sediments is dominated by extension, possibly representing a secondary tectonic system controlled by a local extensional stress field associated with a gravitational instability.

Acknowledgements

Seismic data interpretation was carried out using the Kingdom Suite software (S&P Global), freely available under the S&P Global University Grant Program. Geophysical data were collected during the IONIANS cruise supported by internal CNR funding (https://www.ismar.cnr.it/web-content/rapporto-tecnico-n-11/) and aboard of the R/V L. Bassi – INOGS during POSEIDON cruise supported by the Eurofleet+ program (http://eurofleet.maris2.nl/cds-report/25). The open source for seismological data is https://www.gein.noa.gr/en/services-products/earthquake-catalogs/

BULLETIN OF THE GEOLOGICAL SOCIETY OF GREECE, SP. PUBL.

EXTENDED ABSTRACT 198

The Early Pleistocene vertebrate fauna of Vatera, Lesbos, Greece

George Lyras[1], Athanassios Athanassiou[2], Alexandra van der Geer[3], George Kontakiotis[1], Evangelia Besiou[1], Asimina Antonarakou[1]

(1) Department of Historical Geology-Paleontology, Faculty of Geology and Geoenvironment, School of Earth Sciences, National and Kapodistrian University of Athens, Panepistimiopolis, Zografou, 15784 Athens, Greece, glyras@geol.uoa.gr (2) Hellenic Ministry of Culture, Superintendence of Palaeoanthropology–Speleology, Athens, Greece (3) Naturalis Biodiversity Center, Leiden, the Netherlands.

Background and objectives

Fossil-rich areas are found around the area of Vatera near Vrissa, about 6 km south of the town Polichnitos in the southern region of Lesbos Island. Systematic excavations were conducted here between 1996 and 2007 (Lyras & van der Geer, 2007). Fossil remains from these excavations were deposited in a local museum, alongside fish fossils (Drinia *et al*., 2007) and plant remains (Mantzouka *et al*., 2013) collected from the broader Polichnitos area. This year, renewed interest in Vatera's fossil record has brought the University of Athens back to the region. This contribution aims to provide a context and rationale for the new project in the light of the current knowledge on the terrestrial vertebrate fossils discovered thus far at Vatera.

The Vatera sites and fauna

The terrestrial vertebrate fossils at Vatera were discovered within the fluvial deposits of the Vatera Formation. This formation comprises alternating layers of breccia-conglomerates, sandy clays, sandy conglomerates, and silt. A total of 630 vertebrate fossils have been recovered from seven sites (Figure 1), coded with E, F, DS, H, T, U, and V for the different sites. The mammalian fauna includes the papionine monkey *Paradolichopithecus arvernesis* (van der Geer & Sondaar, 2002), the raccoon dog *Nyctereutes megamastoides*, the badger *Meles thorali*, the scimitar-toothed cat cf. *Homotherium latidens*, the rhinoceros *Stephanorhinus* cf. *etruscus*, the gomphothere *Anancus arvernensis*, the southern mammoth *Mammuthus meridionalis*, the giraffid *Palaeotragus* cf. *inexspectatus*, the small Tegelen deer cf. *Metacervocerus rhenanus*, the antelope *Gazellospira torticornis*, and the large bovine *Leptobos* sp. (de Vos *et al*., 1997). Additional finds include two horse morphotypes: *Equus stenonis* and *Equus* sp. (Eisenmann, 2002), three species of gazelle (*Gazella aegaea*, *G.* cf. *bouvrainae*, and *G.* aff. *borbonica*) (Athanassiou, 2002), and birds. Furthermore, remains of the spur-thighed tortoise (*Testudo graeca*), and a giant tortoise (*Titanochelon* sp.) (de Lapparent de Broin, 2002) were also described.

The monkey of Vatera

Paradolichopithecus arvernensis is a large Old-World monkey. In morphology, it resembles macaques cranially but baboons postcranially (Szalay & Delson, 1979). Among the material thus far excavated at Vatera is a juvenile male mandible (van der Geer & Dermitzakis, 2008), an adult female mandible, an upper canine and, notably, several postcranial elements (van der Geer & Sondaar, 2002). This species is known from several European localities, including three in Greece (van der Geer & Sondaar, 2002; Kostopoulos *et al*., 2018; Sianis *et al*., 2023). However, significant insights into its postcranial morphology are provided by only two sites: Vatera and Valea Grăunceanului (Romania). The postcranial elements suggest that *Paradolichopithecus* was a highly terrestrial monkey, exhibiting a notable frequency of bipedalism in its daily locomotor behavior (Sondaar & van der Geer, 2002; Sondaar et al., 2006).

The giant tortoise of Vatera

A rare and exceptional find in the fauna of F-site is a sample of limb bones and osteoderms, which may belong to a single individual of a giant tortoise. The recovered skeletal elements represent a very large form with an estimated carapace length of approximately 186 cm, one of the largest individuals known in the fossil record (de Lapparent de Broin, 2002). Taxonomically, the giant tortoise from Vatera was originally referred to the species cf. *Cheirogaster* aff. *schafferi*. A recent revision of the fossil Testudines from Greek localities reclassified it to the genus *Titanochelon*, refraining from a species-level attribution (Vlachos, 2022). Given the current biochronological placement of F-site (see below), the Vatera form represents the last giant tortoise of Europe.

Palaeoenvironment and age

The presence of horses, a palaeotragine giraffe, and four bovid species indicates a relatively dry and open landscape. Additionally, the terrestrial characteristics observed in the postcranial elements of *Paradolichopithecus* further support

the idea of an open savanna /bushland environment. Based on the faunal composition the sites have been attributed to the biozone MN 17, or the Saint-Vallier Faunal Unit, or the Dafnero Faunal Unit (middle Villafranchian, earliest Pleistocene) (de Vos *et al*., 2002; Konidaris & Kostopoulos, 2024). However, the presence of two horse species is puzzling and may suggest that more than one faunal assemblage is represented at Vatera (Eisenmann, 2002).

Figure 1. Location of the fossil sites of the Vatera Formation

Conclusion and future work

Vatera is a key locality, because here the remains of two rare and puzzling creatures have been found together: the highly terrestrial macaque *Paradolichopithecus arvenensis* and the giant tortoise *Titanochelon sp.*, one of the largest tortoises in the world. Our future work will focus on reconstructing in detail (a) the stratigraphy of the Vatera sites, (b) the relation between the individual sites, and (c) the palaeoenvironment(s) of Vatera, in order to build a robust local biochronological–biostratigraphic scheme that can be integrated in the broader Eurasian context.

Acknowledgements

We are thankful to Michael Dermitzakis, Konstandinos Taxidis, John de Vos, Jan van der Made and the late Paul Sondaar for making the excavations and the research in Vatera possible.

EXTENDED ABSTRACT 199

Assessing the impact of climate change on olive cultivation in the Peloponnese, Greece: A long-term analysis using climate indices

P. Machaira[1,2], E. Kostopoulou[2], M. Gratsea[1], G. Kitsara[1], C. Giannakopoulos[1]

(1) Institute for Environmental Research and Sustainable Development, National Observatory of Athens, Greece, p.machaira@noa.gr (2) Department of Geography, University of Aegean, Greece

Introduction

Climate change is expected to significantly impact olive cultivation in the Peloponnese, through rising temperatures and decreasing rainfall. Additionally, geological processes, such as soil erosion and changes in hydrological conditions, may intensify the effects of climate change on olive trees. This study aims to evaluate the long-term impacts of climate change on olive cultivation in the region, utilizing climate indices related to temperature and rainfall patterns.

The Peloponnese, a key olive-producing area, is particularly vulnerable to the combination of future climatic changes and geological processes, which could disrupt olive cultivation. Rising temperatures and shifts in rainfall patterns are anticipated to affect flowering dates, irrigation needs, and overall production. Changes in hydrological conditions and soil erosion may negatively affect soil quality and water absorption, further stressing cultivation. The reduction in winter rainfall is expected to negatively impact on olive yields, while an increase in hot days may influence the phenology of olive trees, leading to higher irrigation requirements.

Moreover, climate change, along with increased CO_2 concentrations, is expected to have extensive impacts on olive cultivation. These changes will affect water availability and distribution, pest and disease occurrences, and overall socio-economic development. Key variables likely to be most affected include the duration of phenological stages, crop evapotranspiration, irrigation demands, and biomass growth and yield. These projected changes underscore the importance of adapting agricultural practices to the new climatological and geological conditions to ensure the sustainability of olive oil production in the region.

Material and Methods

Study Area

The Mediterranean has been identified as a climate change "hot-spot" and the impacts are expected to be particularly intense (IPCC, 2021). This specific area is warming 20% faster than the global average (MedECC, 2020). The olive tree (Olea europaea L.) is one of the most significant crops in the Mediterranean basin, which accounts for almost 95% of the global olive oil production. It also holds considerable importance in the Peloponnese region, representing approximately 40% of Greece's olive production. The Peloponnese features a predominantly Mediterranean climate, characterized by mild, wet winters and hot, dry summers. However, significant climatic variation occurs with altitude. Coastal areas experience milder conditions, while mountainous regions, such as Arcadia, have lower temperatures and higher rainfall. These altitudinal gradient influences local agricultural practices, including olive cultivation.

Climate data

For this study, a three-member GCM-RCM sub-ensemble from the Euro-Cordex database (Jacob *et al*., 2014), with a horizontal resolution of 0.11° was used for the study area (Table 1). Daily climate data, including precipitation and temperature, were obtained for three climate periods: historical (1971-2000), near future (2031-2060), and distant future (2071-2100). These data were evaluated under two future emission scenarios: RCP4.5 (a medium mitigation scenario) an RCP8.5 (a high emissions scenario without climate mitigation policies) (Moss *et al*., 2010). The model data were validated against observational data from local meteorological stations, confirming its suitability for this study

Table 1. Three-member GCM-RCM sub-ensemble from the Euro-Cordex database.

Climate indices

For the assessment of the impacts of climate change on olive cultivation, climatic indices based on temperature and precipitation were used. These indices were identified by agricultural sector scientists as appropriate for the olive sector within the framework of the MedGold project. The selection of these indices is in accordance with previous studies on the impact of climate change on olive cultivation in Mediterranean agricultural environments, such as research conducted in Andalusia (Gratsea *et al*., 2022). Specifically, the climatic indices used to assess the impacts of climate change on olive cultivation include the SPRTX index, which is related to the average maximum temperature during the spring months (April-May) and is considered the best indicator for the flowering period of olive trees, aiding in decisions regarding irrigation and management of the olive fruit fly (Perez-Lopez *et al.,* 2008). The SPR32 index, calculated as the number of days with Tmax >32° C in May and June, is linked to early flowering and increased pest and disease risk, providing crucial information for plant management and yield prediction (Ribeiro *et al.,* 2009). The SU38 and SU40 indices, representing the number of days with Tmax >38°C and Tmax >40°C, respectively, are associated with early olive ripening , influencing decisions on harvesting, pest control, and additional irrigation. Additionally, SU40 negatively affects the photosynthesis rate of olive trees (Garcia-Inza *et al.,* 2014). Finally, the WINRR index, which calculates total precipitation from October to May, is crucial for water availability and crop yield. Water deficits during winter and early spring have been shown to reduce yield, while also influencing soil management and long-term crop variety selection (Aissaoui *et al.,* 2016).

Results

Climate indices are essential for characterizing climate variability and investigating the impacts of climate change on olive crops. The effects of climate change on olive cultivation were assessed by analyzing the relationships between primary production, temperature, precipitation, and water availability. Water availability is critical before flowering, while temperature affects fruit development. High summer temperatures can damage fruit surfaces, accelerate ripening and affect overall yield. Climatic indices were calculated annually for three climate periods (historical period, near and distant future) under two emission scenarios (RCP4.5, RCP8.5), focusing on spatial distributions and mean differences. These simulations allow comparison of emission scenario impacts on olive crops and support future agricultural decisions.

Regarding the SPRTX index, it represents the average maximum temperature during spring (April–May), calculated as the mean of daily maximum temperatures between April 1 and May 31. It is a key indicator for olive tree flowering, linked to evapotranspiration and pest development. Warmer climates may accelerate flowering, potentially requiring new varieties or relocation to cooler areas. Higher temperatures will increase evapotranspiration, necessitating more irrigation. While pests and diseases may rise, the olive fly is expected to decrease. In the Peloponnese, the average increase for the near future is about 2°C for RCP4.5 and 3°C for RCP8.5, and for the distant future, 3°C and 5°C, respectively (Figure 1). Similar results were observed by Fraga et al. (2019) for the average temperature of the growing season in the Peloponnese.

Concerning the SPR32 index, it refers to the number of spring days (May and June) with Tmax >32° C. It is linked to early flowering, increasing the risk of pests and diseases (Ribeiro *et al.,* 2009). Rising temperatures will impact flowering and necessitate adjustments in cultivation practices. At temperatures above 35° C, stomatal closure hinders crop growth and productivity (Mavromatis *et al*., 2022). Adaptations such as improved soil management, pruning and increased irrigation during spring will be essential for olive cultivation. Based on the RCP8.5 scenario, the greatest increase in the number of spring days with Tmax >32° C is projected for the distant future (Figure 2), consistent with Mavromatis *et al*. (2022). Specifically, an additional 10 and 14 days with Tmax >32° C per year are projected for the near future under RCP4.5 and RCP8.5, respectively, and 12 and 24 days for the distant future.

The SU38 and SU40 indices represent the number of summer (June, July, August) days with Tmax >38° C and Tmax >40° C, respectively. They are calculated as the annual number of days exceeding these temperature thresholds. Increases in these indices are linked to earlier olive ripening (Garcia-Inza *et al.,* 2014). Notably, SU40 is associated with reduced photosynthetic capacity due to heat stress. Olive production is negatively affected by summer drought, as this is when fruit formation and growth occur (Mavromatis *et al*., 2022). Mitigation measures include adjusting harvest timing, pest control treatments and additional irrigation to support plant resilience. The number of summer days with maximum temperatures exceeding 38° C is expected to increase. The most significant rise is projected for the distant future under the RCP8.5 scenario (Figure 3). Specifically, for the near future, an additional 10 (RCP4.5) and 13 (RCP8.5) days per year are anticipated, while for the distant future, the increase is projected at approximately 15 (RCP4.5) and 40 (RCP8.5) additional days per year, mainly impacting coastal zones. Extreme heat stress, as indicated by the SU40 index, is projected to increase during summer months. The largest rise is expected under the RCP8.5 scenario in the distant future (Figure 4). Average increases for the near future are about 3 (RCP4.5) and 4 (RCP8.5) additional days per year, while for the distant future, the SU40 index is projected to rise by approximately 5 (RCP4.5) and 22 (RCP8.5) additional days annually. Similar to the SU38 index, these changes will primarily impact coastal areas.

Regarding the WINRR index, it refers to the total rainfall from October to May and is closely related to crop yield, as water availability is a crucial factor for the physiological activity of olive trees (Aissaoui *et al.,* 2016). Negative impacts of reduced winter rainfall include increased irrigation demands, decreased water availability due to prolonged droughts, changes in soil

fertility and higher risks of soil erosion associated with droughts and extreme precipitation variability. Projected reductions during winter and early spring are significant for decision-making related to crop yield, soil management and long-term changes in crop varieties (Gratsea *et al*., 2022). The WINRR index is projected to decline in both the near and distant future. The most significant reductions are expected on the western side of the Peloponnese, with largest decreases projected under the RCP8.5 scenario (Figure 5), consistent with Fraga *et al.* (2019). Specifically, for the near future, average reductions are estimated at 9% (RCP4.5) and 16% (RCP8.5). The greatest declines (>20%) are projected for southern-western Peloponnese (Messenia), while the north-eastern regions (Corinthia) may experience smaller reductions (5-10%).

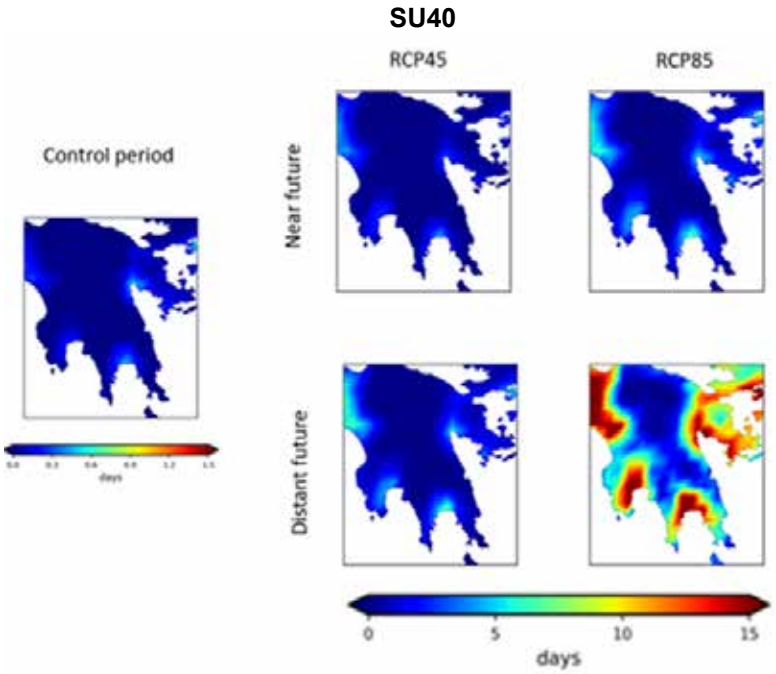

Figure 4. Absolute differences of the number of summer heat days (Tmax>40°C), between the reference period and the near or distant for two climate scenarios (RCP4.5, RCP8.5)

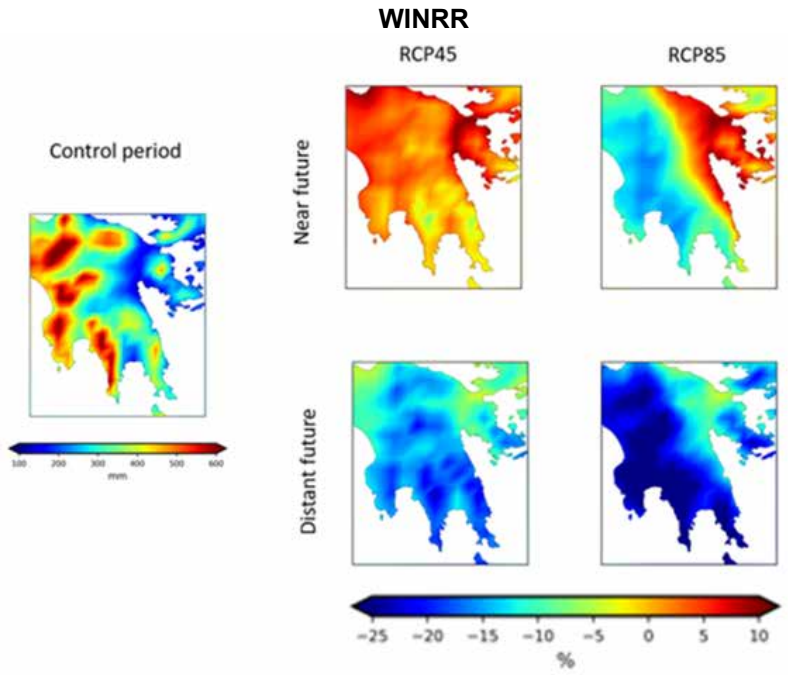

Figure 5. : Relative differences for total winter (Oct-May) precipitation, between the reference period and the near or distant for two climate scenarios (RCP4.5, RCP8.5)

Conclusions

The assessment of climate change impacts on olive cultivation in the Peloponnese, using adapted climate indices highlights significant future challenges. Temperature-related indices, SPRTX and SPR32, show projected increases, indicating accelerated flowering, particularly in coastal areas. Mitigation measures include introducing olive varieties with lower chilling requirements, relocating cultivation to cooler regions, enhancing irrigation and adopting soil conservation practices. Elevated summer temperatures, linked to the SU40 index, are expected to reduce fruit weight (Garcia-Inza *et al.,* 2014), and photosynthetic capacity, particularly in erosion-prone coastal areas, emphasizing the need for additional irrigation and land management strategies. The WINRR index, associated with winter precipitation, is crucial for olive yield. Projected reductions, exceeding 20% in the south-western Peloponnese, highlight the need for integrated water and soil management to sustain cultivation under evolving climatic and geological conditions. Based on these projections, the cultivation requirements of olive trees will change, requiring adaptation to future climate conditions. High temperatures are expected to negatively impact growth and, consequently, productivity. Adaptation strategies will include modifying cultivation practices and land management practices introducing olive varieties with lower chilling requirements or relocating production to cooler areas may become necessary. Water availability is critical during pre-flowering stages (Aissaoui et al., 2016), and reduced annual rainfall is expected to increase water demand. Effective management of soil fertility and optimized irrigation practices will be crucial for sustaining olive cultivation, ensuring both productivity and resilience under changing climatic conditions.

The overall impact of climate change on the expected yields of olive cultivation is expected to be negative, primarily due to rising temperatures and decreasing rainfall. Elevated temperatures are expected to cause heat stress on crops, negatively impacting their growth and development. Heatwaves can damage sensitive crops, reduce yields, and affect the quality of olive products. Additionally, climate change is likely to alter rainfall patterns, potentially leading to droughts and fluctuations in soil moisture levels, which will affect crop growth and irrigation needs. As a result, agricultural production is projected to decline, with an increased risk of diseases and pests. Moreover, the growing frequency and intensity of extreme weather events may cause significant damage to olive trees and their production. Consequently, climate change is expected to affect the dynamics of olive cultivation, with the projected yield losses leading to significant changes in the sector's economy across the Peloponnese, potentially resulting in social impacts.

Short-term adaptation strategies in olive cultivation aim to mitigate the immediate impacts of climate change. Improved water resource management through efficient irrigation systems, the implementation of early warning systems for diseases, and the adoption of sustainable agricultural practices contribute to maintaining productivity.

Additionally, farmers' access to climate information enables the adjustment of cultivation practices to changing conditions, enhancing the sector's sustainability. These strategies provide immediately applicable solutions which, in combination with long-term interventions, can significantly contribute to preserving the productivity and quality of olive production.

Introduction

Both the modern human-made and natural environment face numerous challenges and risks that have direct and indirect consequences on their sustainability and security. Climate change, combined with the accumulated pressures, ageing infrastructure, and the impact of natural hazards, contributes to the rising frequency of phenomena and events that demand effective and intelligent responses (Kyriou *et al.*, 2023). In this context, the need for a modern, multiparametric framework to monitor and provide up-to-date information on the pressures affecting both the environment and critical infrastructure led to the proposal and successful implementation of the research project, "PROION". The project was based on innovative technologies and methodologies that make use of the latest available infrastructure and development tools. From the perspective of optimal observation of critical infrastructure and the surrounding physical environment, the PROION project aimed to acquire, process, organise and make available measurement data both through the use of in-situ sensors and free satellite products that provide valuable information on the ground deformation, as well as the stability of critical infrastructure. Receiving co-funding from the European Union and the Greek Government, PROION (T2EDK-02396) was invited to implement its vision in the region of Achaia (Fig. 1), part of the Enceladus Hellenic Supersite (EHS).

Methodology

The three main study areas were, i) the building of the Department of Geology at the University of Patras campus, ii) the Asterion dam and iii) an active landslide that includes the boundaries of the mountainous settlement of Krini.

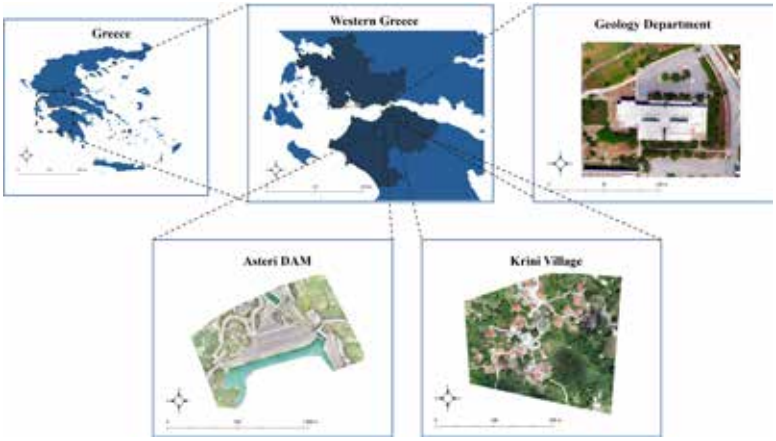

Figure 1. The three sites selected for monitoring in the framework of the PROION project.

In addition, in order to provide the best quality of the final ground displacement products, three SAR triangular aperture reflectors were designed, constructed and installed in the project study areas. For the observation of the study areas, SAR satellite data from the European Sentinel-1 space mission (Tsironi et al. 2022) as well as low-cost GNSS (Ganas *et al.*, 2024) in-situ sensors and accelerometers were used to record local micro-vibrations and seismic events in a timely and accurate manner (Nikolakopoulos *et al.*, 2023). With the acquisition of the multidimensional observations, the InSAR interferometry method was exploited to produce time-series of displacements with 6-12 days repeatability, while GNSS measurements were used to observe the 3-D change in the precise position of the ground and reflectors. In order to accurately render and observe the study areas, regular mapping of these areas was carried out using TLS and UAVs to produce point clouds of high geometric accuracy (Nikolakopoulos *et al.*, 2023). Subsequently, aiming to fully exploit the available information, fuzzy logic algorithms capable of adapting to the temporal behaviour of the observed points and ultimately achieving accurate predictions of their future position were developed. The following graphs (Fig. 2) illustrate the GNSS measurements of the Department of Geology station, acquired and processed for the period of July 2022 to December 2024.

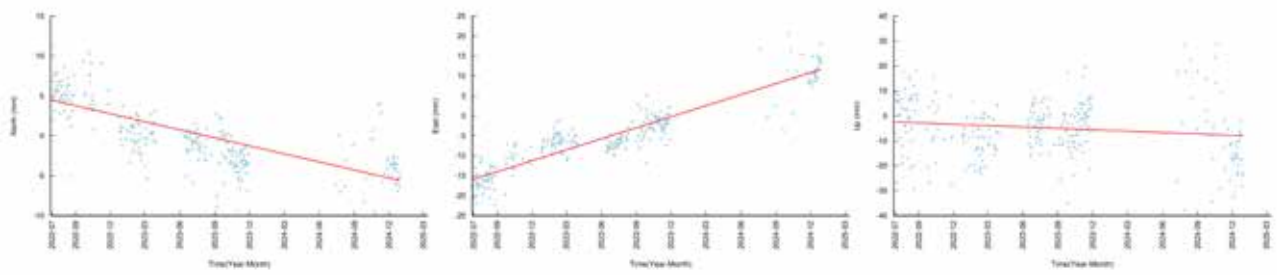

Figure 2. The GNSS measurements of the Department of Geology station from July 2022 to December 2024.

For the success of the overall system, a geospatial database was created both for the organisation and storage of the collected observations and for the subsequent retrieval of these through the compilation of complex spatio-temporal queries. The need for a powerful high-performance relational database led to the use of PostgreSQL with PostGIS software extension to manage spatial information and optimally retrieve it by applying specialised techniques such as spatial indexing (Ďuračiová *et al.*, 2018).

WebGIS platform

Subsequently, to offer an integrated framework for the disposal and visualisation of the generated data, a modern WebGIS platform for multiparametric monitoring was designed and implemented following the most advanced technological standards and specifications. Utilising cutting-edge technologies and modern libraries for the development of web-based geographic information systems, such as Mapbox GL JS, Deck GL, React JS, Chart. js, Flask, etc., a web platform capable of retrieving, managing and visualising spatially and diagrammatically the generated project data in an optimal and user-friendly way was developed. The platform was developed in Software-as-a-Service (SaaS) architectural standard (Capodiferro, *et al.*, 2024), offering easy access and interaction, also achieving easy maintenance and deployment both throughout the project and after its completion. Recognising the advantages of using 3D data visualisation methods for maximum understanding of the projected information, the Mapbox GL JS library was chosen (Zunino *et al.*, 2020), achieving the most complete 3D representation of the observed information through its direct correlation with the topography and morphology of the wider area (Fig. 3).

Figure 3. Illustration of the possibilities for end-user interaction and visualisation with the provided datasets in a cartographic environment. Coloured dots represent Copernicus SAR data (Sentinel-1 time series).

In addition, the platform offers tools for spatio-temporal analysis of longitudinal observations, geospatial data overlay as well as near real-time earthquake epicentres, achieving optimal monitoring of areas of high interest. Finally, in pursuit of a more complete user experience, the Deck GL library was exploited to represent cloud points within the cartographic environment, offering an additional dimension to the observation and understanding of the specific conditions governing each area and infrastructure of interest (Fig. 4), through direct spatial correlation with the ground deformation, geology and seismic phenomena that may occur within or near them.

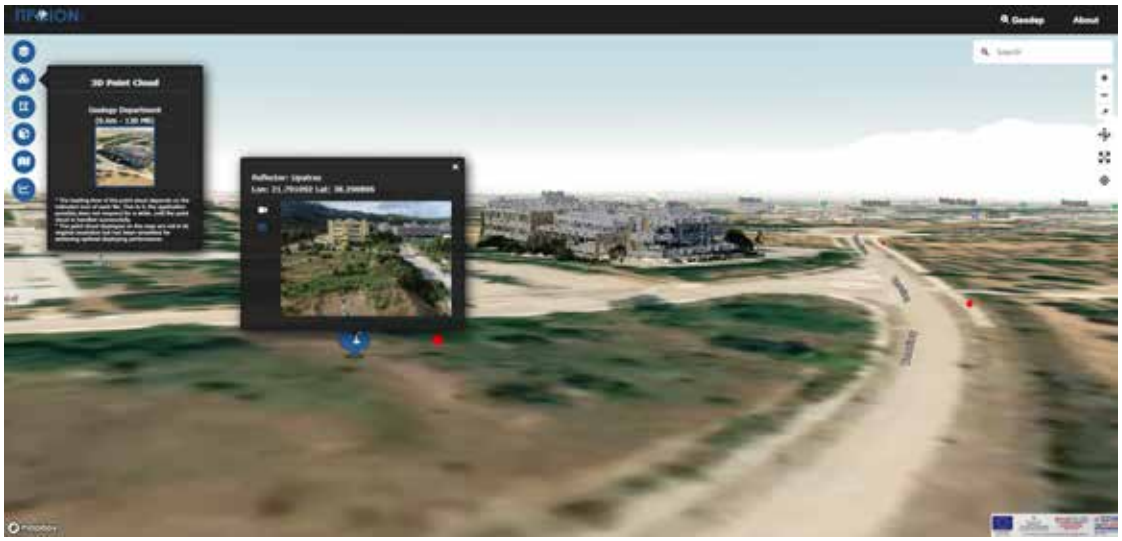

Figure 4. The point cloud of the Department of Geology on the 3D map environment.

Platform Accessibility and Future Prospects

The PROION's WebGIS platform, developed through this project, represents a significant advancement in presenting and analysing ground deformation data to end users. Considering the sensitive insights provided by the platform and the commercialisation of the overall product, the accessibility of the platform remains strict, allowing only authorised users to access the provided data. Therefore, interested parties are able to request access to an online demo of the platform by contacting the authors of the current publication directly via the provided e-mails. Furthermore, the platform shows strong potential for integration into future scientific research or operational monitoring systems, particularly in critical infrastructures and geohazard-prone regions. Its adaptability and scalability could support ongoing efforts in early warning and near-real-time infrastructure monitoring, while further integration of Machine Learning techniques has been explored to expand the current capabilities, aiming to serve as a supporting tool for data-driven decision-making.

Results and Conclusions

The successful implementation of the PROION project and the development of the WebGIS platform have resulted in the provision of a highly relevant system for the monitoring and evaluation of the longitudinal territorial behaviour and mobility of the areas of high interest. In conclusion, the continuous evolution of Remote Sensing and the creation of new and more powerful software technologies extend the possibilities of designing and implementing a sophisticated tool of higher performance and greater added value for the shielding of Greek territory.

Acknowledgements

This research has been co□financed by the European Regional Development Fund of the European Union and Greek national funds through the Operational Program Competitiveness, Entrepreneurship and Innovation, under the call RESEARCH – CREATE – INNOVATE (project code: T2EΔK-02396 Multiparametric monitoring platform with micro-sensors of eNceladus hellenIc supersite).

EXTENDED ABSTRACT 201

An example of DsGSDs in Abruzzo Region (Central Italy): the complex case of Civitella del Tronto

Mangifesta M.[1], Scalella G.[2], Sciarra N.[1]
(1) Science Department, University of Chieti-Pescara, 66100 Chieti, Italy, mmangifesta@unich.it
(2) Special Office for the Reconstruction-Earthquake 2016 Extraordinary Commissary, Bureau of the Council of Ministers, 00187 Rome, Italy

Abstract

Deep gravitational slope deformations (DsGSDs) are geological and engineering challenge with important implications for slope stability, reliability of existing infrastructures, land use and, above all, the safety of settlements. This work focuses on the DsGSD (Cappadonia *et. al.,* 2024) phenomenon that affects a large part of the Borrano hamlet, located in the municipality of Civitella del Tronto (Teramo, Abruzzo, Italy). In the area a monoclinal structure of the Laga Formation (Casero *et. al.* 2006) is present, with dips towards the north-east (Artoni, 2013). The terrigenous fill sediments were generated by turbiditic currents, creating characteristic stratified deposits. The deposits consist mainly of marly clays and clayey marls alternating with pelitic-arenaceous intervals with a thickness of about 1500 m. They are characterised by structures elongated in a north-south direction to the east of the main carbonate-covered fronts of the Central Apennine chain. This process is visible within the Teramo Flysch (Artoni, 2003), where two distinct lithostratigraphic units can be observed (figure 1):

- Arenaceous facies: the structural framework shows a trending monocline, with dips ranging from 38° to 60°. The arenaceous component increases the resistance to erosion, allowing these formations to define the geological subsoil.
- Pelitic facies: they are constituted by marly clays, with intercalations of thin layer arenaceous; the structural arrangement follows that of the predominantly arenaceous interval (higher stiffness), with the direction of the layers approximately N-N-E, but with extremely variable dip of the layers.

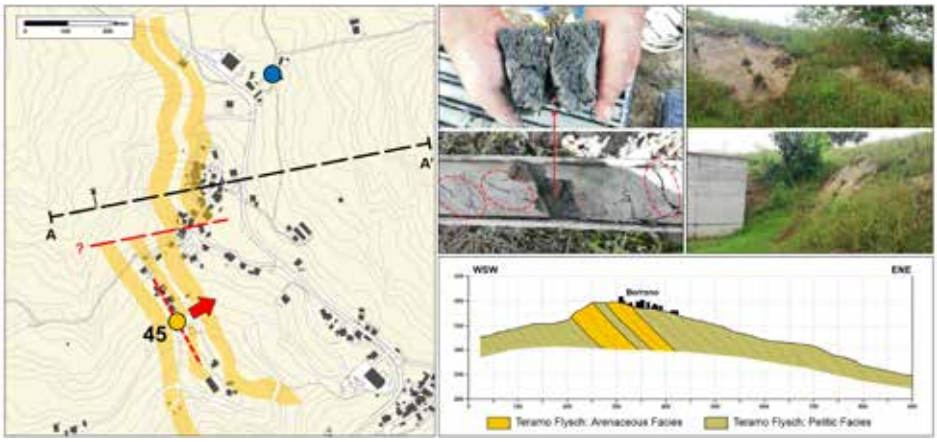

Figure 1. Detail of the Teramo Flysch in predominantly pelitic facies identified in the drill hole at depths of over 30 metres.

In the Borrano area, the identified landslides are of variable extension and mainly consist of slow movements of roto-translative type. The study of the area was carried out using aerial-photographs and Lidar data (Höfle *et al.,* 2011, Gaidzik *e. al.,* 2017) to identify shapes and structural features. The morphology of the terrain, shaped over time by geological processes, reflects the lithological nature of the materials present. The analysis showed that the slopes in the study area are dominated by values between 10° and 30°, with only a few local parts exceeding this range, and the energy of the survey is useful for identifying areas of greater erosion potential and instability. Following the seismic events of 2016/2017, the Borrano area was subjected to a detailed geognostic survey to evaluate slope stability and the vulnerability of existing structures. The damage observed to several local buildings and infrastructure raised significant concerns, indicating the presence of active or potentially reactivatable landslide movements triggered by further seismic or meteorological events. For this, the need arose for a continuous monitoring system capable of detecting any acceleration of the landslide phenomenon in real time and issuing timely warnings to the population to mitigate risk and ensure effective emergency response. A surface monitoring system, shown schematically in figure

2, was installed throughout the area, providing an integrated and technologically advanced system for detecting and analysing the site deformations.

Figure 2. Detail of the installation of the superficial monitoring instruments.

The geognostic survey was realized by boreholes and installed inclinometers and piezometers to a depth of 80 meters. The drilled material shows a complex stratigraphic sequence typical of geological contexts influenced by tectonic and depositional dynamics. The photo-interpretation study has shown a significant evolution of the area. Since the 2000s, it is evident that the entire built-up area was progressively affected by slope movement, indicating a state of activity over time. Significant deformations were identified by deep inclinometers. The image in figure 3 shows the inclinometric analysis (Allasia *et. al.*, 2020) carried out in the area, which provides a complete understanding of the dynamics of the system. It is possible to define a progressive intensification of movements, with significant displacements concentrated at very high depths, suggesting that the deep slip surfaces are active.

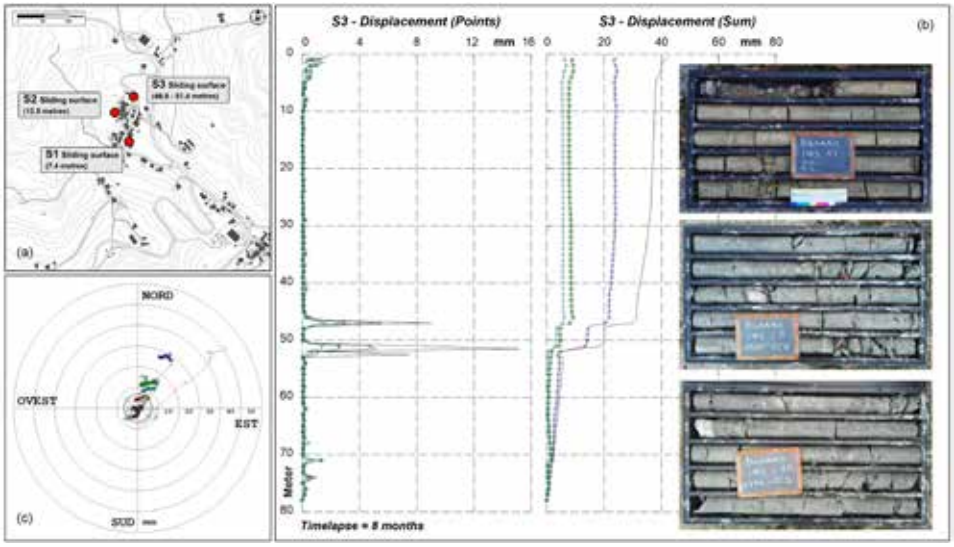

Figure 3. Detail of the inclinometric monitoring.

The successive numerical analyses (Borgatti, 2024) established a good correlation with the monitoring data, revealing in detail the instability of both local and territorial processes. A two-dimensional numerical analysis was carried out in the most critical part of the area to simulate the behaviour of the soil under different loading and saturation conditions. The model parameters (table 1) were calibrated using geognostic data obtained during the investigations, allowing the determination of deformations and stresses at different soil depths.

Table 1. Geotechnical parameters used in numerical analysis.

	Cover Layer	Subsoil	Weakness Planes
Unit weight	19.0 kN/m^3	20.0 kN/m^3	--
Friction angle (j′)	22°	24°	12°
Cohesion (c′)	10.0 kPa	100.0 kPa	0.0 kPa
Elastic modulus	0.01GPa	1.0 GPa	--

The map in figure 3b shows a zone of maximum displacement at the most superficial part, where the alteration cover with less mechanical properties encounters the more compact geological substrate. This transition zone may be affected by alteration, erosion or frictional forces that facilitate movement of the overlying material. At greater depths, secondary failure surfaces develop, which may result from fractures or structural deformation caused by tectonic forces or excessive increase pore pressure. These planes, although less visible on the surface, are critical to the stability of the overall system as they can determine the intensity and direction of deeper and more complex movements of large masses of material. In addition, the graph in figure 3c can be used to identify areas in critical condition where the applied stress exceeds the strength of the material along weakness planes, resulting in creep to failure.

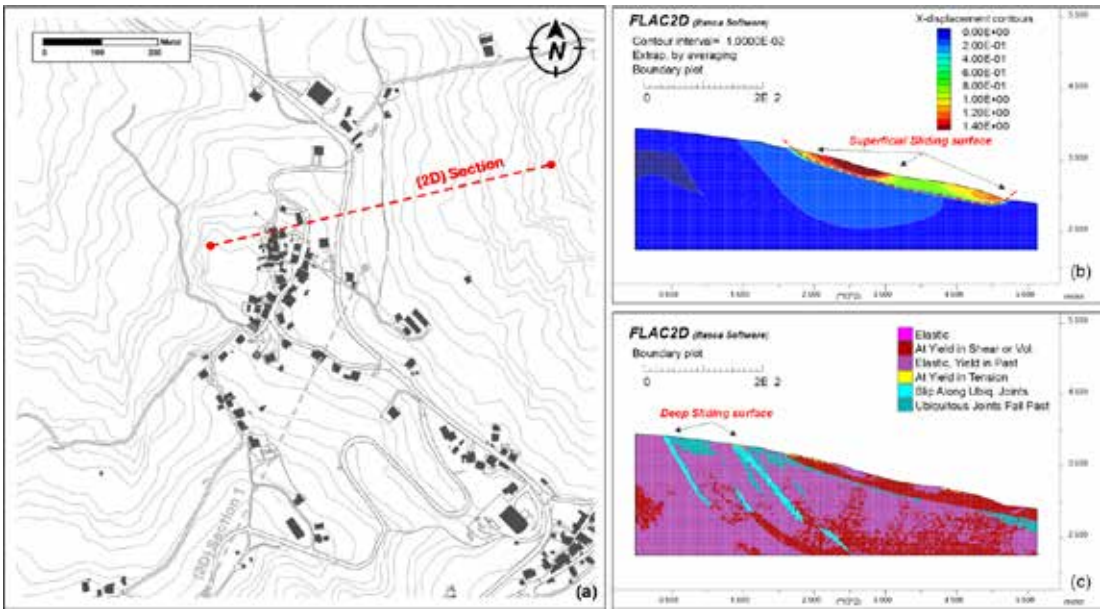

Figure 3. Two-Dimensional Numerical modelling of the section-2.

Because the extent of the potentially unstable area, a three-dimensional numerical model was developed to integrate all the available data and to represent in detail the stress-strain behaviour of the entire analysed area. The model was constructed by incorporating two fundamental components: the surface layers, identified in all the boreholes, and the substrate layer. Particular attention was paid to the modelling of the deep layers, by implementing a constitutive Ubiquitous Joint Plasticity Model (Yang, 1998), capable of describing in three dimensions both the overall mechanical behaviour of the mass (Mohr-Coulomb) and the internal planes of weakness (Zhou *et. al.,* 2018, Azadi *et. al.* 2024). In this specific case, these planes were schematized with a 45° inclination and a preferential north-north-east direction, in accordance with the stratigraphic and structural information obtained from the geological investigations. The mechanical parametrization and the definition of the boundary conditions followed the same criteria as in the two-dimensional model, to ensure consistency and comparability with the real conditions. The three-dimensional approach allowed a detailed analysis of the plastic deformations and their evolution on a local scale, highlighting that a significant part of the inhabited area is affected by widespread plastic deformations, indicating an active instability process. The map of SSI shear rate increments (figure 4) shows red areas of maximum deformation that are large, continuous and characterized by an elongated north-north-east trend. This configuration reflects the geometry of the fracture system and the assumed planes of weakness within the substrate, suggesting significant structural control over the way the ground deforms and slides. These planes of weakness act as stress concentration surfaces, promoting material movement along predefined directions. The results of the three-dimensional model (figure 4) also show good agreement with the real conditions. There is a good comparison with inclinometer measurements (fig. 3), both for deep deformations (inclinometer S3) and surface deformations (inclinometer S1).

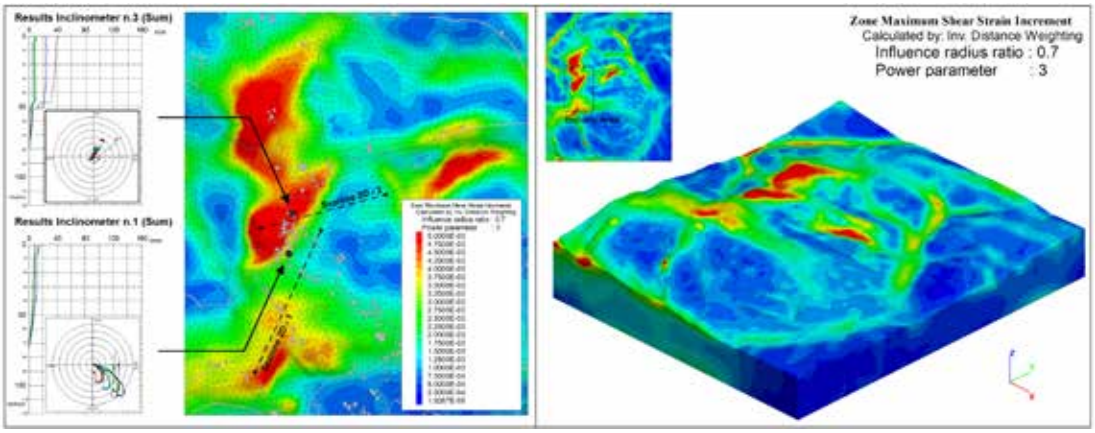

Figure 4. Three-Dimensional Numerical modelling: Shear Strain Increment map.

One crucial aspect is certainly the need to refine the hypotheses on the distribution of water saturation, a parameter that decisively influences the mechanical response of the materials and the local stability conditions. A better understanding of the spatial and temporal variations of saturation could significantly improve the predictive capacity of the models, especially in contexts characterized by intense rainfall or significant seasonal variations. In addition, the detailed study of the local responses of the weakening planes is another fundamental topic of investigation. A more accurate characterization of the geotechnical properties of these surfaces, such as residual shear strength or cohesion under partially saturated conditions, could allow a more realistic representation of the natural processes involved. This would be particularly relevant for improving predictions of surface instabilities, which are often more difficult to model due to their sensitivity to local parameters and variations in environmental conditions. The results of the study provide an essential basis for the development of strategies aimed at planning mitigation and/or relocation measures, which are crucial for the protection of infrastructure and the safety of local communities. The work also highlights the importance of integrated spatial planning, which can combine innovative detection technologies with traditional methods. This approach also makes it possible to optimize land management, making it more effective and sustainable, especially in geologically complex and vulnerable contexts.

EXTENDED ABSTRACT 202

The 'treasure' of aeolianites on the coastal front of Marathopoli Dialiskari, Messinia, Western Coast of the Peloponnese: rhizoliths petrified forest and historical abandoned quarries

Manoutsoglou Emmanouil

Technical University of Crete, School of Mineral Resources Engineering, University Campus, 73500 Akrotiri, Chania, Greece, emanoutsoglou@tuc.gr

Introduction

Aeolianites and rhizoliths are geological structures that occur rarely in spatially limited coastal areas along the coasts of our country (Moraiti & Alexopoulos, 2019; Manoutsoglou, 2022; Μανούτσογλου, 2023). Aeolianites and rhizoliths are associated with the action of natural factors, such as marine activity, wind and vegetation. As fossil dune deposits with carbonate cement mainly of Quaternary age, aeolianites provide key clues for understanding sea-level fluctuations from the Late Quaternary to the Holocene and the dynamic transport of sediments by wind in coastal environments. Since their characteristics are similar to those of recent coastal dunes, such as cross-bedded structures, sand-dominated grain size, and long parallel axes on the shore, these rocks provide records of both past coastal wind-driven dynamics and the complex interactions between aeolian and colluvial river depositional processes in coastal environments. Generally, the morphology of aeolianites reflects the marine dynamics of the region combined with wind direction and changes in climatic conditions during their deposition (Brooke, 2001). Similarly, rhizoliths record the geochemical interaction of soil roots with their environment, indicating the presence of plants and the environmental conditions that prevailed during their formation (Alonso-Zarza, 1999). The description and detailed study of rhizoliths in coastal aeolianites can provide crucial information on the paleoenvironmental conditions of the western coast of the Peloponnese, particularly in the Marathopoli – Dialiskari area (Municipality of Trifylia, Messinia). This study represents one of the first comprehensive attempts to document these features in the region, contributing to a broader understanding of the dynamics of Mediterranean coasts and the interaction between biological and sedimentary processes. While the aeolianites tell a story of natural processes, the historically abandoned quarries in the area, carved into these formations, speak of human ingenuity and resourcefulness. Historically, aeolianite deposits have been exploited as a source of building stone, particularly in coastal areas where other durable rock types are rare. The soft, flexible nature of freshly cut aeolianites makes it an ideal construction material, while its hardening over time ensures the durability of structures built from it. This work aims to highlight the significance of coastal aeolianite rhizoliths forest and abandoned quarries, which represent natural and historically technological 'treasures' for the broader region.

Geological outline

The SW Peloponnese, mainly Messinia, located in the western part of the Aegean arc system, represents one of the most tectonically and seismically active areas of the Africa-Eurasia collision zone. The topographic relief of the SW Peloponnese is characterized by the presence of several mountains and drainage basins with a trend mainly NW-SSE and E-W (Figure 1). The outer part of the western Peloponnese is dominated by extensional tectonics as expressed by the normal faults oriented E-W in its central-western part (Fountoulis *et al*., 2014). According to Αθανασάς (2010), typical marine sedimentation in the submarine areas of Western Messinia seems to start in the Lower Pliocene with a large surface spread. It consists mainly of sandstone formations whose thickness varies. They mainly occupy the plateau between the Pylos-Gargaliannoi-Filiatra heights in the west and the Kyparissia Mountains in the east. They also occur in isolated locations south of Pylos. However, disagreement exists regarding the partial division of the sand-margin formations into Pliocene and Pleistocene. Older stratigraphic studies of the area indicate that this sedimentation began in the Lower Pliocene and became generalized in the Upper Pliocene. Marine deposits consist of calcitic sandstones, marly sandstones, marls and conglomerates of different thicknesses from place to place. Φυτρολάκης (1980) in the geological map (Koroni – Pylos – Skhiza Sheet) considers the calcitic sandstones in the area north of the Romanos to be of Tyrrhenian age, while Αντωνίου και Φυτρολάκης (1988) recognize within the calcareous sandstones of the Petrochori-Romanos coastal front both the aeolian and marine phases and relate them to eustatic events of the Late Pleistocene (Eu- and Neo- Tyrrhenian). Terrestrial deposits consist mainly of conglomerates, red-coloured siliceous sands and sandstones. The multi-coloured sandstones above the marine post-alpine deposits are likely from the Middle and Upper Pleistocene.

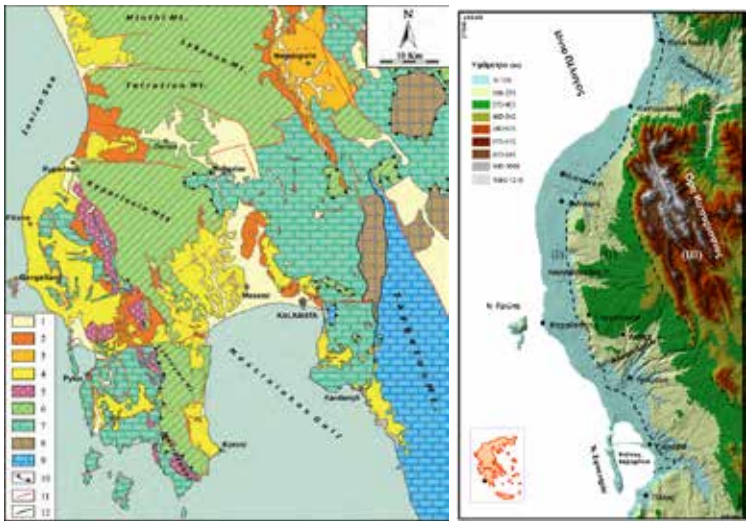

Figure 1. Left, Map depicting the geotectonic units and the post-Alpine deposits of the study area. 1: Holocene deposits; 2: continental deposits; 3: lacustrine deposits; 4: marine deposits; 5: conglomerates of Messinia (molasse); 6: Pindos Unit; 7: Gavrovo-Tripolis Unit; 8: Arna Unit (Phyllites-Quartzites); 9: Mani Unit; 10: thrust; 11: fault zone; 12: detachment fault zone [from Fountoulis et al., 2014]. Right, Three-dimensional visualization of the study area in Western Messinia using ArcGIS. Three basic physical geographical units are distinguished. A smooth surface west of the locations Gialova-Gargalianoi-Filiatra (I), a second, equally smooth but of higher altitudeseast of the previous one (II), which is interrupted by a third even further east that includes the Kyparissia Mountains (III). The altitudes are provided as a graduated color scale every 135 m. The coordinates (top left and bottom right) are given in the EGSA '87 system (from Athanasas, 2010). The study area is in the red boxes.

Sandstones appear in a relatively narrow coastal zone of 50-100 meters that starts north of the Bay of Navarino and extends up to Kyparrissia. Within these sandstones, aeolian deposits were found over a length of approximately two kilometres, spanning from the area north of Marathopolis to the south of Dialiskari. Numerous sites featuring extensive occurrences of rhizoliths were identified within these aeolianites, confirming the presence of a fossilized rhizolith forest in the region. In addition, four abandoned historical quarries were identified nearby, along with the well-known historical salt pan at Dialiskari.

Objectives

According to Brooke (2001), Aeolianite is a type of limestone found in coastal areas, demonstrating the reworking of vast amounts of carbonate sediments of biogenic origin from shallow marine environments into coastal sand dunes. Most aeolianites are calcareous sandstones originating from the biogenic carbonate sediments of shallow marine environments formed through the diagenesis of coastal sand dunes. The cementation of Quaternary-period dunes is the primary source of the aeolianites observed today in numerous island regions of both the northern and southern hemispheres. Most aeolianites consist of multiple generations of older dunes that have undergone diagenesis. When these dunes are cemented (lithified), they preserve the structures imparted by aeolian processes, often retaining their cross-bedded, parabolic, or barchanoid forms. While aeolianites are typical sedimentary deposits of the Quaternary period, instances of Paleozoic and Mesozoic carbonate aeolianites have also been documented (Brooke, 2001). Segments of sand dunes have been identified as distinct due to their association with well-developed paleosols, correlating with sea-level changes driven by glacial cycles. Geochronological records of extensive aeolianite deposits in both hemispheres indicate that eustatic sea-level changes largely controlled the timing of large-scale coastal carbonate dune formations. For an extended period, interpretations of coastal carbonate dunes were limited to their formation during glacial periods, with the majority dating to the Late Tertiary and Quaternary periods. Recent discoveries of aeolianites from interglacial periods challenge the belief that aeolianite formations are exclusive to glacial periods. Instead, these findings highlight the impact of large sea-level fluctuations, which reflect the cyclical growth and melting of continental ice sheets (Frébourg *et al*., 2008).

In the studied region, aeolianites are extensively developed in a relatively narrow coastal zone of 50-100 meters over a length of approximately two kilometres, spanning from the area north of Marathopolis to the south of Dialiskari. These deposits exhibit prominent and distinctive cross-bedding and served historically as a source of quarry material. The study of ancient quarries has evolved from a historical focus in the 19th century to a multidisciplinary field involving archaeologists, geologists, and engineers. Initially perceived as secondary production sites, quarries gained importance with the realization that their technical and economic aspects were crucial to understanding ancient construction. The late 20th century saw systematic excavation methods and geochemical analyses enhancing research. Today, quarry studies integrate archaeological surveys, geological

mapping, and digital tools, providing insights into ancient economies and craftsmanship. Despite challenges, interest persists in medieval quarries, revealing their cultural and economic significance (Lamesa *et al*., 2021). The historical abandoned quarries described for the first time in this work in the area are not registered in the databases and catalogues of historical quarries in Greece (Κουκουβού, 2010; Κοκκορού-Αλευρά κ.α., 2014; Τσιλιγκάκη, 2014). The only historical abandoned quarry in the area has been recorded in the corpus of ancient quarries with number 713. ‘’location: Pylos, Dialiskari-Marathoupoli”. At the same location (Figure 2), a possible salt marsh has been described from the first excavations of the Swedish archaeological mission about a century ago in the area: “..On the rock they have carved half a meter above the sea a 6mx3m. On two sides a groove allows the tank to communicate with the sea. It is probably a salt marsh..” (Valmin, 1930).

Figure 2. Left is the place where the ancient salt lake was built. On the right, you can still see the excavation of the seawater supply channel.

The first quarry that bears traces of recent exploitation (Figure 3) is the largest in dimensions and is located north of Marathopolis, where the coastal aeolianites have the greatest width and width in front of the coast, exceeding one hundred meters. What is left is an abandoned ancient quarry with rugged and uneven terrain filled with large rocks and boulders. The quarry is surrounded by steep, weathered rock walls, which appear eroded over time. There are no exploitation levels, only a front located on the east side, as opposed to the coastal front located on the west side of the site. The quarry’s remnants highlight the historical stone extraction, possibly for construction or other purposes, with evidence of human intervention still visible in the surrounding formations.

Figure 3. The first and largest abandoned quarry is located north of Marathopolis.

The second quarry (Figure 4) is located about 500 meters south of the Church of Agios Nikolaos, which was built in the small bay of Dialiskari. The second quarry is an abandoned ancient quarry with visible layers of stone extraction. The quarry’s rock face is marked by precisely cut, rectangular sections, indicating past human activity and extraction methods. The ground appears rugged and uneven, strewn with smaller rocks and debris, characteristic of a long-abandoned excavation site. On the right, the image displays visible wedge marks on the rock surface, indicating the stone extraction techniques used in antiquity. These wedge marks appear as small, evenly spaced holes or indentations, likely created by inserting wooden or metal wedges to split the stone. Over time, natural weathering and erosion have partially obscured some of these marks, but their distinct pattern remains visible. The presence of these wedge marks provides valuable insight into the methods employed by ancient quarry workers to extract large stone blocks for construction and other purposes.

Figure 4. Left, the second abandoned quarry is located about 500 meters south of the Church of Agios Nikolaos, which was built in the small bay of Dialiskari; on the right, traces of wasps associated with the method of exploitation.

The third quarry is located next to Barlas beach, 4 km from Marathopoli (Figure 5) and is approximately 10 m above sea level. The colour of the aeolianites without containing layers of paleo-soil is red. However, the colour of the extracted material is uniform throughout the quarry. The surface of the rocky aeolianites shows distinct cutting marks and stepped formations, indicating systematic quarrying techniques. The surrounding area consists of weathered stone with patches of sand and small debris. The layout of the quarry suggests that it was used for the quarrying of large stones, with clear signs of chiselling and splitting methods. Throughout the quarry surface, there are characteristic residual cut marks and grooves indicating wedging techniques, where wooden or metal wedges were inserted into pre-cut grooves to split the stone. These grooves, often arranged in parallel, herringbone, or lattice patterns, suggest a systematic technique in stone quarrying. In addition, the presence of tool marks, such as chisel marks and wedge holes, provides valuable information about the methods used by ancient workers to extract large stones with precision. The creation of stepped steps during quarrying suggests an excavation process preserved to this day, where successive layers of stone were removed. The surrounding environment, with scattered debris and partially worked boulders, reflects the operational phases of the quarry, from initial extraction to preparation for transport. The erosion and weathering of the exposed rock faces suggest that the quarry has been abandoned for a long time. The 1 m wooden stick has been placed on the surface for scale reference.

Figure 5. The third quarry is located by Barlas Beach, 4 kilometres from Marathopoli. On the right, the image shows a close-up view of an abandoned ancient quarry with clear signs of quarrying activity. The rock face exhibits distinct vertical and horizontal tool marks, likely created using chisels and wedges to extract stone blocks. The marks are characterized by parallel grooves and stepped formations, which indicate a systematic quarrying process used to detach large stone blocks from the bedrock.

Comparing the image with documentation and visual records from ancient quarries, the quarrying methods shown here are consistent with those used in classical antiquity. In this era, a combination of hand tools and water-based wedge techniques was employed to split the rock along desired lines. These techniques allowed for the efficient production of stone blocks for construction purposes, such as temples, fortifications, and public buildings.

As well as building material mined in many places, the aeolianite formations along the Marathopoli – Dialiskari coastline exhibit well-preserved examples of fossilized root structures, i.e. rhizoliths, indicative of ancient dune stabilization by vegetation. These features were mapped and analyzed to determine their spatial distribution and morphological characteristics. The fossilized roots appear as vertical to sub-vertical tubular structures, often branching, which are associated with paleo-vegetation that thrives under specific climatic and geomorphic conditions. Rhizoliths, formed by the mineralization of root systems, were observed in association with paleosol layers within the aeolianite sequence, reflecting periods of dune stability and soil development. Klappa (1980) identified five primary types of rhizoliths: (1) root molds, which are tubular cavities left by roots that no longer exist; (2) root casts, formed by the infilling of root molds with sediment and/or cement; (3) root tubules, which are cemented cylindrical structures surrounding root molds; (4) rhizocretions, representing pedo diagenetic mineral accumulations around plant roots; and (5) root petrifactions, involving the mineral impregnation or replacement of organic material, preserving root anatomical features either wholly or partially.

Dozens of rhizoliths were counted in a relatively small area of a few hundred square meters. The first rhizoliths in the area were found within the first quarry north of Marathopolis. The second place is located in Dialiskari (Figure 6). Rhizoliths are visible as irregular, branching grooves and cavities, creating a rugged and porous texture across the terrain. Like many other fossils in the study area, rhizoliths in full development can be observed on aeolianite surfaces formed by marine erosion. The erosion has exposed these rhizoliths, revealing their complex network, which likely developed through the gradual dissolution of sandstone. The excellent preservation of a multitude of roots of various sizes indicates that most rhizoliths in the study area possess greater resistance to marine mechanical erosion compared to the surrounding aeolianites. This observation serves as an initial indication that the majority of the rhizoliths are not mere “root casts” but are very likely mineralized, fossilized roots. If they were simply root casts filled with the surrounding sediment of the aeolianites, they would not have withstood marine mechanical erosion. Detailed mapping has revealed that the distribution of rhizoliths corresponds to distinct stratigraphic horizons, suggesting episodic phases of vegetation growth and sediment stabilization. These intervals are interspersed with layers of reworked aeolian sands, indicative of dune reactivation during climatic aridity or increased wind intensity. The stratigraphic position of the rhizoliths provides a valuable framework for reconstructing the paleoecological and climatic history of the region.

Figure 6. Extensive surface with rhizoliths within the quarry at the Dialiskari location. The settlement and the bay are clearly visible.

Apart from the root system, they were distinguished by positions and remains of fossilized tree trunks (Figure 7). The fossilized tree trunks exhibit significant erosion, with their surfaces marked by deep grooves and cavities resulting from prolonged exposure to marine erosion. Despite the wear, the cylindrical shape and woody texture remain discernible, indicating their origin as tree trunks. The size and orientation of these trunks suggest they were once part of a forested landscape, subsequently buried and preserved through geological processes. Surrounding and connected to the fossilized trunks are rhizoliths.

Figure 7. The provided images depict heavily eroded fossilized tree trunks accompanied by rhizoliths, showcasing the intricate interplay between ancient vegetation and sedimentary processes.

Rhizoliths occur and spread on the flat erosional surfaces of aeolianites (Figure 8 and Figure 9). At the same time, they start from the underlying paleosoil that appears by position. The various rhizoliths differ in size (length, diameter, branching, etc.). Mega-rhizoliths and biokarst dissolution pipes were recognized.

Figure 8. A coastal landscape is characterized by a dense network of rhizoliths and mineralized root structures formed through the diagenetic processes of ancient vegetation. These rhizoliths are visible as elongated, branching, and interconnected features across the eroded limestone surface.

Figure 9. A more detailed look at the rhizolith structures reveals intricate branching patterns with visible root voids and mineralized traces. The rhizoliths exhibit a well-preserved morphology, retaining their cylindrical and tapered shapes

Conclusions

The coexistence of rhizoliths and historical abandoned quarries within aeolianites presents an intriguing juxtaposition: on the one hand, fossilized roots offer a glimpse into ancient ecosystems shaped by natural forces; on the other, quarries stand as monuments to human adaptation and transformation of the landscape. These elements underscore the dynamic relationship between nature and culture, revealing how landscapes evolve under the combined influence of environmental change and human activity. Studying this intersection enhances our understanding of past environments and societies and has contemporary relevance. Understanding how ancient communities adapted to their environments can offer valuable lessons as we face ongoing climate change and increasing pressure on natural resources.

Introduction

Samaria gorge National Parks is located at the White Mountains mass, at the southwestern part of Crete (Figure 1). It is one of the most significant geomorphological structures in the Mediterranean region globally recognized by numerous international distinctions: 1) UNESCO Man and the Biosphere Reserve, 2) European Diploma of Protected Areas, awarded by the Council of Europe, 3) European Biogenetic Reserve of the Council of Europe, 4) Important Bird Areas by the Birdlife international, 5) NATURA 2000 protected area, under code GR4340014 (Zone of Special Protection: ZSP). The wider area of White Mountains belongs to the Natura 2000 European Network of Protected Areas (under code GR4340008H) and it is certified as a Place of Universal Importance (PUI).

Among geophysical methods, electrical resistivity tomography (ERT) has become a valuable tool for imaging seawater intrusion due to its low cost in combination with the effectiveness and quick interpretation. Automated data collection using multi-electrode resistivity surveying instruments, made the electrical tomography ERT method one of the most widely used geophysical methods for near-surface investigations. Fast acquisition 3D data instruments and inversion algorithms enhance the reliability of the method (Hamdan and Vafidis, 2009).

This study employs the ERT and seismic tomography geophysical methods for sea water intrusion imaging and monitoring at Samaria gorge. The geophysical survey conducted in the National Park of Samaria gorge employed the 3D ERT method which is more efficient due to the 3D nature of this geological structure. Dipole-dipole and gradient arrays were chosen to detect both lateral and vertical resistivity variations.

Geological setting

Crete located just over the active subduction zone of the eastern Mediterranean oceanic plate beneath the Eurasian one, exhibits a gradual uplift and complicated active tectonics (Pavlaki and Perleros, 2015; Manoutsoglou, et al., 2022) The Alpine tectonostratigraphic regime indicates compression tectonics, such as folding. The major tectonic units of Crete (stratigraphically from the lower to the upper one) are:

i) Plattenkalk Group (para-autochthonous),
ii) Phyllite Nappe,
iii) Tripolis Nappe,
iv) Pindos Nappe and
v) Uppermost Nappe.

Various lithological formations, composing these nappes, tectonically overlie different parts of the Plattenkalk Group formations. Plattenkalk Group is predominantly structured by HP/LT affected metamorphic rocks. Furthermore, the Ravdoucha (slate-carbonate) beds tectonically overlie the dynamo-metamorphic sequence in different parts of Western Crete, constituting the lower part of Tripolis Zone, while its upper part includes the carbonate sequence and flysch.

Considering the model relating geological processes and geomorphological features, the following remarks arise for the Samaria gorge area:

1. The entire region is a part of mega structure, consisting of metamorphic unsorted stromatolite limestones (Mt Gigilos). On either side of this mountain, the dip direction of the formations is differentiated, maintaining the same NNE-SSW striking and indicating that Mt Gigilos is a tectonic window.
2. The Trypali Unit occurs at the southwestern part of Samaria gorge according to field observations (Figure 1c).
3. The formations inclination is directly associated with the tectonic processes and the geomorphological evolution of the region.
4. The phyllites and slates (Gigilos formation) are characterized by medium dip angles and smooth relief. On the contrary, the meta-carbonate formations with cherts of Plattenkalk Group are accompanied by high (up to vertical) dip angles. These formations exhibit sharp slopes with height up to 300 m in some locations on both sides of the stream that crosses Samaria gorge.
5. Overall, Samaria gorge constitutes a typical catchment area, in which the surface runoff is favored at the northern part, due to outcropping lithological formations, while the underground one is favored at the southern part.

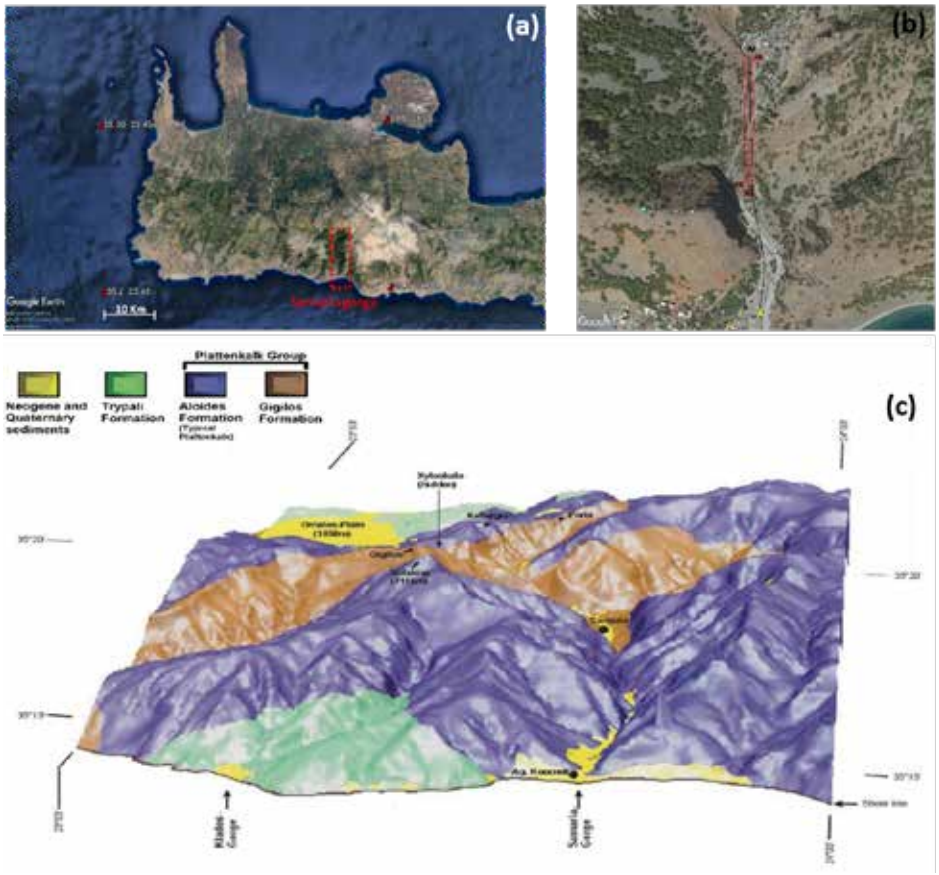

Figure 1. (a) Aerial photograph of Western Crete indicating in red dotted box the Samaria gorge area, (b) South portion of Samaria gorge wherein red are the geophysical lines and (c) the geological model for the wider region of Samaria gorge (modified from Manoutsoglou, et al., 2001).

Electrical tomography survey

The electrical tomography survey scanned the Samaria gorge area during four periods (October 2022, September 2023, June 2024 and October 2024) with 2 ERT lines and a grid (900 m x 30 m) consisting of 4 lines (A0, A1, A2 and A3 from east to west) to inspect seawater intrusion at different time periods. ERT data were acquired using Dipole-Dipole and Gradient arrays and 21 electrodes. The electrode spacing ranges from 10m to 45m. Apparent resistivity data were collected with a 10-channel SYSCAL Pro Switch™, IRIS Instruments system at 19-30 depth levels per line. Resistivity data were processed using the RES2Dinv™ software. Outliers from the original 2D data were removed by trimming data which contributed to high errors. Trimmed data were used for 3D inversion using both the RES3Dinv™ and EarthImager3D™ software packages resulting to a volume of electrical resistivity for the surveyed grid.

The inversion technique gives reasonably accurate images of three-dimensional structures, enabling the 3D imaging of the subsurface using cost–effective 2D electric tomography techniques (Dahlin and Loke, 1997). Since the inversion results deduced from 2 different software packages were similar, the EarthImager3D™ software was utilized for the visualization of 3D data.

The geoelectrical sections (Fig. 2) and the 3D geoelectrical model (Fig. 3) exhibit a lower resistivity zone with resistivity values between 5-40 Ohm.m attributed to sea water intrusion. The geoelectric section along Line A1, acquired during 2022 (Fig. 2a), exhibits lower resistivity values in this zone indicating that the seawater intrusion front extents to more than 650 m from the beginning of the line. Comparing the geoelectrical section Line A1 with the one acquired during 2023, (Fig.2b), the lower resistivity zone is reduced to approximately 600 m from the beginning of the 2023 lines. Finally, the geophysical survey of 2024 (June and October, Fig.2c-d) has shown that the sea water intrusion front is withdrawn to 550m of line A1 on June (Fig.2c), while on October, extents again to more than 650 m from the beginning of the line. The absolute altitude of the sea water intrusion front in the hinterland ranges from -50 to -120 meters.

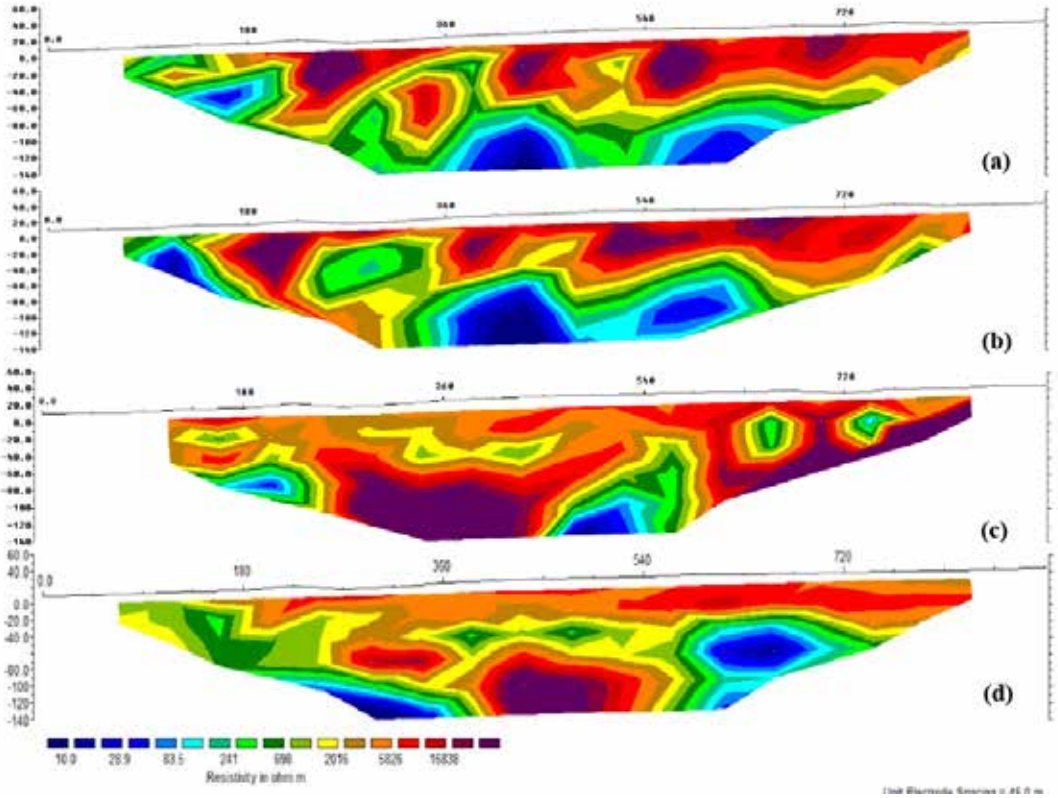

Figure 2. 2D geoelectrical sections along Line A1 surveyed using Gradient electrode array. Data collected during (a) 2022, (b) 2023 and (c-d) 2024 survey (June and October, respectively).

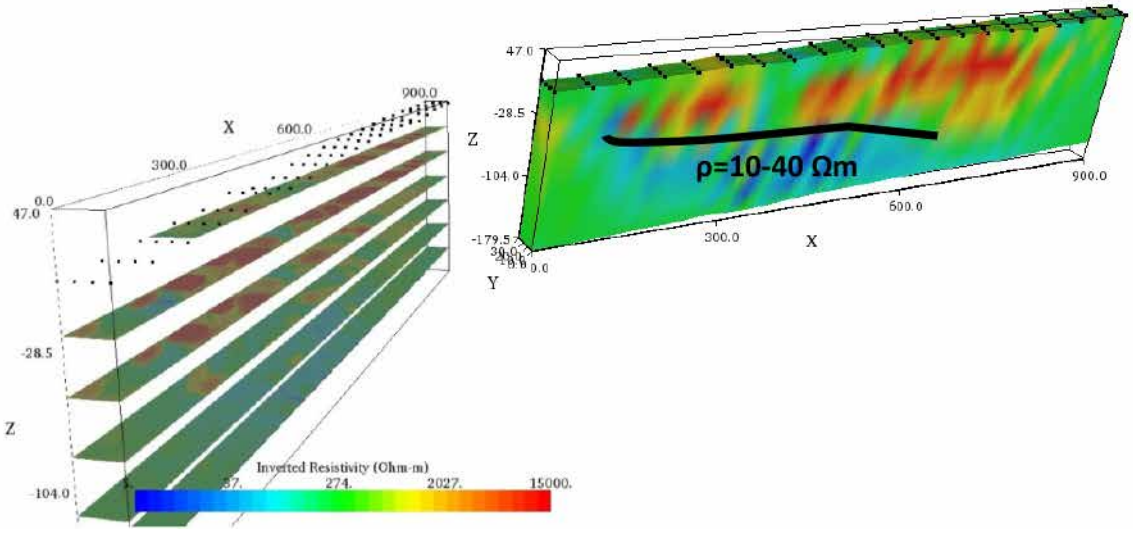

Figure 3. (a) 3D resistivity model (c) Horizontal slices from 3D model for the grid scanned during the 2023 survey.

Seismic tomography survey

The seismic refraction tomography (SRT) survey was conducted at Samaria gorge area during two periods (June and October of 2024) with 2 lines at different positions along ERT line A1. The main target of SRT survey was to delineate the interface between the alluvial deposits and the carbonate bedrock, as well as to estimate the depth to the healthy (unfractured) limestone (with Vp ≥ 3500m/s). SRT data were acquired using 24 geophones in 5m spacing and an 8gk sledgehammer as seismic source. The seismic section acquired on June of 2024 shown that alluvial deposits do not

exceed the thickness of 3-4m, while the fractured limestone appears up to the depth of 20m at the northern part of the section (Fig. 4).

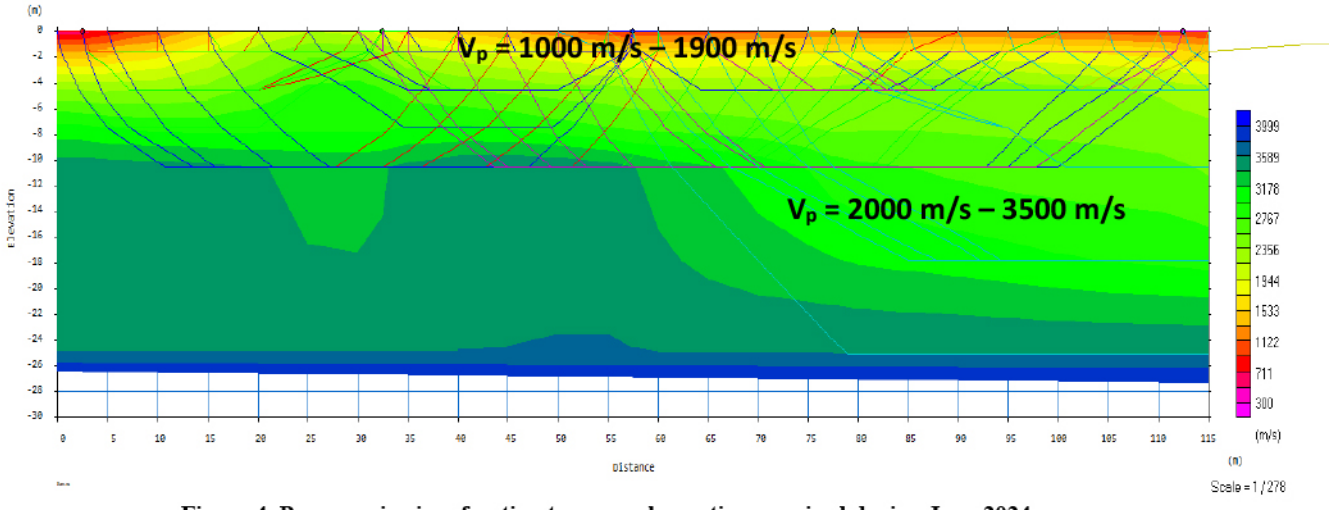

Figure 4. P-wave seismic refraction tomography section acquired during June 2024 survey.

Conclusions

A geophysical survey conducted during two periods namely 2022 and 2023 in the National Park of Samaria gorge employed the ERT method and dipole-dipole and gradient arrays to image the intrusion of sea water whose front appeared at 600 m from the beginning of the scanned lines during the 2023 survey and more than 650 m from the beginning of the scanned lines during the 2022 survey. The geophysical survey of 2024 (June and October) has shown that the sea water intrusion front was withdrawn to 550m of line A1 on June, while on October, extended again to more than 650 m from the beginning of the same line. This rapid change between June and October 2024 can be explained by the fact that infiltration of seawater into the hinterland is performed through the existing faults of the studied area.

Introduction

On July 9, 1956, two earthquakes struck in the central Aegean Sea (Perissoratis and Papadopoulos, 1999; Okal et al., 2009; Friederich et al., 2014; Brüstle et al., 2014)in Greece and adjacent regions, constitute the most tsunamigenic areas in Europe. The most recent large tsunami was a 20 m high wave that generated on 9 July 1956 in the Amorgos Basin, South Aegean Sea, in association with a M(s. The first earthquake had a magnitude of Ms = 7.4 and was located SE of Amorgos Is. (Fig 1) and occurred at 25 km depth. The second earthquake, M_S= 7.2 occurred just 13 min later close to Anafi Is. at more than 100 km depth. The tsunami that followed reached run-up heights of up to 30 meters along the southern coast of Amorgos marking the highest run-up value in the 20th century in the Mediterranean Basin (Soloviev et al., 2000). Detailed investigation of the run-up values along the Cyclades, Crete, Dodecanese Islands and the Turkish shoreline and propagation modeling by Okal et al. (2009) showed that the tsunami can't be explained by the co-seismic fault-rupture alone. These authors suggested that submarine landslide(s) must have been triggered by the earthquake(s) and contributed to the generation of the tsunami.

The sea floor between Amorgos and Astypalaia Islands is underlain by thick sediments, primarily due to the deposition of slumps debris and mass flows, which mostly consist of fine sand and silt, with occasional coarse sand present (Perissoratis and Papadopoulos, 1999; Tsampouraki-Kraounaki et al., 2021)in Greece and adjacent regions, constitute the most tsunamigenic areas in Europe. The most recent large tsunami was a 20 m high wave that generated on 9 July 1956 in the Amorgos Basin, South Aegean Sea, in association with a M(s. Sakellariou et al. (2021) and Manta et al. (2022) have shown high-resolution seafloor mapping, sub-bottom profiling, and sediment coring descriptions, which provide clear evidence of recent mass transport deposits below the seafloor in the area triggered by the 1956 earthquake(s).

This study provides new sedimentological and geochemical evidence derived from two gravity cores collected south of Amorgos and Anafi Islands, respectively, which confirm the occurrence of submarine landslide deposits linked to the 1956 earthquake(s). The 1956 Mass Transport Deposits (MTDs) vary in thickness from 55 to 100 cm. They are characterized by a gray color, calcite dilution, higher gamma density values, a terrestrial origin, sharp boundaries, and a mixture of cohesive and non-cohesive flows. Additionally, they contain lower amounts of phosphorus (P), calcium (Ca), magnesium (Mg), cobalt (Co), chromium (Cr), iodine (I), manganese (Mn), nickel (Ni), and strontium (Sr). The differences in sedimentological characteristics of the MTDs are attributed to their proximity to the seismic event. The rapid deposition during the seismic shaking preserved the old seafloor, maintaining its physical and chemical characteristics. The predominant fraction of the sediments is clay, followed by sand, while silt is negligible.

Methods

Two sediment cores (Fig. 1) retrieved from water depths between 720 and 1,030 meters. The core from the Amorgos basin (SA-1B: 25°52.974' E, 36°40.304 N) was obtained from a depth of 320 meters and has a length of 144 cm. The second core, SA-4 (26°00.835 E, 36°04.873 N), with a total length of 133 cm and was collected from the South East Aegean Sea. Initially, both cores were scanned using a multi-sensor core logger (Geotek) at 1 cm sample intervals to determine key attributes such as magnetic susceptibility, gamma-ray density, and P-wave velocity. Subsequently, the cores were longitudinally split into two halves. One half was photographed and described macroscopically, and samples were collected for grain size analysis, total organic carbon (TOC), total carbon (C), nitrogen (N), and both major and minor elements. In total, 83 samples were collected from core SA-1B, and 62 samples were obtained from core SA-4. The second half of each sediment core subjected to X-radiography using a Faxitron apparatus (cabinet X-ray). Grain size analysis was performed using a SediGraph device (Micromeritics SediGraph III Plus). Textural sediment classification followed the criteria established by Folk (1974). For carbon and TOC measurements, samples were processed in a CHN Elemental Analyzer (Fisons Elemental Analyzer EA1108) according to standard analytical procedures. The C/N ratios were calculated to estimate terrestrial organic matter inputs, according to Meyers (1994). The chemical composition of major and trace elements was analyzed through fuse beads in an X-ray fluorescence spectrometer (Phillips PW–2400). Terminology that used in this study follows Shanmugam and Wang (2015).

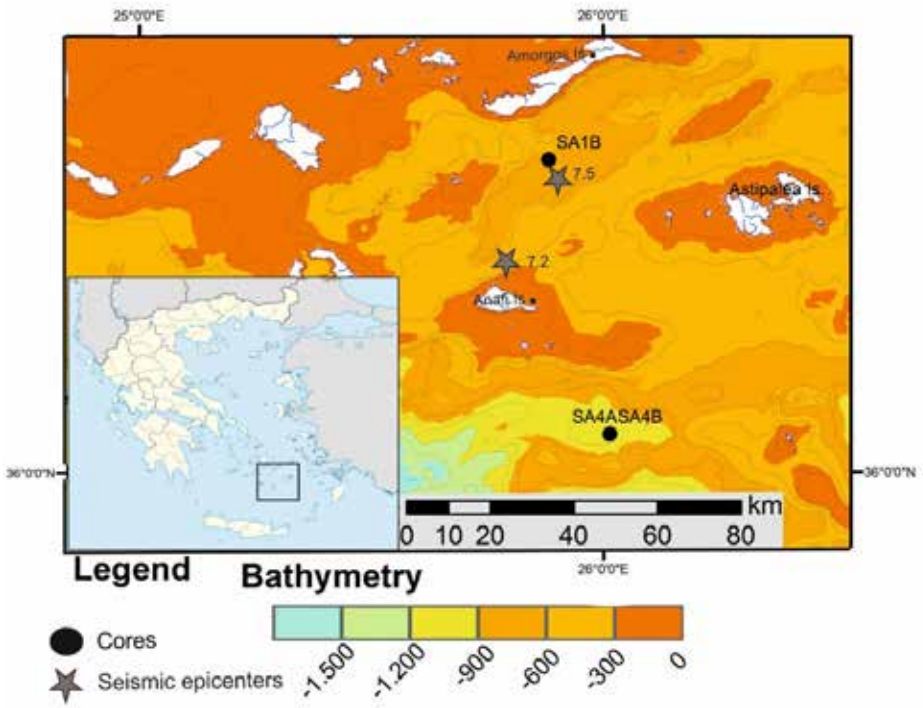

Figure 1. Location and bathymetry (in meters; grid interval of100 m) of the study area. Black circles show the location of the cores. Brown stars show the proposed epicenters for the two seismic events with their magnitude from Perissoratis and Papadopoulos (1999) and Okal et al., 2009.

Results

In core SA-1B, the uppermost 10 cm are characterized by a dull yellow color. Below this layer, the sediment transitions to a light gray hue, extending to a depth of 88 cm. Between 88 cm and 110 cm, the sediment exhibits a gray coloration. From 110 cm to 117 cm, the sediment is light yellow, followed by a dull yellow interval. Finally, the lowermost 19 cm (126–145 cm) of the core are composed of yellowish-gray sediment. The core is mostly composed of clay fractions except for some centimeters wherein sand fractions are dominant. X-radiographic analysis reveals a diagonal erosional surface with pumice at 2–5 cm, and a sandy horizon with pumice at 9 cm. At 79–82 cm, undisturbed sediment is observed at the bottom with an intrusion of sand, while the upper section of this interval is distorted. Hummocky cross-stratification is identified at 85 cm, and horizontal laminations are evident from 95–100 cm. These sediments exhibit high water content. Mud clasts and bioturbation are observed between 33–103 cm, while sand injection and erosional surfaces are present from 105–120 cm. Physical properties, including P-wave velocity and fractional porosity, exhibit similar downcore distributions, with maximum values recorded at 93–94 cm. In contrast, gamma density demonstrates an inverse trend. Total Organic Carbon (TOC) values and calcium carbonate ($CaCO_3$) exhibit parallel downcore trends, while the C/N ratio indicates a mixture of marine and terrestrial input, with the highest value (55) at 10 cm and the lowest (6.2) at 40 cm. Major element profiles reveal abrupt changes at key depths. Elements such as Al, Ba, Si, and K show significant declines at 115 cm, whereas P, Ca, Ti, Fe, Co, Cr, I, Ni, Sr, and V display pronounced increases at the same depth. Maximum values for As, Bi, Br, Sb, and Te occur at 119 cm, while Ce, Ga, and La reach their lowest values at the same depth. Proxies including Fe/Al, Mg/Al, Ca/Al, Br/Al, and Mn/Al show minimum values between 15 and 115 cm, whereas Zr/Sr peaks in this interval (Fig.3).

The uppermost section of the core represents the modern seafloor, consisting of a mixture of hemipelagic sediment and turbidites. Between 10 and 110 cm, mass transport deposits (MTDs) dominate, likely triggered by the 1956 earthquake. Below this, from 110 to 130 cm, the core records ‘old’ seafloor processes. The final section, from 130 to 144 cm, also reflects MTD deposition (Fig. 2).

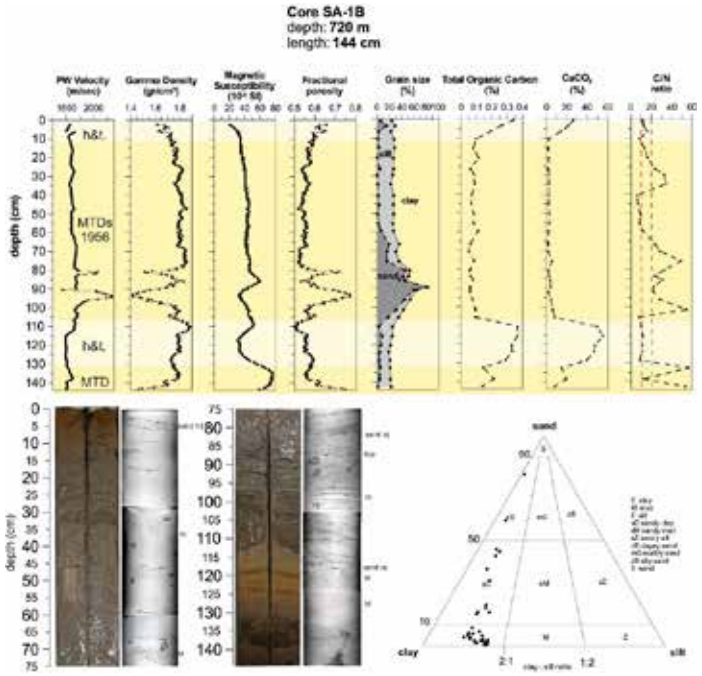

Figure 2. Downcore of plots: P Wave Velocity (m/s), Gamma-ray Density (g/cm³), Magnetic Susceptibility (10^{-5}), Fractional Porosity, Grain size distribution (dw%), Total Organic Carbon (dw%), CaC03 (dw%) and, C/N ratio, with red lines being discriminator between marine or terrigenous origin according to Meyers (1994). Photographs and X-radiographs (negative), as well as the Folk classification of grain assemblages. With light pink the sea floor is noted (h&t) and with pale yellow are marked the MTDs.

In core SA-4, the upper 18 centimeters exhibit a dull yellow-orange coloration (Fig. 4). Between 18 and 28 centimeters, the sediment transitions to a grayish-yellow hue. From 30 to 81 centimeters, the sediment is predominantly gray. The color reverts to dull yellow-orange from 81 to 89 centimeters before darkening further between 89 and 98 centimeters. From 98 to 123 centimeters, the sediment is characterized as grayish yellow, while the final 9 centimeters (123–132 cm) are dark grayish yellow. The core is primarily composed of clay, with the exception of the interval between 30 and 38 centimeters, which consists of sandy clay. Limited occurrences of broken shell fragments are found in the uppermost centimeters and at 95–96 centimeters. Small amounts of sand and pebbles are present at 4–5 centimeters and 90–91 centimeters. Pumice fragments are observed at 20–21 centimeters and 119–120 centimeters, along with volcanic sand identified at 130–131 centimeters. X-radiography of the core reveals a diagonal erosional surface at 3–5 centimeters, accompanied by a few pebbles and mud clasts. Another erosional surface is noted at 18–20 centimeters. Changes in sediment stiffness are observed at depths of 25 and 126 centimeters. P-wave velocity values generally increase downcore, reaching a depth of 77 centimeters, except for an anomaly at 24 centimeters where a value of 1500 m/s is recorded. Gamma density values range between 1.71 and 1.92 g/cm³, showing an overall increase downcore until 80 centimeters, where a local decrease to 1.65 g/cm³ is observed. Magnetic susceptibility values demonstrate an increasing trend, ranging from 23 × 10^{-5} at 1 centimeter to 143 × 10^{-5} at 59–60 centimeters. Fractional porosity displays an inverse relationship with gamma density, decreasing with depth. Total Organic Carbon (TOC) and calcium carbonate diagrams exhibit similar trends, with both showing decreasing values until 80 centimeters, followed by a peak and subsequent decline at greater depths. The C/N ratio indicates that sediments in the upper 30 centimeters and between 80 and 120 centimeters are of marine origin, while the rest of the core is composed of terrestrial material. Major element trends reveal an increase in aluminum (Al), silicon (Si), and potassium (K), from 27 to 75 centimeters. In contrast calcium (Ca), phosphorus (P), magnesium (Mg), manganese (Mn), and sulfur (S) show a decline over the same interval, with Ca and Mg reaching their lowest values. Trace elements such as arsenic (As), cobalt (Co), chromium (Cr), copper (Cu), iodine (I), nickel (Ni), antimony (Sb), and strontium (Sr) display reduced concentrations between 25 and 82 centimeters. Elements such as gallium (Ga), molybdenum (Mo), rubidium (Rb), zirconium (Zr), and yttrium (Y) increase until 40 centimeters, followed by a minor decline and subsequent increase at greater depths. Fe/Al, Mg/Al, Ca/Al, Br/Al, Mn/Al, and Zn/Al ratios decrease between 27 and 75 centimeters, while the Zr/Sr ratio exhibits an opposite trend (Fig. 3).
The uppermost centimeters of the core represent the seafloor and consist of a mixture of hemipelagic sediment

and turbidites. Between 25 and 80 centimeters, mass transport deposits (MTDs), triggered by the 1956 earthquake, dominate the stratigraphy. Below 80 centimeters, extending to 102 centimeters, the “old” seafloor processes are evident. The final section from 102 to 134 centimeters is composed of MTDs, reflecting both marine and terrestrial contributions (Fig. 4).

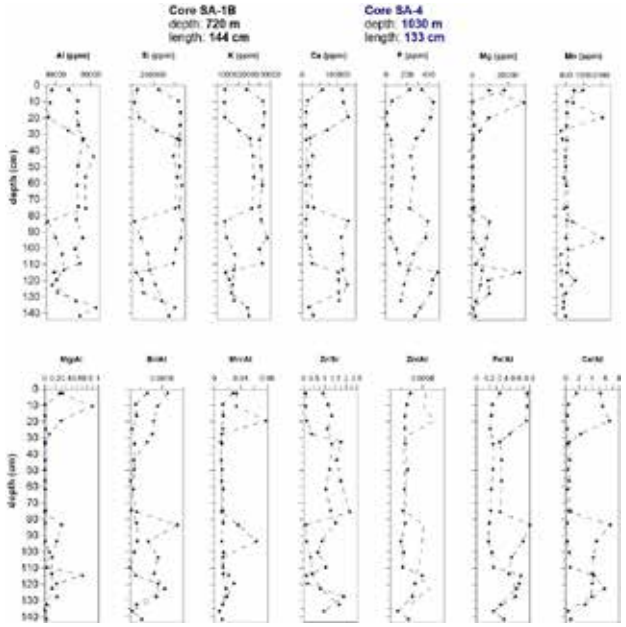

Figure 3. Downcore of plots: Al (ppm), Si (ppm), K (ppm), Ca (ppm), P (ppm), Mg (ppm), Mn (ppm), Mg/Al, Br/Al, Mn/Al, Zr/Sr, Zn/Al, Fe/Al, Ca/Al. Black dashed line are values of core SA-1B and blue dashed line for core SA-4.

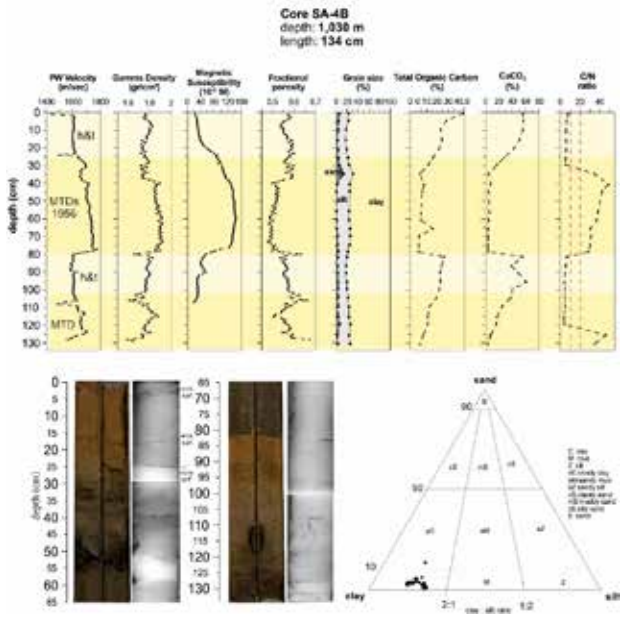

Figure 4. Downcore of plots: P Wave Velocity (m/s), Gamma-ray Density (g/cm^3), Magnetic Susceptibility (10^{-5}), Fractional Porosity, Grain size distribution (dw%), Total Organic Carbon (dw%), CaC03 (dw%) and, C/N ratio, with red lines being discriminator between marine or terrigenous origin according to Meyers (1994). Photographs and X-radiographs (negative), as well as the Folk classification of grain assemblages. With light pink the sea floor is noted (h&t) and with pale yellow are marked the MTDs.

Synthesis

The sediment cores in this study consist of mass transport deposits (MTDs), hemipelagites and turbidites, focusing on MTDs triggered by the 1956 Amorgos earthquakes. The MTDs identified in the cores are classified as debris flows, which can exhibit both cohesive and cohesionless behaviors. In core SA-4, the clayey debris flows are structure-

less, while in core SA-1B from the Amorgos Basin, mud clasts and sedimentary structures are observed. Notably, in core SA-1B, the flow demonstrates a mix of cohesive and non-cohesive behavior, featuring approximately 20 cm of non-cohesive sandy debris flows at depths ranging from 80 to 100 cm. This core also exhibits soft-sediment deformation structures (SSDS), including hummocky cross-stratification, which indicate liquefaction processes potentially triggered by seismic events such as the 1956 earthquake. Both cores share similarities in their sedimentological facies, as illustrated in Figures 2 and 4. The uppermost sections of both cores represent the "present" seafloor, followed by the deposition of large gravity flows (debrites and sandy debrites) during the 1956 earthquake(s). Beneath these layers lies the "old" seafloor, containing older MTDs that predate the 1956 earthquake. These findings align with the work of Perissoratis and Papadopoulos (1999), who reported that sediments between Amorgos and Astypalaia Islands predominantly consist of mass flows, slumps, and debrites.

Core SA-1B, retrieved from the Amorgos Basin, shows a significantly high sand content, reaching up to 80%. This elevated sand fraction is likely attributed to two factors: a) the proximity to Amorgos Island, contributing coarser material to the basin, and b) the location near the epicenter of the 1956 seismic event. The currents generated by the earthquake are believed to have flowed into several channels on the seafloor, resulting in high-energy flows that deposited thick sediment layers. Near the epicenter, MTDs reach up to 1 meter in thickness, while nearly 50 km away measure about 55 cm thick.

The MTDs in both cores consist of a mixture of marine and terrestrial material, as confirmed by various geochemical indicators. The C/N ratio in these sediments shows values up to 60, and a clear decrease in $CaCO_3$ content correlates with the dilution of the sediments by terrigenous material. Additional proxies, such as the calcium-to-aluminum (Ca/Al) ratio (Rothwell and Croudace, 2015), along with elevated levels of silicon (Si), aluminum (Al), potassium (K), and rubidium (Rb), further corroborate this observation. These deposits exhibit high gamma density values and lower fractional porosity, which can serve as diagnostic criteria for classifying similar deposits in the region.

The rapid deposition of MTDs in the study area enabled the underlying sediments to retain their original characteristics. The "old" seafloor layers in both cores are composed of oxidized clay, marked by a distinct color change at the transition to these deposits. Although some differences exist between the two cores, the overall trends remain consistent. Both cores display marine-origin sediments in the present and old seafloor layers, as indicated by the C/N ratio, bromine (Br), and total organic carbon (TOC) values. Furthermore, calcium (Ca) in these deposits is primarily sourced from biogenic $CaCO_3$, as evidenced by the co-variation of calcium (Ca) and strontium (Sr). Manganese (Mn) values tend to be higher in the upper layers than underlying sediments, decreasing downcore. Nevertheless, distinct peaks in Mn concentrations are observed at the same depth intervals where the "old" seafloor is found.

These findings enhance our understanding of the sedimentological and geochemical features of mass transport deposits (MTDs) in the central Aegean Sea, particularly those associated with the 1956 Amorgos earthquakes. The characteristics of these deposits can serve as diagnostic criteria for identifying similar deposits in the surrounding area. By applying the thickness of these facies to a model alongside other numerical calculations, we can gain insights into the volume and direction of the flows generated during these seismic events. Furthermore, numerical modeling of the 1956 tsunamis, combined with the sediment characteristics, is essential for evaluating the impact of tsunamis and providing predictive insights for future seismic events.

Conclusion

- The mass transport deposits resulting from the twin earthquakes exhibit similar characteristics. These deposits consist of both cohesive and cohesionless flows, show a gray color, and vary in thickness from 55 cm to 1 m. They are primarily composed of a very high clay content and possess similar chemical properties. The variation in thickness is attributed to their proximity to the epicenter of the main earthquake.
- The chemical signatures reveal that core SA-4 contains terrestrial materials, while core SA-1B consists of a mixture of terrestrial and marine origins. This suggests that most deposits have traveled from shallower depths and undergone intense remobilization.
- During the seismic shaking and the rapid deposition of these mass transport deposits (MTDs), the old seafloor remains intact, preserving its physical characteristics, color, and geochemical composition. The seafloors before and after the deposition of the MTDs in 1956 show similar characteristics.
- The sedimentological and geochemical signatures of the aforementioned deposits are reliable criteria for distinguishing similar deposits from the 1956 twin earthquakes in the central Aegean Sea.

(4) Earthquake Planning and Protection Organization, Athens, Greece

1. Introduction

Seismic waves from earthquakes propagate quickly, impacting natural and built environments before emergency measures can be implemented, posing challenges for Civil Protection authorities. Earthquake early warning systems (EEWS), which detect primary seismic waves and issue alerts, help mitigate damage and casualties by enabling timely precautionary actions (Cremen and Galasso, 2020). Despite their benefits, EEW systems are not universally applicable due to the complex geodynamic and seismotectonic characteristics of many regions. In such cases, seismic risk reduction depends largely on preparedness actions taken during standard operational phases, as reliable short-term earthquake forecasts remain elusive. Therefore, for most seismic events, the transition from standard preparedness to emergency response is immediate, making the enhanced preparedness phase impractical. In case of experiencing increased seismic activity, Civil Protection authorities may implement increased preparedness actions through public risk communication, structural assessments, and stakeholder engagement, aiming to enhance awareness, influence behavior, and improve community resilience (Musacchio et al., 2023). A notable case occurred during the early 2025 seismic sequence between the Santorini and Amorgos Islands in the southern part of the Aegean Sea (Greece), a rare and unprecedented event globally. This sequence raised significant concerns regarding its evolution, duration, and potential link to magmatic and volcanic activity. It affected mainly the daily activities of the population, affecting services, and economic sectors such as tourism and transportation. This event marked the first instance in Greece where increased preparedness measures were activated in anticipation of a potential major earthquake. This study examines the measures implemented by the Greek Civil Protection authorities and operational agencies in response to the ongoing and escalating seismic sequence. Emphasis is placed on safeguarding both residents and visitors, while proactively reducing the potential risks associated with the occurrence of a more powerful earthquake that could have significant consequences for both the natural and built environments.

2. Disaster Prevention and Management Framework in Greece

Civil Protection in Greece is primarily governed by Law 4662/2020 (Government Gazette of the Hellenic Republic - GGHR, 2020), as amended by Law 5075/2023 (GGHR, 2023), which enhance disaster management and reorganize operational structures. These laws define the roles and coordination mechanisms among key agencies, including the General Secretariat for Civil Protection (GSCP), Fire Service, Hellenic Police, and Armed Forces, across all disaster phases. The GSCP, under the Ministry of Climate Crisis and Civil Protection (MCCCP), coordinates emergency responses for natural and technological hazards at all levels of administration. Strategic disaster management is guided by the national “Xenocrates” Plan, which ensures interagency coordination for disaster risk reduction and response (GGHR, 2003). Earthquake management is outlined in the “Enceladus” Plan, initially issued in 2020 and then updated in the version “Enceladus 2” (GSCP, 2022), while the “Talos 2” Plan focuses on volcanic hazards, particularly for the Santorini volcanic complex (GSCP, 2023). These earthquake plans have been tested through operational exercises (Mavroulis et al., 2025) and real events, including the 2020 Samos (eastern Aegean) earthquake and the 2021 Thessaly (central Greece) and Crete (southern Greece) earthquakes (Mavroulis et al., 2022).

The earthquake contingency plan outlines a four-phase disaster management framework: (i) standard prevention and preparedness measures, (ii) heightened preparedness in anticipation of an imminent earthquake, (iii) emergency response involving immediate mobilization and impact management, and (iv) short-term relief and rehabilitation of affected populations (GSCP, 2022). However, due to the unpredictability of seismic events and the absence of reliable short-term forecasting, the second phase has never been activated. In practice, the standard preparedness before a strong earthquake is followed by emergency response and subsequent relief and recovery after its generation. Notably, the second phase was conceived as an enhancement, not an acceleration, of standard preparedness activities.

2.1. Standard Preparedness Prevention Actions

During the prevention phase of standard preparedness, all involved stakeholders implement measures aimed at enhancing preparedness for earthquake emergencies and the rapid management of their effects. These actions include pre-seismic building inspections, contingency plan revisions, development of action memoranda, and allocation of financial resources. The functionality of emergency communication systems and the efficiency of information exchange are assessed to support coordinated decision-making. Maintenance of emergency equipment, identification of assembly sites and waste disposal areas, and readiness of shelters are also prioritized. Memoranda of understanding with private entities are established to secure additional resources, while public awareness campaigns promote self-protection. Local and regional Coordination Bodies convene to strengthen interagency collaboration, supported by structured training programs and operational exercises for Civil Protection personnel.

2.2. Enhanced Earthquake Preparedness Actions

Given the limitations of short-term earthquake forecasting, early warning systems are not included in Greece's seismic risk management framework. Nonetheless, the Secretary General of Civil Protection may increase operational readiness based on evaluations from the specialized seismic hazard committees of the Earthquake Planning and Protection Organization (EPPO). In response, Municipal and Regional authorities are responsible for implementing or accelerating preventive actions, while local coordination bodies, convened by Mayors or Deputy Mayors, facilitate interagency collaboration. Simultaneously, Civil Protection operational structures review and update emergency plans, enhance capabilities in high-risk zones, and actively participate in coordination efforts at both local and regional levels.

2.3. Emergency response and short-term earthquake impact management

Upon a strong earthquake, the Civil Protection mobilization system is activated under the "Enceladus 2" Plan, coordinating response actions across six areas: (i) search and rescue (SAR) and emergency medical services, (ii) restoration of critical infrastructure and essential services, (iii) protection of affected populations, (iv) operational coordination and administrative measures, (v) public communication and awareness, and (vi) international cooperation (Mavroulis et al., 2022, 2025). The Fire Brigade leads SAR, provides medical aid, and oversees evacuations. Authorities collect real-time data for decision-making, while infrastructure rehabilitation includes inspections, debris clearance, and restoration of utilities. Civil Protection Coordination Bodies manage response efforts locally and regionally, with support from the Armed Forces, volunteers, and public communication initiatives. If needed, evacuations are organized, and international support is requested through the European Civil Protection Mechanism

.

2.4. Immediate relief and rapid rehabilitation actions

In the post-earthquake relief phase, immediate recovery efforts focus on supporting affected populations, conducting damage assessments, and facilitating efficient administrative response. Priority is given to assisting homeless and displaced individuals through municipal welfare services, which provide financial aid for basic needs and essential household replacements. Concurrently, damage to buildings is documented, affected zones are delineated, and housing assistance is granted based on official decisions. Financial support is also extended to impacted businesses, including industrial, commercial, agricultural, and non-profit entities. Restoration of critical infrastructure, such as water, electricity, telecommunications, and road networks, is undertaken by the responsible technical services.

3. The early 2025 Santorini – Amorgos Earthquake Swarm and its Impact

3.1. Seismotectonic Setting of Santorini-Amorgos Area

The central Aegean region, dominated by the Cyclades islands, is geologically defined by the NE-SW trending Anydros, Santorini-Anafi, and Amorgos grabens, within the Santorini-Amorgos Tectonic Zone, an extensional structure 60-70 km long and 20-25 km wide between the Cyclades and Anafi-Astypalaea Plateaus (Tsampouraki-Kraounaki et al., 2021). These grabens, bounded by major faults and separated by horsts, exhibit NW-ward tilt and reach depths of up to 755 m. The area has a history of destructive seismicity, most notably the 9 July 1956 Amorgos earthquake, the strongest in 20th-century Greece. It caused widespread damage across several islands, resulting in 53 fatalities and 100 injuries (Papazachos and Papazachou, 2003). It also triggered the largest tsunami reported in the 20th century over the whole Mediterranean Basin with run-up values up to 30 m in several islands of the southern Aegean Sea (Okal et al., 2009). It was triggered either by offshore landslides (Ambraseys, 1960) or large seafloor rupture (Leclerc et al., 2024).

3.2. Evolution, Seismological Properties and Environmental Effects of the 2025 Earthquake Swarm

After the first significant episode since 2011-2012, seismic activity reemerged between June 2024 and January 2025 within the Santorini caldera, with intensification observed from mid-September. Over 1,200 earthquakes were detected in the Santorini–Kolumbo area using machine-learning-based methods, with the largest event (M=3.8) occurring off Thirassia Island on 25 January

(Interdisciplinary Risk and Crisis Management Committee of the University of Athens, 2025). A new seismic cluster emerged east of Kolumbo on 26 January, with activity peaking on 3 and 4 February at 136 and 140 events, respectively (Seismological Laboratory of the National and Kapodistrian University of Athens – SL-NKUA, 2025) (**Figure 1**). Earthquakes with M ≥ 4.0 were most frequent between 1–12 February, particularly on 4–5 February (19 events per day), and the strongest event (M 5.2) was recorded on 10 February (SL-NKUA, 2025). Seismic activity gradually declined after mid-February, with no M ≥ 4.0 earthquakes after 27 February (SL-NKUA, 2025).

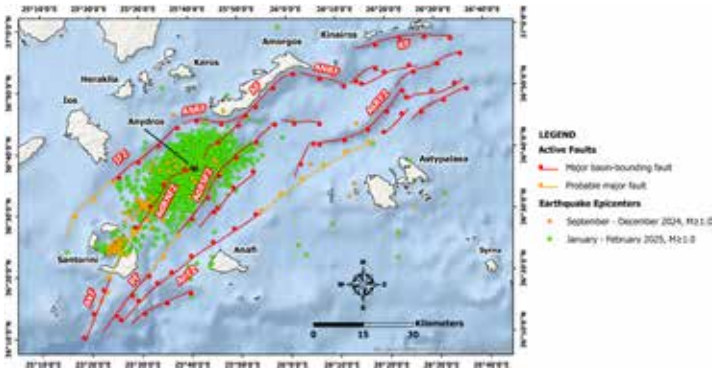

Figure 1. The Santorini – Amorgos area that was mainly affected by the early 2025 earthquake swarm along with the major basin bounding faults and the probable major faults based on Tsampouraki-Kraounaki et al. (2021). The epicenters in the affected area from September 2024 to February 2025 were recorded from the SL-NKUA (2025). AdRNFZ: Anydros Ridge North Fault Zone; AdRSFZ: Anydros Ridge South Fault Zone; AF: Amorgos Fault; AkF: Akrotiri Fault; AnFZ: Anafi Fault Zone; ANRF: Amorgos North Relay Fault; ASRF: Amorgos South Relay Fault; AsRFZ: Astypalaea Ridge Fault Zone; IFZ: Ios Fault Zone; KF: Kinairos Fault; PF: Perissa Fault.

Spatially, initial epicenters were located northeast of Santorini and east of the offshore Kolumbo volcano, later migrating toward and around Anydros islet (SL-NKUA, 2025). Most seismicity occurred southwest of Anydros, though epicenters periodically shifted northeast or appeared simultaneously on both sides of the islet (SL-NKUA, 2025). This pattern highlights a dynamic and evolving seismic sequence concentrated within the Santorini – Amorgos area.
The early 2025 earthquake swarm triggered landslides in three areas: the southern coastal zone (e.g., Red and Vlichada beaches), the central-eastern caldera slopes (e.g., Athinios, Alonaki, Fira, Imerovigli and Skaros), and the northern part of the island along the Fira-Oia road (**Figure 2**).

Figure 2. The spatial distribution of the landslides in Santorini triggered by the 2025 earthquake swarm.

Common geomorphological features at these sites include steep slopes, unstable volcanic formations, and landslide deposits. Impacts varied from debris accumulation at Red beach to sediment mobilization at Vlichada. Minor landslides in the Athinios area posed no threat to infrastructures, while rockfalls near Fira occurred downslope of residential zones without damage. In the north, rockfalls along the Fira-Oia road created hazardous conditions, requiring caution for drivers.

4. Increased preparedness actions for anticipation of an imminent earthquake

4.1. Joint meetings of seismic and volcanic risk assessment committees and public information dissemination

In response to ongoing seismic activity in the Santorini–Anydros–Amorgos region, the EPPO's Permanent Scientific Committees for Seismic Hazard Assessment and Volcanic Arc Monitoring convened to analyze the evolving seismic sequence. Official communications from the MCCCP summarized their findings, noting potential links between seismicity, offshore faults, and magmatic and volcanic processes. Recommended preventive measures included suspending educational activities, avoiding gatherings in unstable structures, restricting port access, removing hazardous building elements, selecting safer routes near landslide-prone areas, and evacuating coastal zones. Key meetings took place in January and February 2025, including a major session on 5 February chaired by the Prime Minister and Minister for Climate Crisis and Civil Protection, followed by a public broadcast featuring experts from the National and Kapodistrian University of Athens and Aristotle University of Thessaloniki, discussing related hazards and risks.

4.2. Awareness raising efforts

The EPPO, Greece's authority on earthquake policy implementation, also plays a vital role in public education and awareness to reduce seismic risk and assess seismic hazard. Its initiatives target diverse groups, including professionals, educators, Civil Protection personnel, tourism workers, and vulnerable populations such as individuals with disabilities. In response to the 2025 seismic sequence, and alongside committee meetings and official announcements on risk reduction, the EPPO conducted awareness and training activities for the affected population. Notably, it organized a webinar titled "Experiencing an Earthquake Period: Earthquake Protection of School Units" in collaboration with the Municipality of Thira, which was attended by local school directors, kindergarten heads, and nursery managers.

4.3. Strengthening security forces in affected islands

In response to the seismic sequence in Santorini and the surrounding islands, multiple Greek authorities coordinated efforts to increase preparedness and public safety. The Hellenic Fire Service deployed specialized disaster management units (EMAK in Greek), rescue dogs, drones, forest operations teams, and a mobile operations center ("Olympos") equipped with advanced technology to monitor and manage disaster response. Additional search and rescue teams were stationed across nearby islands, with aerial rescue teams on standby. Concurrently, the Hellenic Police reinforced local law enforcement with personnel and vehicles from Athens, the capital of Greece, implementing nightly patrols and security checks to prevent criminal activity and safeguard abandoned properties, ensuring public order and a sense of security amid widespread evacuations. The Hellenic Coast Guard implemented strict emergency measures in Santorini's ports, including restricted access, vessel movement controls, and safety protocols for mooring and navigation, backed by enforcement of legal sanctions. The Coast Guard also instructed vessel operators to maintain high alert for both seismic and potential hydrometeorological hazards. Meanwhile, the Hellenic Armed Forces remained on standby, deploying essential logistics infrastructure such as cranes, lighting systems, tents, portable kitchens, and liaison officers to coordinate with Civil Protection authorities. Strategic naval assets, including a tank landing ship and a support vessel, were positioned near Santorini to enable rapid response capabilities across the affected island region.

4.4. Strengthening health services in affected islands

In response to the ongoing seismic activity, all leaves for medical, nursing, and support staff at Santorini Hospital were revoked to ensure full operational readiness. The National Center for Emergency Assistance, under the MCCCP, reinforced its teams on Santorini, Amorgos, and Ios with personnel from the Special Department of Disaster Medicine, including doctors, rescuers, medical equipment, and additional ambulances. The Health Operations Centre and the Unified Coordination Operations Centre maintained high alert for continuous coordination. The 2nd Health Region of Piraeus and Aegean also enhanced readiness by deploying medical teams from "Attikon" General University Hospital and Naxos General Hospital – Health Center, and a psychological support unit from "Dafni" Psychiatric Hospital of Attica. Plans were in place to mobilize all private doctors in the affected islands if needed. Additionally, an evacuation exercise was conducted at Thira General Hospital, supervised by the Deputy Minister of Health and hospital leadership, reflecting the elevated state of preparedness.

4.5. Contribution of public utilities

To mitigate the risk of a widespread blackout during a major earthquake, the Hellenic Electricity Distribution Network Operator deployed generator-equipped trucks to Santorini, while the Municipality enhanced the island's electrical infrastructure by reinforcing networks and installing additional poles and conductors. Simultaneously, the Ministry of Digital Governance, in collaboration with mobile and satellite communication providers, ensured the deployment of mobile units and generators across the affected islands to maintain uninterrupted telecommunications during potential power failures. In response to the increasing number of residents leaving Santorini due to escalating seismic activity, and following a request from the MCCCP, airlines introduced extra flights, offering free tickets to children and teachers, along with a free return ticket valid until 20 August 2025 for those who had evacuated. Ferry companies also initiated emergency services and committed to adjusting schedules as needed to support residents and visitors departing the island.

4.6. Notifying the population via European Emergency Number 112

During the January – February 2025 seismic sequence, Greece's 112 emergency warning system was activated for the first time in response to landslide hazard. On 3 February, a geotargeted alert was issued to Santorini residents warning of landslides due to seismic activity and prohibiting access to Ammoudi and Armeni ports and the old port of Fira, while urging compliance with official instructions. A second message followed, sent to residents of Ios, Amorgos, Santorini, and Anafi, advising heightened alertness and adherence to Civil Protection directives amid ongoing seismic activity.

4.7. Municipal authorities' coordination with Civil Protection agencies

In February 2025, the Municipality of Thira issued the updated Civil Protection plan "Thiras 2" (Municipality of Thira, 2024) emphasizing preventive evacuation of at-risk populations. The plan featured thematic maps identifying emergency shelters, coastal embarkation points, and airdrop zones, selected based on terrain, accessibility, evacuation routes, and minimal tsunami risk. Designated pick-up points for vulnerable groups and students were included, and shelter locations were widely shared through social media and local announcements. To support seismic risk management, the municipality ensured continuous public communication in line with EPPO guidelines. Pre-seismic inspections by the Ministry of Infrastructure confirmed the structural safety of schools. Following landslides in Santorini and, to a lesser extent, in Amorgos, causing limited disruption, authorities enforced access restrictions and installed warning signs near hazardous areas and unstable structures to protect residents.

4.8. Municipality of Thira emergency declaration

On 6 February 2025, the MCCCP declared a State of Emergency in Civil Protection for the Municipality of Thira (MCCCP, 2025a), within the Regional Unit of Thira in the South Aegean Region. This measure was taken to address emergency needs and manage the impact of seismic activity that occurred between January and February in the study area. The declaration was in effect from February 1 to March 1. This action primarily facilitates the bypassing of bureaucratic procedures in public administration to ensure a more efficient response to the seismic crisis.

4.9. Ministerial decisions on earthquake impact mitigation and risk reduction

To mitigate the risks associated with seismic activity and secondary hazards such as landslides, preventive measures were enacted on Thira and Thirassia Islands through a ministerial decision (GGHR, 2025), co-signed by key governmental bodies including the MCCCP. In force from March 14 to May 14, 2025, these temporary restrictions targeted high-risk zones, particularly those with frequent tourist activity or proximity to landslide-prone areas. Measures included limitations on access to ports and adjacent offshore areas without port authority approval, restricted movement on selected roadways and footpaths, controlled access within specific settlement zones, suspension of operations in residential, hospitality, and healthcare facilities, and a ban on vehicular traffic in designated road sections.

4.10. Voluntary team actions for the public and vulnerable groups

During the earthquake swarm in the southern Aegean, the Hellenic Red Cross (HRC) played a crucial role by deploying specialized volunteer teams to Santorini, including Samaritan-Rescuers, psychosocial health professionals, and trained K9 units. These teams provided psychological support to vulnerable populations such as the elderly, chronically ill, and disabled individuals, conducting home visits and counseling for 60 families to address uncertainties regarding emergency contacts and shelter. Additionally, the HRC organized mental health first aid courses, training 198 residents in crisis-response skills, and conducted an evacuation exercise at the Elderly Care Center. On Amorgos, HRC teams collaborated with local Civil Protection agencies to provide community-wide psychosocial support and established a temporary Operations Center in Aegiali area. Volunteers also led awareness campaigns in schools to improve seismic preparedness. These efforts enhanced local capabilities for psychological support, emergency readiness, and resilience.

4.11. Web platform for emergency shelter dissemination

Amid the ongoing seismic activity, the Ministry of Digital Governance, in collaboration with the National Observatory of Athens, launched a web platform to inform and guide citizens on the location of safe assembly points across Greece (MCCCP, 2025b), including seismically affected islands of Santorini, Amorgos, and Ios. The platform ensures user-friendly, real-time access to officially approved assembly points without requiring application installation, and is progressively updated with additional information tailored to various natural hazard scenarios.

5. Discussion

5.1. Adequacy of implemented measures during the early 2025 seismic sequence

During the early 2025 crisis, Civil Protection authorities focused on institutional preparedness through infrastructure assessments, operational readiness, and public announcements. However, community engagement was limited, with minimal participation of

residents and visitors in preparedness actions. Although seismic inspections and safety measures were implemented, the lack of inclusive actions reduced the overall effectiveness of public preparedness efforts. This gap was addressed by the HRC, which deployed trained volunteers to provide psychosocial support, first aid training, and mental health awareness programs, particularly to vulnerable groups such as people with disabilities and the elderly. These interventions played a critical role in enhancing individual psychological preparedness and social resilience, complementing the institutional response and filling crucial gaps in community-level risk reduction. Holistic preparedness also included physical measures like retrofitting and emergency planning for key infrastructure, alongside campaigns promoting risk awareness. The integration of psychological and physical preparedness, as seen in both Civil Protection and HRC efforts, underlines the importance of multi-dimensional strategies for enhancing resilience.

5.2. Further proposed measures to reduce risk

To reduce risks in the Santorini volcanic complex and surrounding areas, early actions are vital, particularly through continuous geophysical, seismological, and geochemical monitoring. Predictive models, combined with real-time data, enable authorities to issue timely warnings and initiate preparatory actions to mitigate human and economic losses. Risk communication, including regular exercises and training for Civil Protection authorities and the public, is crucial for effective disaster preparedness. However, challenges remain, as no full-scale exercises have been conducted since the approval of the “Enceladus” and “Talos” plans in 2020. While awareness efforts are important, they must be more frequent, especially for vulnerable populations. Infrastructure improvements, including safe evacuation routes and emergency ports, are essential, as delays during the 2025 crisis hindered timely responses. Pre-seismic inspections and strengthening critical infrastructure, such as schools and healthcare facilities, are necessary for long-term resilience.

6. Conclusions

The unpredictability of early 2025 Santorini-Amorgos seismic sequence emphasized the need for increased preparedness actions. In response, the authorities and the operational structures of the Civil Protection system in Greece implemented unprecedented preparedness measures, marking the first time in the country that proactive actions were taken in anticipation of an imminent earthquake. These included strengthening security and health services, activating the European Emergency Number 112, enhancing infrastructure resilience, updating emergency plans, and launching public awareness campaigns. Volunteer groups also provided support to vulnerable populations. This comprehensive practice, tailored to the specific geological conditions of the region, can be considered a model approach for managing seismic emergencies and offers valuable lessons for other areas with similar geodynamic risks.

EXTENDED ABSTRACT 206

Application of GIS-Based Multicriteria Decision Analysis and Analytic Hierarchy Process for Flood-Hazard Mapping in the Messapios River Basin, Central Evia Island, Greece

Mazarakis V.[1], Tsanakas K.[1], Greenbaum N.[2], Batzakis D.-V.[1], Sorrentino A[3], Tsodoulos I.[1], Valkanou K.[1], Karymbalis E.[1]

Introduction

Floods are among the most frequent and devastating natural hazards worldwide, causing widespread fatalities, significant property damage, and environmental degradation. In recent decades, the occurrence of extreme flood events has risen dramatically, leading to both immediate impacts, such as loss of life, property and infrastructure destruction, and longer-term effects, including health issues caused by pollution and financial difficulties for individuals and communities. Statistics emphasize the scale of the issue, with floods consistently accounting for a large proportion of natural disasters, deaths, and economic losses globally (CRED, 2023). The increasing frequency and intensity of floods highlight the pressing need to understand their underlying causes and implement effective strategies for risk mitigation. Flood-hazard assessment and mapping have become essential tools for prevention and spatial management. A widely used approach involves integrating GIS-based Multi-Criteria Decision Analysis (MCDA) with the Analytic Hierarchy Process (AHP), which allows for a systematic evaluation of multiple factors contributing to flooding and their relative importance (Ouma & Tateishi, 2014; Gigovic *et al*., 2017; Das, 2018; Radwan *et al*., 2019).

This study applies a GIS-based MCDA methodology in combination with AHP to assess and map flood hazard in the Messapios River catchment, a flood-prone area in Central Evia Island, Greece. The analysis incorporates critical factors influencing flooding, including those that affect water flow during extreme runoff events, and assigns weights to these factors based on expert input. This approach aligns with similar studies conducted across Greece, indicating its effectiveness in flood-hazard assessment and providing significant insights for spatial planning and disaster prevention.

Study Area

The Messapios River, an ephemeral stream in central Evia Island, is approximately 34 km long with a catchment area of 216 km² (Figure 1).

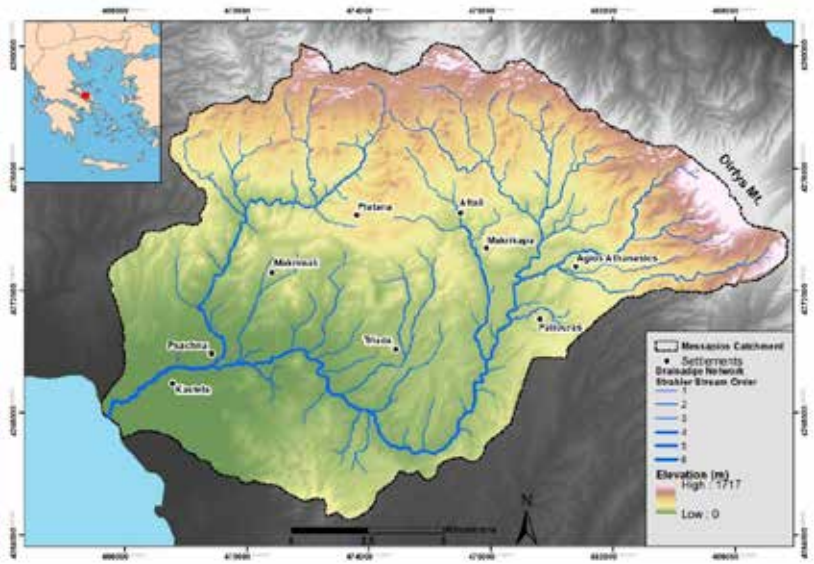

Figure 1. Map of the Messapios River drainage network and catchment.

The drainage network drains a rugged mountainous area, reaching elevations of up to 1,743 m on Mount Dirfys, with steep slopes averaging 24.1% that promote surface runoff. The lowland fan delta near the river's mouth, characterized by gentle slopes, enhances sediment deposition and rainwater infiltration. The catchment consists of geological formations of the Sub-Pelagonian geotectonic zone, including ophiolites, limestones, and flysch, as well as Neogene sedimentary rocks, and Holocene

alluvial deposits.
The climate of the study area is subtropical Mediterranean with hot, dry summers and mild, wet winters, with annual precipitation averaging 450 mm. Hydrologically, the Messapios River catchment falls within the Eastern Sterea Hellas Water District, which recorded 181 flood events between 1939 and 2018. Severe floods in 2006 and 2020 caused significant damage to settlements, infrastructure, and farmland, particularly during the 2020 "Thalia" storm, which resulted in eight fatalities and extensive property destruction.
Administratively, the catchment is part of the Municipality of Dirfys-Messapia, with 15,934 residents, half of whom live in the low-lying plains. Key settlements include Psachna, Kastella, Triada, and Makrykapa. The rural economy relies heavily on agriculture, with 35% of the population engaged in farming, supported by the fertile soils over the plains, and olive cultivation.

Methodology
This study aims to assess and map flood risk within the Messapios River catchment using a model that integrates Multi-Criteria Decision Analysis (MCDA) and the Analytic Hierarchy Process (AHP). This approach enabled the selection, calibration, and integration of five critical factors: slope, elevation, proximity to higher-order stream channels, land cover, and hydro-lithological characteristics of the geological formations. These factors, identified from a review of established methodologies in the literature (Haan *et al*., 1994; Kazakis *et al*., 2015; Bathrellos *et al*., 2016; Patrikaki *et al*., 2018; Skilodimou *et al*., 2021; Feloni *et al*., 2020; Karymbalis *et al*., 2021), influence water flow when drainage systems are overwhelmed by high runoff. A single-level hierarchy was used to maintain a straightforward weighting process for each factor's impact on flood hazard, avoiding potential subjectivity in grouping criteria and following the approach used in similar studies.
Each factor was initially divided into five classes with defined boundaries and then reclassified on a standardized scale from 1 to 5, representing increasing flood hazard levels, as shown in Table 1. A rating of "1" corresponds to a very low flood hazard level, while a rating of "5" represents a very high flood hazard level. The spatial distribution of each factor was visualized through thematic maps, where the values were classified and standardized to ensure consistency in assessing overall flood hazard.
The slope analysis for the study area was conducted using ArcGIS/ArcMap ESRI® software, utilizing a high-resolution 5-meter Digital Elevation Model (DEM) provided by the Hellenic Cadastre (Ktimatologio S.A.). This DEM also served to derive the elevation grid for the area and to extract the drainage network. The stream channels were ranked according to Strahler's stream order system (Strahler, 1957) using ArcGIS/ArcMap. To determine the "proximity to the stream channel" factor, buffer zones were created in ArcMap, generating polygons around both sides of stream channels with a Strahler order greater than 3, at specified distances. A Strahler order greater than 3 was chosen to prioritize larger channels that have a greater potential to contribute to flood hazards due to their size and drainage capacity. Land cover data was obtained from the Copernicus CORINE Land Cover database (Copernicus CORINE Land Cover, 2018) and the Agricultural Blocks dataset (ILOTS 2012) provided by the Ministry of Rural Development and Food. Geological formations in the catchment were sourced from the 1:50,000 scale geological map provided by the Institute of Geology & Mineral Exploration of Greece (IGME, 1981).
The AHP was employed to assign weights to each criterion (Saaty, 1990a; Saaty, 1990b). A pairwise comparison was conducted by the authors based on their expertise in flood hazard assessment from similar studies to assess and rank the criteria based on their relative significance. After determining the weights, the overall flood-hazard score for the Messapios River catchment was calculated by linearly combining the weighted criteria. This process involved overlaying the thematic maps of the factors, each assigned a specific weight, within a vector-based GIS environment. The criteria were integrated using the Weighted Linear Combination (WLC) method, expressed by the formula:

$$H = \sum_{i=1}^{n} w_i X_i$$

where H represents the flood hazard degree, n is the number of criteria, w_i is the weight of criterion i, and X_i is the rating of criterion i.
The result was a final thematic layer depicting the flood hazard across the entire catchment. A sensitivity analysis was also conducted to assess the robustness of the model. This involved applying a slight adjustment to the weight of the most influential criterion while proportionally modifying the weight of the second most influential criterion, ensuring that the changes did not undermine the model's effectiveness.
To validate the flood hazard map, it was compared with the Zoning of Flood-Prone Areas established by the Special Secretariat of Water, Ministry of Environment and Energy, as well as with past flood records in the study area. This comparison helped to assess the consistency of the results. Additionally, to provide an initial estimate of the catchment's vulnerability to flooding, the spatial distribution of settlements and critical infrastructure—such as roads, bridges, schools, industrial facilities, and electricity substations—was analyzed in relation to the mapped flood hazard zones.

Table 1. Classification matrix for flood-hazard criteria, detailing the assigned rating categories and the corresponding area covered by each category for every criterion.

Flood-hazard Criterion	Class	Rating	Area (km²)	Area (%)
Slope (°)	>40	1	10.03	4.65
	25–40	2	50.42	23.35
	15–25	3	45.01	20.24
	5–15	4	61.06	28.27
	<5	5	49.44	22.89
Elevation (m a.m.s.l.)	901-1717	1	14.97	3.93
	501-900	2	39.29	18.19
	301-500	3	27.92	12.93
	151-300	4	55.58	25.74
	<150	5	78.20	39.21
Proximity to the stream channels (m)	>80 for the 3rd order streams, >100 for 4th order streams, >120 for 5th order streams, and >150 for 6th order stream	1	205.03	94.94
	60-80 for the 3rd order streams, 80-100 for 4th order streams, 100-120 for 5th order streams, and 130-150 for 6th order stream	2	1.88	0.87
	40-60 for the 3rd order streams, 60-80 for 4th order streams, 80-100 for 5th order streams, and 100-130 for 6th order stream	3	2.15	0.99
	20-40 for the 3rd order streams, 30-60 for 4th order streams, 40-80 for 5th order streams, and 50-100 for 6th order stream	4	3.15	1.46
	<20 for the 3rd order streams, <30 for 4th order streams, <40 for 5th order streams, and <50 for 6th order stream	5	3.75	1.74
Land cover	Forests (broad-leaved, coniferous, mixed), Sclerophyllous vegetation, Transitional woodland-shrub	1	129.90	60.13
	Olive groves, natural grasslands, shrub and/or herbaceous vegetation associations	2	16.15	7.47
	Complex cultivation patterns, and principally occupied by agriculture, with significant areas of natural vegetation	3	23.54	10.90
	Non-irrigated arable land, sparsely vegetated areas	4	41.38	19.19
	Discontinuous urban fabric, industrial or commercial units,	5	4.99	2.31
Geological formations	Permeable alluvial deposits	1	49.85	23.08
	Permeable carbonate rocks	2	103.44	47.90
	Semi-permeable alternations of conglomerates, marls, clays, sandstones	3	20.91	9.68
	Semi-permeable igneous and metamorphic rocks	4	27.79	12.87
	Flysch formation	5	13.97	6.47

Results

The thematic maps in Figure 2 illustrate the spatial distribution of the five criteria employed in flood hazard assessment, categorized into five hazard levels according to their respective impact on flooding. The slope in the study area ranges from 0° to 76°, with 51% (~110 km²) of the catchment categorized as "highly" or "very highly" susceptible to flooding, primarily in the central, southern, and western plains of Psachna and Triada. Steeper slopes with "low" to "very low" flood risk are located in the northern and eastern mountainous regions, including Mount Dirfys (Figure 2a). Regarding the elevation criterion, approximately 65% of the area (~137 km²), which includes most settlements and all documented flood events, lies below 300 m and falls within the "high" and "very high" flood hazard susceptibility zones (Figure 2b). Based on the classification used for the "proximity to the stream channels" criterion, flood-prone zones are primarily along the 6th order Messapios River main channel, as well as along its major 5th order tributaries, the Mantania and Vailelekas streams (Figure 2c). Regarding the "land cover" criterion, areas covered by forests and semi-natural vegetation, which have "very low" flood susceptibility, account for approximately 60% of the catchment. The highly susceptible areas (~19%) with arable land and sparse vegetation are concentrated in the central and

western parts of the catchment, while less resistant agricultural land and artificial surfaces account for approximately 18% and 3.5% of the catchment area, respectively (Figure 2d). Finally, substantial portions of the catchment are occupied by permeable carbonate rock formations (~48%) and highly permeable alluvial deposits (~23%), which reduce flood susceptibility (Figure 2e).

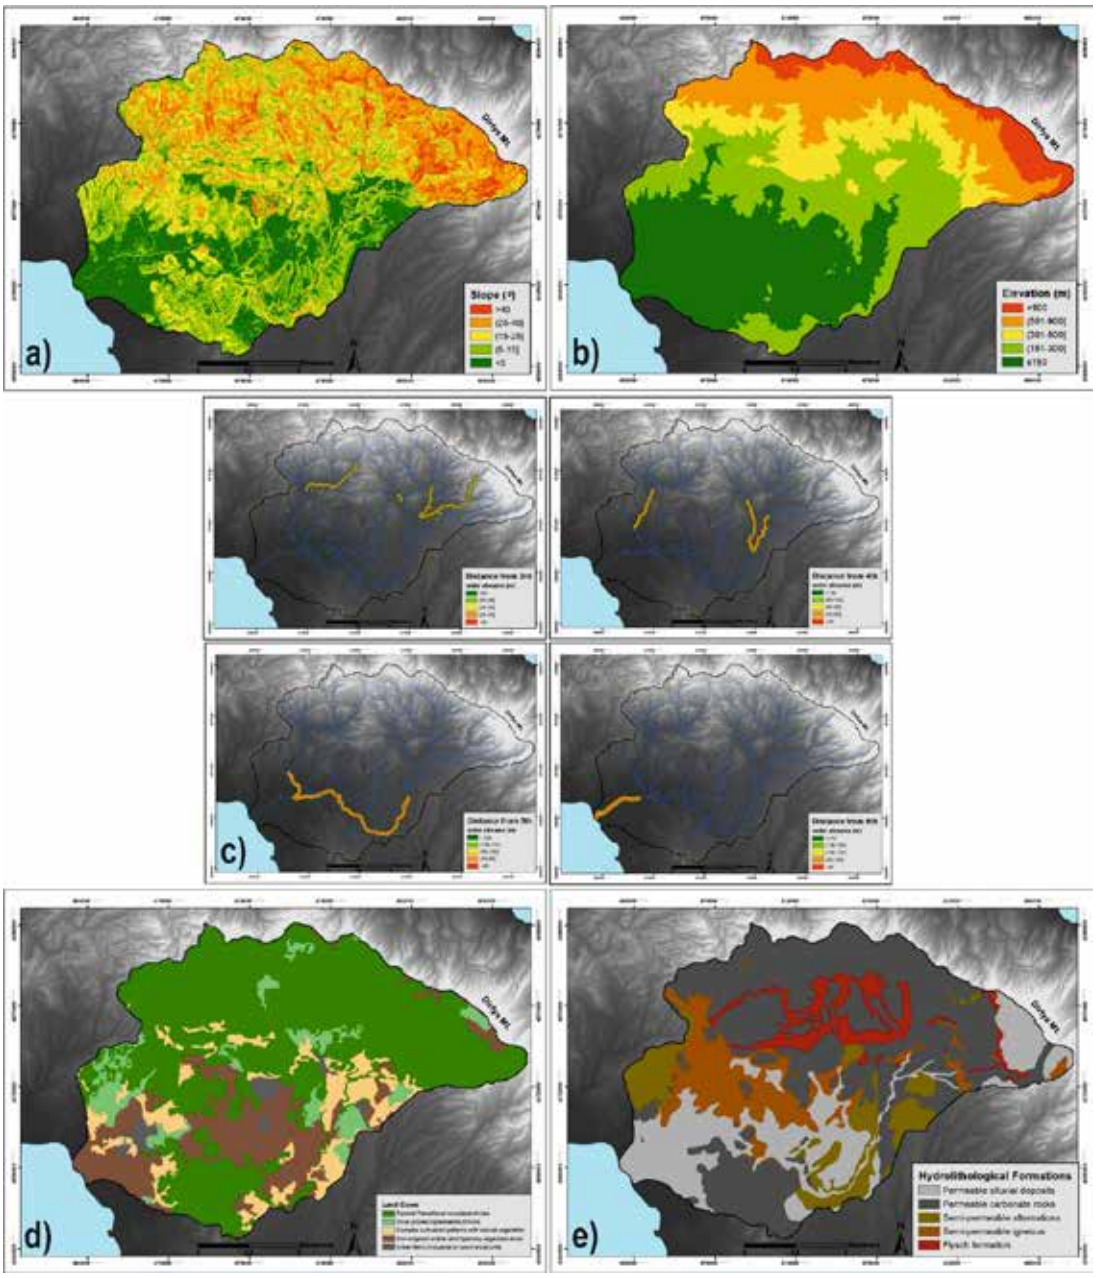

Figure 2. Maps of the Messapios River catchment illustrating the classification of: a) slope values, b) elevation, c) proximity to the stream channel, d) land cover, and e) geological formations into five categories. The rating for each criterion class is presented in Table 1.

The results of the AHP, including the pairwise comparisons matrix and the criteria weights, are given in Table 2. The estimated value of the Consistency Ratio is 0.0296, which is well below the 0.1 threshold, confirming that the hierarchy and pairwise comparisons of the criteria exhibit an acceptable level of consistency.

Two scenarios were considered for the sensitivity analysis: in Scenario 1, the weight of Slope was increased by 0.05, and the weight of Elevation was decreased by 0.05; in Scenario 2, the adjustments were reversed. The updated weights resulted in minimal deviations between the scenarios and the original AHP model, with the largest deviation being -1.57% in Scenario 1 and +1.71% in Scenario 2. These small variations indicate that the model is stable and significantly not affected by minor

changes in the weights.

Table 2. Pairwise comparison values, derived from expert insights grounded in experience with fluvial geomorphology and flood-hazard analysis, reflecting a consensus of their recommendations. W represents the relative weight of the criteria.

	Slope	Elevation	Proximity to the stream channel	Land cover	Geological formations	W
Slope	1.00	2	3	3	4	0.395
Elevation	0.50	1.00	2	2	3	0.239
Proximity to the stream channel	0.33	0.50	1.00	2	3	0.173
Land cover	0.33	0.50	0.50	1.00	2	0.119
Geological Formations	0.25	0.33	0.33	0.50	1.00	0.073
Sum	2.41	4.33	6.83	8.50	13	

To validate the results, the AHP-based flood hazard map, produced using the WLC method, was compared with the Flood Prone Zones from Greece's Special Secretariat of Water and with past flood event locations within the Messapios River catchment (Figure 3). The comparison revealed strong alignment between "high" and "very high' flood hazard areas obtained using the AHP method and the Flood Prone Zones provided by the Special Secretariat of Water of the Ministry of Environment and Energy of Greece. In addition, all past flood events (5 in total) have occurred within the "very high" flood hazard zone. This confirms that the model is reliable for flood risk assessment and management in the Messapios River catchment.

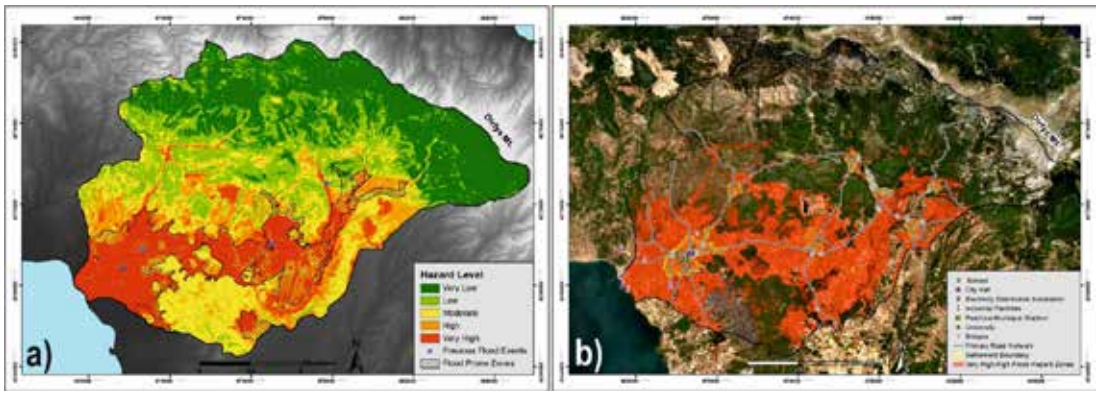

Figure 3. a) Flood hazard map of the Messapios River catchment, which also includes the Flood Prone Zones delineated by the Special Secretariat of Water of the Ministry of Environment and Energy of Greece, as well as the locations of past flood events. b) A comparative map showing the flood hazard zones identified in this study, juxtaposed with the distribution of settlements and critical infrastructure, including the primary road network, bridges, schools, industrial facilities, and electricity distribution substations.

Table 3 summarizes the areas corresponding to each of the five flood susceptibility zones from the flood hazard assessment map of Figure 3a. Approximately one-third of the catchment is classified as "very high" (17.86%) and "high" (18.02%) flood hazard areas. These zones are primarily concentrated in the central, southern, and western parts of the study area, primarily along the channels of the main streams (Messapios, Mantania, Makrimalli, Vailelekas, Makrikapiatiko), in the lower reaches of the catchment, and at the fan delta near the mouth of the river. In contrast, the "very low" and "low" flood-hazard areas are found in the northern and eastern parts, characterized by a rough mountainous relief with steep slopes and dense vegetation.

Table 3. Area (in km² and percentage) of the Messapios River catchment classified by flood-hazard levels, as determined through the Weighted Linear Combination (WLC) method using criteria weights derived from the AHP approach.

Flood Hazard Ranking	Area (km²)	Area (%)
Very low	47.14	21.83
Low	44.85	20.77
Moderate	46.48	21.52
High	38.91	18.02
Very high	38.58	17.86

The spatial comparison of settlements and critical infrastructure—such as roads, bridges, schools, industrial facilities, and power substations—with flood hazard zones highlights the area's significant vulnerability to flooding (Figure 3b). Nearly all settlements, except Platana, are in "high" or "very high" flood-prone areas, exposing approximately 9,000 residents. Psachna and Makrykapa are at greatest risk due to their proximity to major rivers with a history of severe flooding, including recent events like the "Elias" storm on September 27, 2023. Key infrastructure is also at risk: a substantial portion of the road network (~60 km) and all bridges are in "high" and "very high" flood hazard zones, as well as five major industrial facilities in the Messapios River fan delta. The General High School of Psachna, attended by students from across the municipality, and the adjacent municipal stadium are also within this zone, while the Psachna and Triada plains, vital for local agriculture, lie almost entirely in the "very high" flood hazard area, posing severe economic risk. Additionally, the Public Power Corporation substation's location in this zone signifies the potential for widespread disruption during floods.

The flood-hazard assessment map is a crucial tool for regional land-use planning, helping identify areas suitable for development while guiding long-term policies. This is particularly relevant in the study area, where ongoing land cover changes, primarily due to wildfires, have enlarged flood risk.

Concluding Remarks

This study led to the following conclusions:

- The MCDA approach effectively assessed flood hazard in the Messapios River catchment, integrating factors like topography (slope, elevation, and proximity to stream channels), land cover, and hydro-lithological characteristics of the geological formations.
- About one-third of the catchment, primarily its central, southern, and western parts, is classified as "high" or "very high" flood hazard zones, while the mountainous northern and eastern regions are less susceptible.
- Approximately 9,000 residents, key settlements (Psachna, Triada, Kastella, Makrykapa), critical infrastructure (five industrial facilities, one school, one stadium, and the power substation), and vital agricultural plains are situated in highly flood-prone zones.
- The findings emphasize the need for targeted flood mitigation measures and strategic land-use planning to reduce risk and safeguard lives, infrastructure, and economic assets.
- MCDA offers a structured, objective framework to prioritize vulnerable areas, optimize resource allocation, and guide efficient flood management strategies.

Introduction / Background

Indium and tellurium are critical metals for renewable energy and advanced technologies. Tellurium is essential for cadmium telluride (CdTe) solar cells, while indium is vital for indium tin oxide (ITO) coatings used in displays and solar panels (Müller et al. 2025). Both elements are primarily obtained as by-products of base-metal mining (e.g., zinc and copper refining), making their production highly dependent on these industries. Understanding their geological occurrences is crucial for enabling more targeted exploration and efficient extraction, thereby reducing reliance on imports. This is of high significance, as China dominates global production, creating supply chain vulnerabilities (Müller et al. 2025). The Pefka high- to intermediate-sulfidation deposit hosts the highest indium and tellurium grades in Greece (1160 ppm In and >1000 ppm Te), making it an ideal case to study the enrichment processes of these metals in an epithermal environment (Voudouris et al. 2022; Melfou et al. 2023). Studies on the distribution of elements like In and Te in multi-mineral assemblages, where sphalerite is rare, remain scarce, despite their importance (Cook and Ciobanu 2015). The objective of this study is to investigate the capacity of minerals to incorporate indium and tellurium at various stages of mineralization and the processes that control their enrichment. These particularly include roquesite for indium and tellurides/goldfieldite for tellurium, but also in minor proportions galena, luzonite, chalcopyrite, and Cu-rich varieties of tennantite-tetrahedrite. This study also aims to assess the potential of pyrite to provide insights into ore-forming conditions within a deposit characterized by a complex paragenetic sequence with numerous mineral phases.

Geological context

The Rhodope metallogenic province in Greece (Fig. 1a), located within the broader Western Tethyan metallogenic belt, is a highly productive district for epithermal mineralization hosted in Oligocene-Miocene volcanic rocks (Melfos and Voudouris 2017; Voudouris et al. 2019). This region is characterized by metamorphic core complexes exhumed during the Late Cretaceous and Tertiary, as well as supra-detachment sedimentary basins, and mafic to felsic magmatism dating from the Late Eocene to Early Miocene (Marchev et al. 2005; Voudouris et al. 2022). The Pefka-Loutros area, as part of the supra-detachment northern Hellenic Thrace basin, is associated with both sedimentary and calc-alkaline to locally shoshonitic volcanic rocks. These formations are linked to the Tertiary syn- to late-orogenic extensional processes in the Rhodope province (Kilias et al. 2013). The Pefka deposit, located within this area, is one of many high- (HS) and intermediate-sulfidation (IS) epithermal mineralizations hosted in hydrothermally altered volcanic rocks and tuffs, which exhibit intermediate argillic to sericitic-argillic and locally adularia alteration (Fig. 1b). The HS to IS epithermal Pefka deposit is structurally controlled and is characterized by multistage quartz and quartz-carbonate veins and breccias with a complex ore mineralogy. This includes sulfosalts (e.g., enargite, luzonite, tennantite), sulfides (e.g., pyrite, chalcopyrite, galena), and tellurides (e.g., hessite, altaite, coloradoite). The mineralization is enriched in base, rare, and critical metals (e.g., Cu, Fe, Au, Ag, Pb, Zn, Bi, Sn, Ge, Ga, In, Mo, V, As, Hg, Te, and Se), exhibiting an exceptional ore mineralogy that includes a wide variety of sulfides, sulfosalts, tellurides, and native metals (Dimou et al. 1994; Voudouris 2006; Melfos and Voudouris 2012; Repstock et al. 2015; Voudouris et al. 2019, 2022). Bulk ore concentrations in rock chips reach up to 2300 ppm Se, 1160 ppm In, >1000 ppm Te, 390 ppm Ag, 345 ppm Au, and 250 ppm Bi, making the deposit the richest one in Te and In grades in Greece (Melfou et al. 2023). The deposit displays at least three distinct mineralization styles. The early NNW-trending Se-rich galena-quartz vein system crosscuts the altered host rocks. This early stage is followed by an NE-trending HS vein system composed of quartz, enargite/luzonite, goldfieldite, watanabeite (Biagioni et al. 2024), colusite, chalcopyrite, roquesite, tennantite/tetrahedrite-(Cu), tennantite-(In), and native gold (Voudouris 2006; Repstock et al. 2015; Voudouris et al. 2022). Tennantite-(Cu) marks the transition from the HS to the IS stage (Voudouris et al. 2022). The late-stage mineralization is characterized by a NE-trending IS vein system primarily composed of carbonates, tellurides, and tetrahedrite-(Zn), tetrahedrite/tennantite-(Fe) (Voudouris 2006; Repstock et al. 2015; Voudouris et al. 2022). The galena-bearing assemblages are the most In-rich, while the samples with carbonate gangue are the most Te-rich.

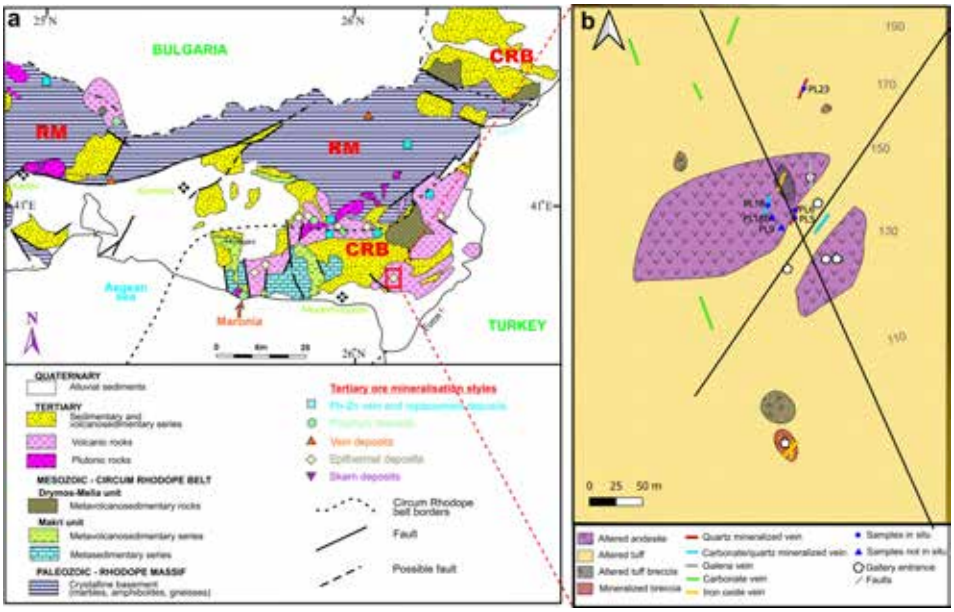

Figure 1. Regional and local simplified geological maps of the study area. (a) Geological map of the Rhodope Metallogenic Province in northern Greece, highlighting the different styles of mineralization (Melfos and Voudouris 2012). (b) Local lithological map of the Pefka HS-IS epithermal deposit, showing the locations of the samples used in this study.

Methods

Ore samples were collected from outcrops of the vein systems in the Pefka deposit and from piles outside abandoned galleries (Fig. 1a, b). Six polished sections and three polished mounts were analyzed using Electron Microprobe Analysis (EMPA) to determine the major and minor element composition of various sulfide and sulfosalt minerals. The analyses were performed with a JEOL JXA-8200 Superprobe equipped with five wavelength-dispersive X-ray spectrometers (WDS) at the GeoZentrum Nordbayern, Germany. The trace element content of sulfide and sulfosalt grains from the Pefka deposit was further analyzed by Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICP-MS), which was conducted at the GeoZentrum Nordbayern, Germany. An Analyte Excite 193 nm laser (Teledyne Photon Machines) coupled to an Agilent 7500a ICP-MS was used for this purpose, using beam diameters of 20 to 35 µm. Data processing for LA-ICP-MS measurements were performed using GLITTER. Where significant interferences were observed, such as between ^{115}In and ^{115}Sn or between ^{74}Ge and ^{74}Se, mathematical corrections were applied. Due to reduced accuracy in ^{74}Ge measurements on most analytical days, only ^{73}Ge was used.

Results

A modified paragenetic sequence of ore formation at the Pefka deposit, compared to that of Voudouris et al. (2022), is presented in Figure 2a. This study focuses on the most abundant minerals analyzed using LA-ICP-MS to link the petrographic and geochemical observations. The mineralization was divided into three main stages: Pb-Se stage 1, Cu-As-Au-In-V-Sn stage 2a and 2b, and Zn-Te-Sb stage 3 (Fig. 2b-m). Stage 1 is characterized by massive Se-rich galena veins. Stage 2a hosts luzonite and enargite that are typical for high-sulfidation (HS) environments, while Stage 2b (tennantite/tetrahedrite-(Cu) and -(Fe), watanabeite, goldfieldite, colusite) marks the transition from high- (HS) to intermediate-sulfidation (IS) conditions. Stage 3 is characterized by chalcopyrite, tellurides, tetrahedrite-(Zn) that are associated with IS environments. Galena (Fig. 2b, f, g) commonly has enargite and tetrahedrite-(Cd) inclusions in Stage 1, which is accompanied by gangue quartz, forming massive 1–2 cm thick veins. Roquesite forms at the edges of the galena (Fig. 2g), suggesting their close genetic relation (Fig. 2f). The galena is crosscut by Stage 2a-b enargite, bournonite, tennantite-(In), tennantite-(Fe), and tennantite-(Cu) (Fig. 2f). The Stage 2a mineralization predominantly consists of luzonite (Fig. 2c) or enargite, often associated with pyrite. However, the enargite and luzonite of this stage are replaced and usually appear as tennantite-(Cu) of stage 2b (Fig. 2j). Pyrite occurs in two varieties, including py_{1a} that is bright in BSE images and inclusion-rich py_{1b} that is darker in BSE mode. Py_{1a} forms thin semi-massive veins (up to 0.5 cm) (Fig. 2d) and microscopically consists of anhedral grains surrounded by tennantite-(Cu) (Fig. 2i). $Pyrite_{1a}$ usually hosts large luzonite inclusions (Fig. 2h). $Pyrite_{1b}$ is found as disseminations in quartz veins related to sericite or along with barite, sometimes enclosing py_{1a} (Fig. 2i). Chalcopyrite (ccp_1) accompanies enargite in this stage. This stage includes gray quartz containing native gold grains associated with subhedral

py_2, goldfieldite, or tennantite-(Fe) (Fig. 2k). Other sulfosalts, such as colusite and watanabeite, hosting metals like V and Sn, are part of the sulfosalt assemblage in this stage (Fig. 2j). Quartz veins from Stages 2a and 2b are associated with sericite and minor APS (aluminum phosphate-sulfate) minerals, including svanbergite ($SrAl_3(PO_4)(SO_4)(OH)_6$).

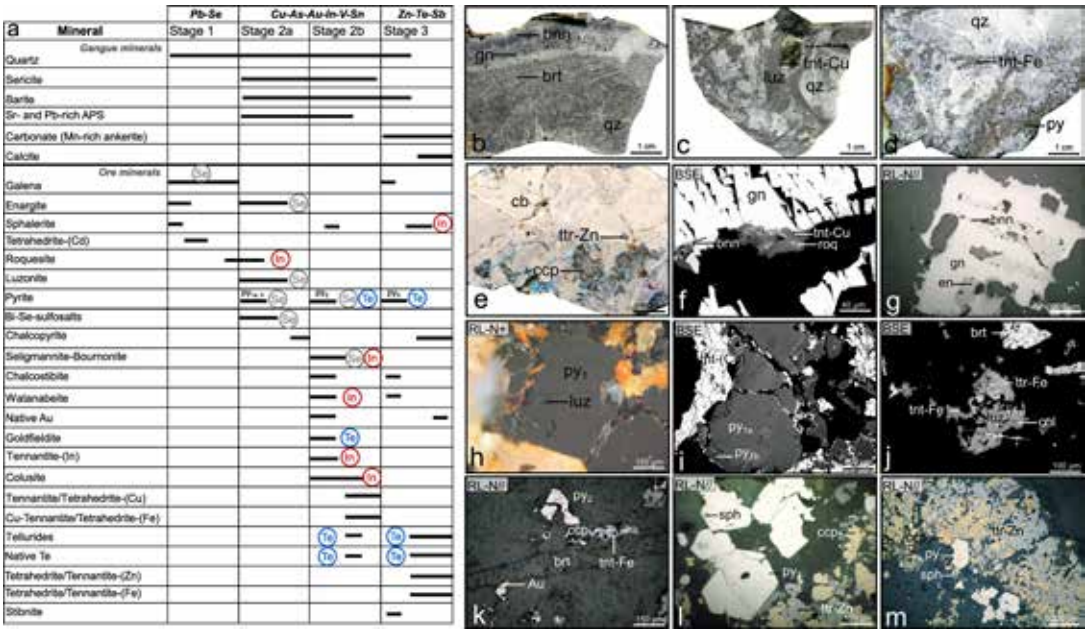

Figure 2. Simplified paragenetic sequence and macroscopic/microscopic photographs of the high-grade ore at the Pefka deposit. (a) Simplified paragenetic sequence of the Pefka deposit, focusing on analyzed sulfides and sulfosalts. (b) Galena (gn)-quartz (qz) vein of stage I, replaced by bournonite (bnn) and crosscut by an Au-rich quartz (qz) vein with barite (brt) grains. (c) Quartz vein with massive luzonite (luz), surrounded by tennantite-(Cu) (tnt-Cu). (d) Quartz vein from HS stage 2a with massive pyrite (py_{1a}) surrounded by tennantite-(Fe) (tnt-Fe) and disseminated pyrite (py_{1b}) within a sericite-rich matrix. (e) Carbonate (cb) vein of the IS stage, containing minor quartz, chalcopyrite (ccp), tetrahedrite-(Zn) (ttr-Zn), tellurides, and pyrite (py_3). (f) Galena replaced by bournonite, tennantite-(In) (tnt-In), and roquesite (roq). Remnants of galena are observed between roquesite and tnt-In. (g) Galena replaced by bournonite and enargite (en). (h) Subhedral py_1 containing luzonite mineral inclusions. (i) Anhedral, bright (in BSE) inclusion-poor py_{1a} and darker, inclusion-rich py_{1b} at the rims, surrounded by tennantite-(Cu). (j) Luzonite crosscut by barite and replaced by tetrahedrite-(Fe) (ttr-Fe) and colusite (col), accompanied by barite veins. (k) Native Au at the rims of a barite grain, accompanied by subhedral py_2 and tennantite-(Fe). (l) Euhedral py_3 hosting sphalerite (sph) and tetrahedrite-(Zn) inclusions in contact with chalcopyrite and tetrahedrite-(Zn) (m) Euhedral py_3 surrounded by chalcopyrite and tennantite-(Zn), which hosts telluride inclusions and minor sphalerite.

Stage 3 represents the IS stage, characterized by quartz and carbonate veins (Fig. 2e) comprising chalcopyrite, tetrahedrite-(Zn) and -(Fe), sphalerite, and tellurides. These are associated with euhedral pyrite (py_3), which contains numerous mineral inclusions (Fig. 2l-m). This stage is also accompanied by sericite and barite.

Variations in the elemental composition of the different pyrite generations, combined with the presence of other elements, offer valuable insights into the physico-chemical conditions of ore formation (Fig. 3a). Selenium and Te concentrations have high median values of 113 ppm and 2 ppm, respectively in py_2, while Ge is higher in py_1, with median at 2 ppm. Silver concentrations are elevated in py_1, with median values at 5 ppm, while Co is elevated in py_2, reaching 150 ppm (Fig. 3a).

Indium and Te concentrations obtained from LA-ICP-MS analyses vary among the sulfide groups, including pyrite (py_1–py_3), chalcopyrite (ccp_1-ccp_2), and galena. In pyrite, In and Te reach up to 0.5 ppm and 22 ppm, respectively, while in galena, they reach up to 30 ppm and 20 ppm, and in chalcopyrite ccp_2, up to 500 ppm and 100 ppm, respectively (Fig. 3b). LA-ICP-MS analyses of sulfosalts include luzonite from Stage 2a and bournonite, colusite and watanabeite from Stage 2b. Luzonite exhibits high Te contents of up to 3000 ppm. Luzonite is In-depleted, while bournonite of stage 2b hosts up to 30 ppm In. Colusite and watanabeite contain up to 550 ppm In and 7000 ppm Te (Fig. 3c). Indium in tennantite and tetrahedrite species reaches up to 2 wt% in the analyzed data, while previous reports noted up to 6 wt% In in the tennantite-(In) (Voudouris et al. 2022). Stage 2b tennantite/tetrahedrite-(Cu) and -(Fe) ranges from In- and Te-poor to In- and Te-rich, with tennantite/tetrahedrite-(Zn) reaching up to 1500 ppm In and 1.3 wt% Te (Fig. 3d). A slight positive correlation between In and Te content ($R^2 = 0.5$) is observed in these minerals.

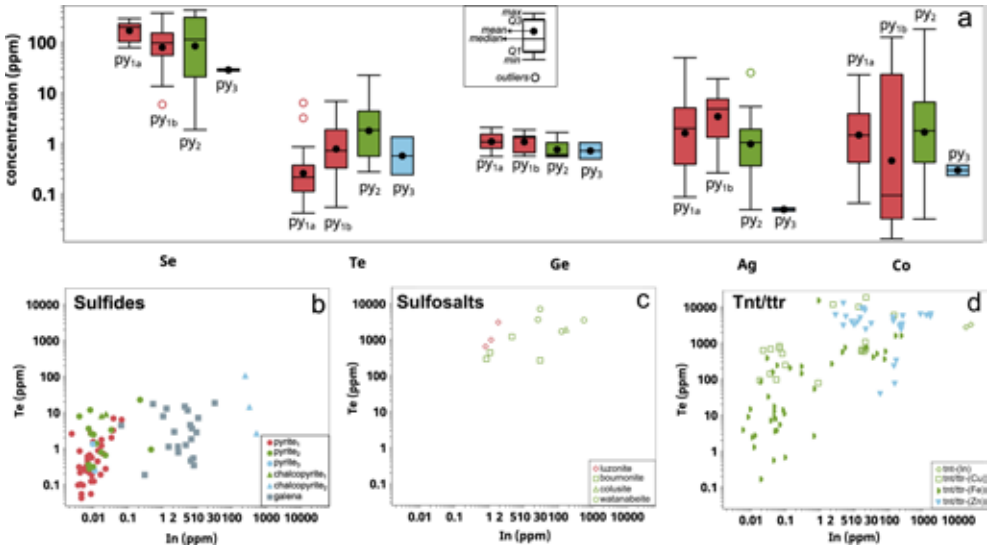

Figure 3. Geochemical variations analyzed with LA-ICP-MS from the Pefka deposit across different stages of pyrite (a), sulfides (b), sulfosalts (c), and varieties of tennantite and tetrahedrite (tnt/ttr) (d). (a) Selenium, Te, ^{73}Ge, Ag, and Co variations in the different pyrite generations. (b) In versus Te contents in different types of pyrite, chalcopyrite, and galena. (c) Indium versus Te contents in stage 2a minerals (luzonite) and stage 2b minerals (bournonite, colusite, watanabeite). (d) In versus Te contents in tennantite/tetrahedrite varieties from stage 2a (tennantite-(In), tennantite/tetrahedrite-(Cu) or -(Fe), and stage 3 (tennantite/tetrahedrite-(Zn)). Colors are indicative of the different stages: Stage 1 is grey, stage 2a is red, stage 2b is green and stage 3 is pale blue.

LA-ICP-MS profiles focusing on In and Te patterns (Fig. 4) in the different minerals suggest either micro-inclusions or the presence of these elements in solid solution. Other elements, such as Cu, Au, Ag, and Pb, were monitored to detect inclusions potentially forming phases with In and Te. Notably, only galena shows evidence of inclusions in the LA-ICP-MS patterns (Fig. 4a). In contrast, sulfosalts display smooth patterns for In and Te, suggesting that In and Te are within the mineral structures (Fig. 4b-h). However, Pb exhibits spiky patterns in tennantite-(In) and tetrahedrite-(Zn) (Fig. 4d, g), likely due to remnants of earlier galena.

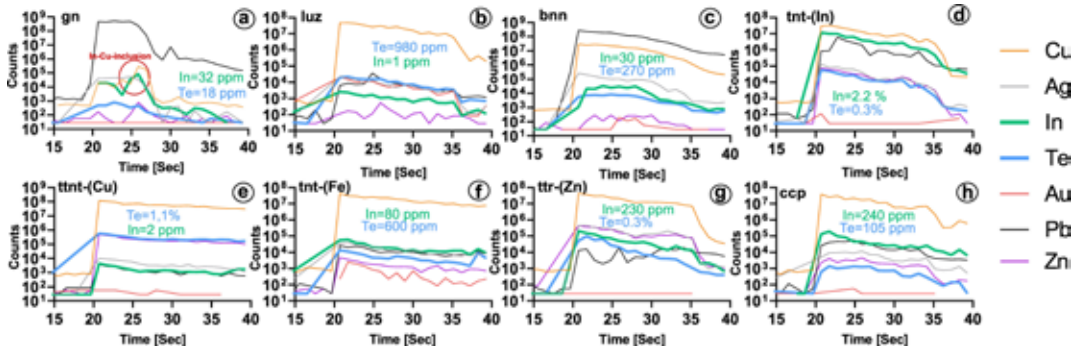

Figure 4. LA-ICP-MS time patterns of (a) galena (gn), (b) luzonite (luz), (c) bournonite (bnn), (d) tennantite-(In) (tnt-In), (e) tennantite-(Cu) (tnt-Cu), (f) Tennantite-(Fe) (tnt-Fe), (g) tetrahedrite-(Zn) (ttr-Zn), and (h) chalcopyrite (ccp). Indium and Te are illustrated with thick green and blue lines, respectively, and their concentrations after data reduction are stated. These patterns are also accompanied by those of Cu, Ag, Au, Pb, and Zn to highlight the presence of mineral inclusions or zonation.

Discussion

The Pefka deposit hosts, to our knowledge the most In and Te rich mineralization in Greece, with the presence of these two metals in a variety of minerals. The main carriers of In are roquesite that hosts 48 wt% In and tennantite-(In) that hosts up to 6 wt% In (Voudouris et al. 2022, 2023). Both minerals belong to stage 2, while roquesite also appears at the end of stage 1. Indium is also present in sphalerite of stage 3 (up to 0.31 wt%; Voudouris et al. 2022). The main carriers of Te are stage 2b goldfieldite that host up to 23 wt% Te and stage 3 tellurides (e.g., hessite, petzite, coloradoite, native Te, etc), in which Te is the main constituent of the minerals. The tellurides also occur in minor amounts in stage 2b in association with goldfieldite. The in-situ LA-ICP-MS analyses revealed the ability of sulfides, including pyrite, galena, and chalcopyrite, as well as sulfosalts like tennantite-tetrahedrite, enargite, colusite, bournonite, and watanabeite to host In and Te in their

structure or in the form of micro-inclusions. Galena shows a moderate enrichment of In, but as revealed by the LA-ICP-MS spectra, this is related to the presence of micro-inclusions, probably of roquesite. Stage 2a minerals like luzonite show no enrichment in In (up to 2 ppm) and a moderate enrichment in Te (up to 3000 ppm) (Fig. 4c and 5b). The sulfosalts of stage 2b, excluding the main carriers (i.e. roquesite), host up to 550 ppm In and 1.9 wt% Te. Stage 3 of the mineralization hosts up to 2500 ppm of In and 2 wt% of Te. Therefore, it is indicated that all stages host In, while Te is mainly hosted in stages 2b and 3. Higher In grades in global epithermal/polymetallic deposits have been detected in Sn-rich systems (Mejías et al. 2023). This fact is also seen at the Pefka deposit with the co-occurrence of In-rich minerals of stage b like tennantite-(In)/bournonite and Sn-rich minerals like colusite that have also high In-contents.

Pyrite, a well-studied and ubiquitous mineral in epithermal deposits, serves as a valuable indicator of ore-forming conditions throughout the different mineralization stages. Different pyrite generations in the Pefka deposit show a progressive evolution in chemistry, particularly in specific elemental ratios, which provide insights into processes like cooling, fluid mixing, and boiling (Keith et al. 2022; Falkenberg et al. 2024). The Se/Te ratio has been used to indicate temperature changes (Keith et al., 2022; Falkenberg et al., 2024). Pyrite data from the Pefka show that py_{1a} formed at higher temperatures, with median Se/Te ratios around 1000, while py_3 exhibits median Se/Te ratios closer to 1, suggesting lower temperatures of formation (Fig. 5a). Other pyrite generations fall progressively between these values: py_{1b} has a median ratio of ~100, while py_2 displays median values around 10. In the Koloula (Solomon Islands) and Maronia (Greece) porphyry-epithermal systems, pyrite formed above 350 °C has median Se/Te ratios >50, while lower-temperature pyrite shows ratios <50 (Keith et al., 2022; Falkenberg et al., 2024). This aligns with mineralogical evidence from Pefka, suggesting its initial HS sulfidation occurred above 300 °C (Voudouris et al., 2022).

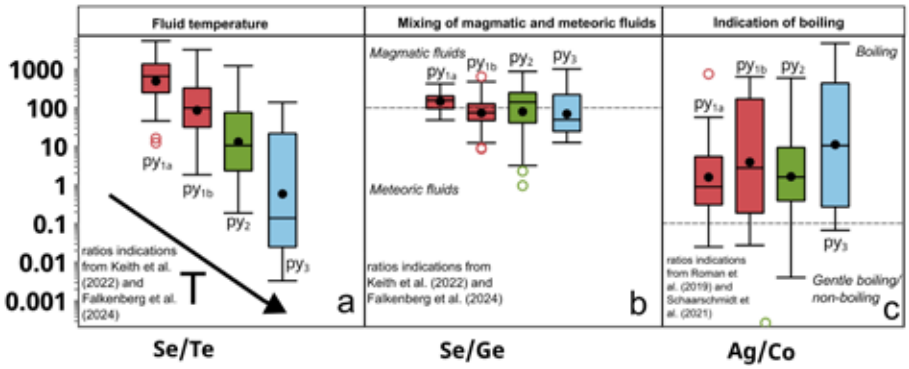

Figure 5. Boxplots from ratios derived from in-situ LA-ICP-MS data in pyrite from the Pefka deposit, used to infer physicochemical parameters of the ore-forming conditions. (a) The Se/Te ratio, which indicates cooling of the fluid temperature (Keith et al., 2022; Falkenberg et al., 2024). (b) The Se/Ge ratio, which reflects the mixing of magmatic and meteoric fluids (Keith et al., 2022; Falkenberg et al., 2024). (c) The Ag/Co ratio, that reflects boiling or non-boiling conditions (Román et al., 2019; Schaarschmidt et al., 2021). Colors are indicative of the different stages: Stage 1 is grey, stage 2a is red, stage 2b is green and stage 3 is pale blue.

The Se/Ge ratio has been applied to indicate fluid mixing, particularly between magmatic and meteoric fluids (Keith et al. 2022; Falkenberg et al. 2024). $Pyrite_{1a}$ and py_2, have median Se/Ge ratios that fall within the magmatic fluid field while the Se/Ge ratio of py_{1b} and py_3 points towards ore fluids with a mixed magmatic and meteoric fluid component (Fig. 5b). It is notable that the high-In stage 2b shows elevated Se/Ge ratios, suggesting important contribution of the magmatic fluids at the In-rich stage. The Ag/Co ratio of pyrite has been used in studies to differentiate boiling from non-boiling environments (Román et al. 2019; Schaarschmidt et al. 2021). At Pefka, all pyrite grains have Ag/Co ratios above 1, indicative of boiling conditions (Fig. 5c). Evidence for boiling at Pefka is also provided by the telluride mineralogy and the presence of adularia alteration in the surrounding rocks, including the andesitic host rock (i.e. Voudouris et al., 2022).

Conclusion

The outcome of this study is the In and Te partitioning in a multi-mineral assemblage where sphalerite is volumetrically rare, providing valuable insights into their distribution in various sulfide and sulfosalt species. Early-stage galena shows moderate enrichment, with In and Te concentrations reaching up to 30 ppm and 20 ppm, respectively, possibly because of the presence of inclusions. In contrast, later-stage tetrahedrite-tennantite varieties exhibit significantly higher concentrations, with up to 6 wt% In and 1.9 wt% Te. Pyrite, analyzed across multiple generations, provides valuable insights into the evolution of the hydrothermal system. A systematic decrease in the Se/Te ratio of pyrite—from magnitudes around 1000 to values close to 1—indicates progressive cooling of the ore-forming fluids. Additionally, Ag/Co ratios in pyrite suggest boiling conditions during both the high-

sulfidation (HS) and intermediate-sulfidation (IS) stages. The LA-ICP-MS analyses reveal that sulfosalts play a critical role in hosting In and Te, from HS, during the transition and final IS stages. Minerals such as tennantite-tetrahedrite, colusite, and watanabeite act as significant carriers, with In and Te present both in solid solution and as inclusions. These findings underscore the importance of sulfides and sulfosalts not only as repositories of critical metals but also as proxies for reconstructing the physicochemical processes that governed ore deposition in the Pefka deposit. Future research will focus on the distribution of other elements in sulfosalts and sulfides, such as Se, Ag, and Au, which are particularly enriched at Pefka. Additionally, pyrite trace element ratios, which provide insights into ore-forming conditions, will be compared with those from similar systems.

Acknowledgements

Dr. H. Brätz is thanked for her assistance during the LA-ICP-MS analyses and data processing. Boliden Mineral AB is gratefully acknowledged for providing financial support to the PhD thesis of M. Melfou entitled “Mineralogy geochemistry and ore genesis of the critical and rare metals enrichment in the high- to intermediate-sulfidation epithermal systems at the Pefka-Loutros area, Rhodope, Greece”.

Research Highlights

The geological mapping of Crete, undertaken over several decades, represents a monumental effort to document the island's complex and diverse geology. However, the varying methodologies, technologies, and scientific approaches employed during different survey periods have resulted heterogeneity in the maps produced. This paper highlights advancements in the visualization and integration of geological data within a GIS environment, providing new opportunities for cohesive and comprehensive geological interpretations of Crete.

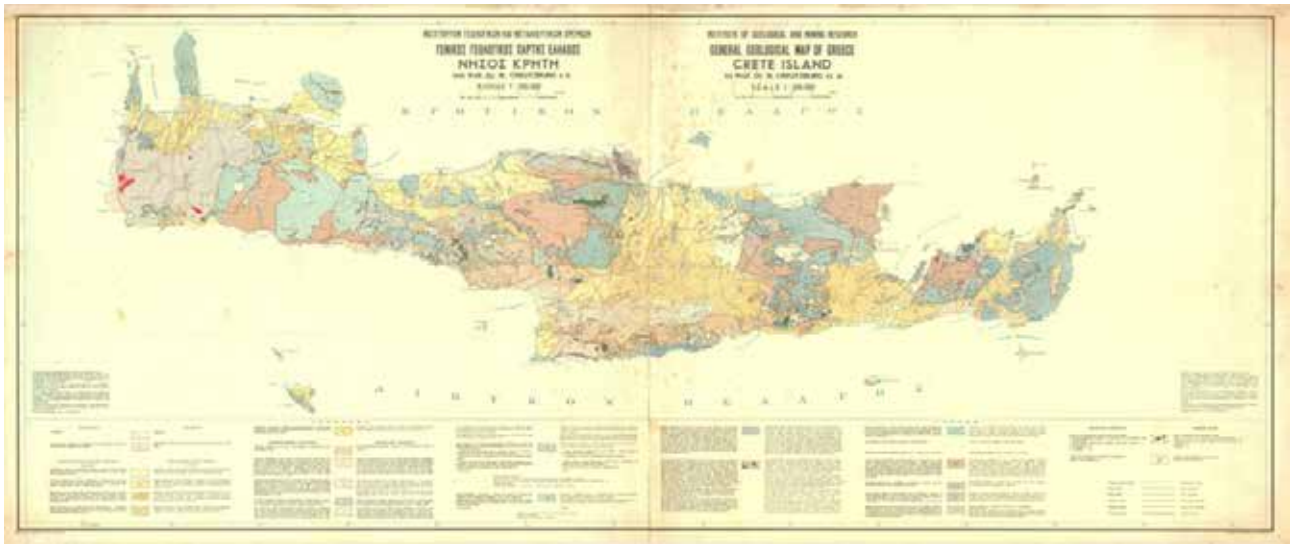

Figure 1. The General Geological Map of Greece / Island of Crete, published by the Institute of Geological and Mining Research (IGMR) in 1977, at a scale of 1:200k (*Commonly known as the Geological Map of Crete by Creutzburg et al.*).

Introduction / History of Publication of Geological Maps of Crete

The geological framework of the island of Crete is extensively documented in the General Geological Map of Greece / Island of Crete, published in 1977 by the Institute of Geological and Mining Research (IGMR), at a scale of 1:200k (Figure 1). This foundational and legacy map represents one of the most significant milestones in capturing the geological complexities of the island. Crete (including Gavdos island) is covered by 24 map sheets (Figure 2) that form part of the Basic Geological Map of Greece (BGMG), produced by the Institute for Geology and Subsurface Research (IGSR)—later renamed the Institute of Geology and Mineral Exploration (IGME), and now known as the Hellenic Survey of Geology and Mineral Exploration (HSGME). These maps, published at a scale of 1:50k between 1956 and 2013, provide a more detailed account of Crete's geological units and structures. The geological mapping of Crete reflects a systematic and iterative process spanning several decades, undertaken by HSGME and its predecessor organizations (IGSR, IGMR, and IGME).

Background / Geological Map Sheets of Crete

The geological mapping of Crete has undergone remarkable advancements over decades of systematic surveys, as summarized in Table 1 and illustrated in Figure 2. The need for a detailed geological map to capture the island's complex geological framework became evident as early as the mid-20th century (Aronis, 1949). In the following years, the IGSR focused on extensive fieldwork, resulting in foundational geological maps at a scale of 1:50k. Notable examples include the Alikianos (Vatolakkos) map sheet in Western Crete (Christodoulou & Tataris, 1969; Figure 4.2) and the Kato Chorio (former Ierapetra) map sheet in Eastern Crete (Papastamatiou et al., 1959; Figure 4.1). These pioneering efforts provided critical insights into the geological structure of the island and paved the way for future

advancements. Figures 4.1 and 4.2 depict the updated versions of these map sheets—soon to be released by the HSGME—showcasing significant progress in geological mapping techniques and visualization. These updates are part of the BGMG series, reflecting the integration of modern methodologies and technologies focused on creating a more cohesive and accurate geological framework for the region.

In 1977, the IGMR published the General Geological Map of Crete at a scale of 1:200k, consolidating decades of geological research (Creutzburg & Papastamatiou, 1966; Creutzburg et al., 1977) and serving as a foundational resource for understanding the island's geology. In the subsequent decades, the IGME (now the HSGME) advanced this work by completing the island's detailed geological framework as part of the BGMG series (Table 1). These endeavors were concentrated on diverse methodologies and advancements in earth science techniques, including petrographic and micropaleontological analyses. The historical evolution of geological mapping in Crete reflects monumental scientific labor, laying the groundwork for modern geological studies while addressing the challenges of heterogeneity in methodologies and outputs over time.

Table 1 (as a reference) provides an overview of the geological map context of Crete (including Gavdos sheet), summarizing critical data such as map sheets, scales, publication bodies, years of publication, and survey periods. This information underscores the extensive involved effort in documenting the island's complex geological framework (Figure 2). The figure effectively organizes these map sheets across the region, optimized by their publication years, showcasing the chronological progression of geological surveys. This dataset highlights the evolution of geological documentation in Crete, beginning with foundational surveys in the mid-20th century and advancing to modern updates that incorporate sophisticated methodologies. However, despite these extensive efforts, several objective difficulties and challenges remain. These include the integration and evaluation of historical and modern bibliographic data, georeferencing older map sheets to contemporary grids, and homogenizing geological data across varied methodologies and periods. Addressing these challenges is critical for achieving a cohesive and accurate geological framework for the region.

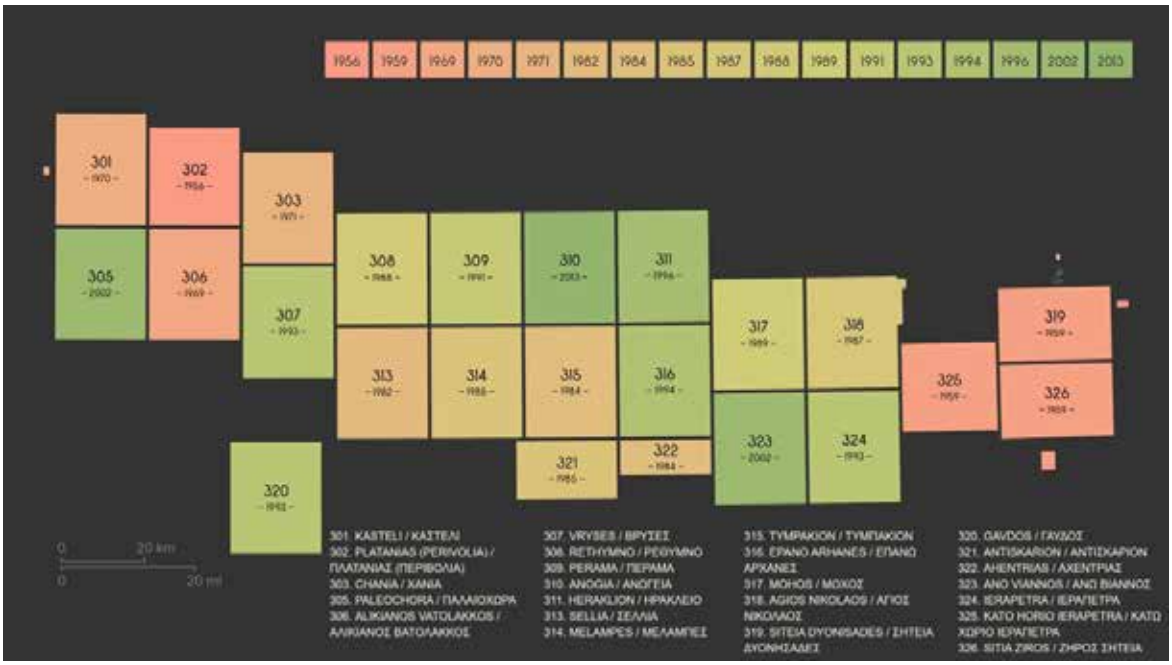

Figure 2. The spatial distribution of the 24 map sheets of the BGMG series, covering the region of the island of Crete (and Gavdos). Optimization based on the publication year.

Objectives

The geological mapping of Crete, conducted over several decades, represents a monumental effort to document the island's intricate and diverse geology. However, the use of varying methodologies, technologies, and scientific approaches during different survey periods has introduced heterogeneity into the resulting maps. This study aims to provide an overview of the Geological Map Sheets of Crete produced by IGME, as well as the ongoing progress by HSGME in advancing this work. A critical focus is on the integration of these maps within a GIS environment, which represents a significant step toward achieving a comprehensive and cohesive geological understanding of Crete.

Table 1. The geological context of the island of Crete is documented in the "General Geological Map of Greece / Island of Crete", published by the IGMR in 1977 at a scale of 1:200k. Additionally, the region of Crete is covered by 24 map sheets from the BGMG series produced by the IGSR (later IGME and now known as HSGME) between 1956 and 2013.

Methods and Challenges

The revision of the geological mapping of Crete and its tectono-stratigraphic structure of alpine and post-alpine formations involved a combination of intensive field mapping, field tectonic measurements, sampling, and laboratory analysis. These efforts were further supported by the application of remote sensing techniques and Geographic

Information Systems (GIS) methods (Figures 3.1 & 3.2). The integration of these tools allowed for detailed geological cartographic results, which were subsequently homogenized and correlated with neighboring geological map sheets. This ongoing process (as part of the projects referenced in the Acknowledgements), has contributed to the development of the BGMG at a scale of 1:50,000, accompanied by a detailed explanatory document for each map sheet.

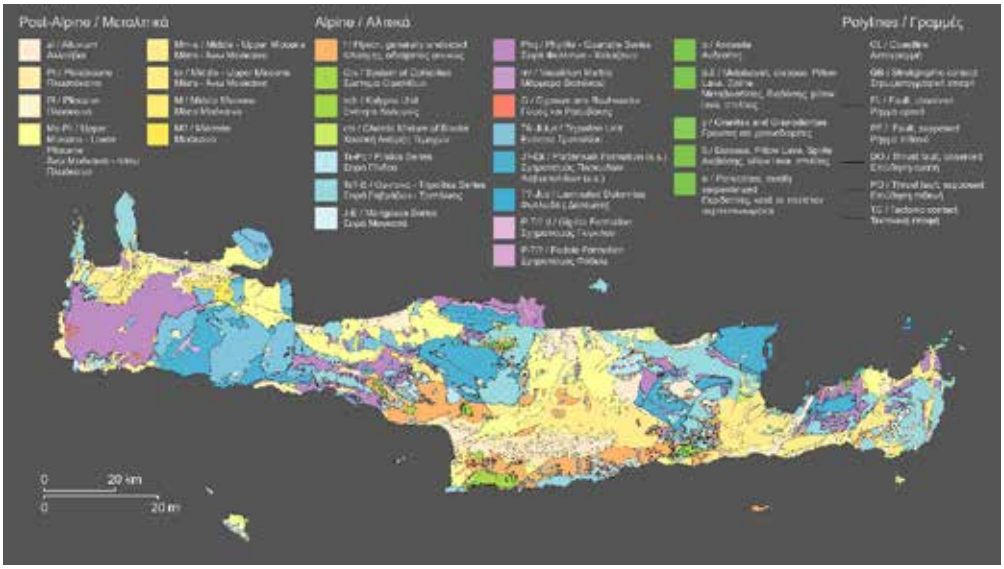

Figure 3.1. The geological setting of the island of Crete, as depicted in the 1:200k Geological Map by Creutzburg et al. (1977), has been further optimized and refined through the application of GIS for enhanced spatial analysis and accuracy.

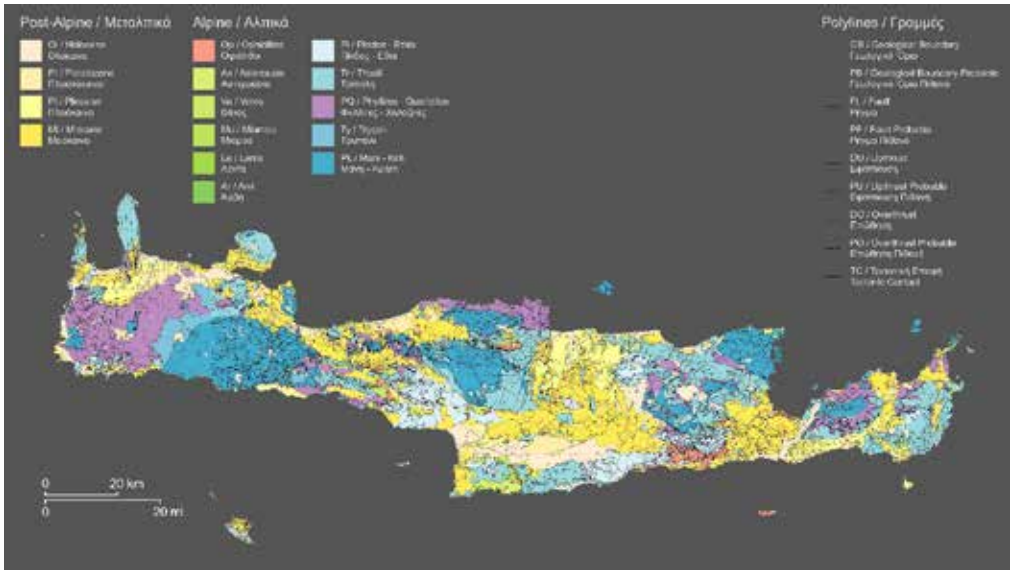

Figure 3.2. The geological setting of the island of Crete, as depicted by the 24 map sheets of the BGMG series, produced by the IGME (1956-2013).

Over the decades, numerous researchers contributed to geological maps of Crete, but these were often based on different methodologies and topographic bases. As a result, discontinuities emerged in the positioning of geological boundaries, in the classification of lithological formations, and in the depiction of tectonic elements, leading to problems, not only in the margins of adjoining map sheets. Various researchers from various schools of thought have carried out geological maps over extended periods, and their results have consequently been projected on different topographic maps. This resulted in the accommodation of geological boundaries in the exact locations and content of the lithological formations with tectonic elements, not coinciding with neighboring sheets.

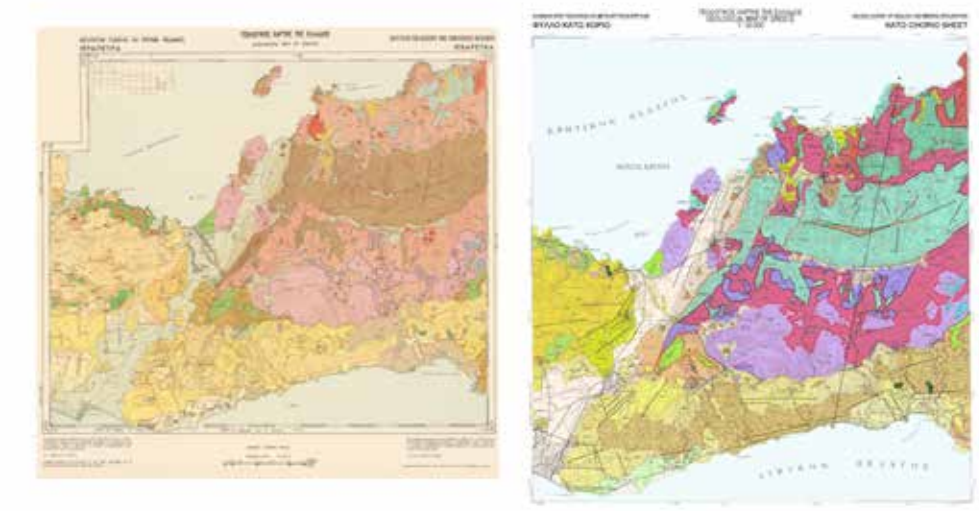

Figure 4.1. The evolution of geological mapping for the Kato Chorio (Ierapetra) map sheet in Eastern Crete. On the left is a segment of the original map, published in 1959 by IGSR, representing one of the foundational efforts in geological documentation. The right panel presents the updated version of the same sheet—soon to be released by HSGME.

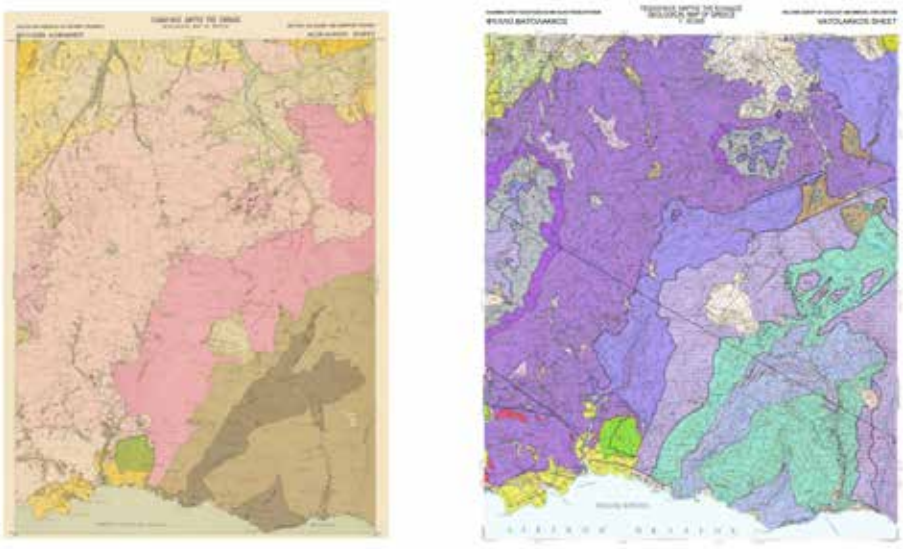

Figure 4.2. The evolution of geological mapping for the Alikianos (Vatolakkos) map sheet in Western Crete. On the left is a segment of the original map, published in 1969 by the IGSR, showcasing one of the foundational efforts in documenting the region's geology. On the right is the updated version of the same sheet—soon to be published by the HSGME.

Addressing these challenges required a multifaceted approach including collection, evaluation, and utilization of bibliography, georeferencing of older maps, grouping and homogenization of geological data, integration of modern geological perspectives, field mapping and data collection, physical and logistical barriers, GIS and cartographic optimization. To meet the objective difficulties and challenges, the fieldwork mapping effort was based on sampling and evaluation of on-site data along with parallel laboratory information and using broadly a modern bibliography. With the georeferencing of older map sheets in Greek Grid (*in Greek EGSA 87'*), in the documentation and appropriate interpretation, grouping-homogenization of geological elements, significant problems were identified within the boundaries of the formations, in the compilation and integration of new data (e.g. geochronological data) and tectonostratigraphic views on the geological structure of Greece. All observations and correlations were focused on the grouping and differentiation of geological formations, primarily categorized into basic lithostratigraphic sequences.

Results

Significant progress has been achieved in revising and homogenizing the 24 geological map sheets of Crete, including Gavdos. Two prominent examples illustrate this advancement: the geological map sheets of Vatolakkos (Western Crete) and Kato Chorio (Eastern Crete). These revised maps (Galanakis et al., 2024; Photiades & Kalogiannis, 2024) incorporate detailed geological cross-sections and tectonostratigraphic unit columns (pre-alpine and post-alpine formations), all compiled using a unified legend. Comparative analyses of these sheets highlight significant differences in both cartographic quality and geological structure (Figures 4.1 and 4.2). For instance, the Vatolakkos sheet in Western Crete extensively represents the full Plattenkalk sequence, ranging from the Upper Triassic to the Eocene, overlain by a meta-flysch formation dated to the Upper Eocene–Lower Oligocene (Figure 4.2). In contrast, the Kato Chorio sheet in Eastern Crete depicts only the uppermost members of the Plattenkalk sequence (Eocene) and the meta-flysch formation (Figure 4.1). Based on these maps, a new comprehensive geological map of Crete has been compiled. This updated map addresses many of the interregional inconsistencies and challenges that arose due to temporal and methodological gaps in the historical geological mapping of Crete (Table 1). The systematic revision and digitization of geological maps provides a valuable foundation for addressing modern challenges. These maps contribute substantially to sustainable development by enabling better planning for large infrastructure projects, optimizing the utilization of natural resources, and improving the management of natural hazards associated with the climate crisis.

Conclusions

The historical progression of geological mapping in Crete represents a monumental scientific endeavor, highlighting decades of systematic surveys that have substantially advanced knowledge of the island's intricate geology. Despite these achievements, challenges such as inconsistencies in methodologies, outdated bibliographic data, and issues in georeferencing older map sheets must be addressed to achieve a unified and accurate representation of Crete's geological context. Moving forward, continued efforts to integrate, update, and modernize the island's geological data are essential. These initiatives will not only build upon the foundational work of past surveys but also ensure that the resulting geological framework supports future research and contributes to the sustainable management of Crete's natural resources.

Acknowledgements

The authors would like to express their sincere gratitude to the personnel of the HSGME who contributed to *the Hydrogeological Mapping at a Scale of 1:100,000: Case Study of the Island of Crete* (part of the National Development Programs for the period 2021–2025, Ministry of Environment & Energy) and to the personnel involved in the revision and homogenization project of the Basic Geological Map of Greece (2019–2023), carried out within the framework of Project GEOINFRA: *Geological Mapping of Greece towards Support of Innovation and Entrepreneurship* (NSRF 2014–2020).

EXTENDED ABSTRACT 209

Water Wells in Crete: Distribution by Municipality, Use, and Ownership—Results of a Systematic Inventory in Greece.

I. Michalakis[1], E. Tsolaki[1]
(1) Hellenic Survey of Geology and Mineral Exploration, Regional Branch of Crete, Rethymno, Greece, michalakis@eagme.gr

Research Highlights

One of the recent projects undertaken by the Department of Hydrogeology at the Hellenic Survey of Geology and Mineral Exploration (HSGME), co-financed under the European Union's Corporate Regional Development Agreement for the 2014-2020 period, involved a systematic inventory of water wells (boreholes) throughout the country of Greece. In Crete and the island of Gavdos, extensive fieldwork conducted by experienced personnel from HSGME spanned from July 2019 to January 2023, lasting a total of 43 months. This comprehensive effort resulted in the identification and documentation of 5,349 water wells (boreholes) across the 24 municipalities of the region (Figure 1).

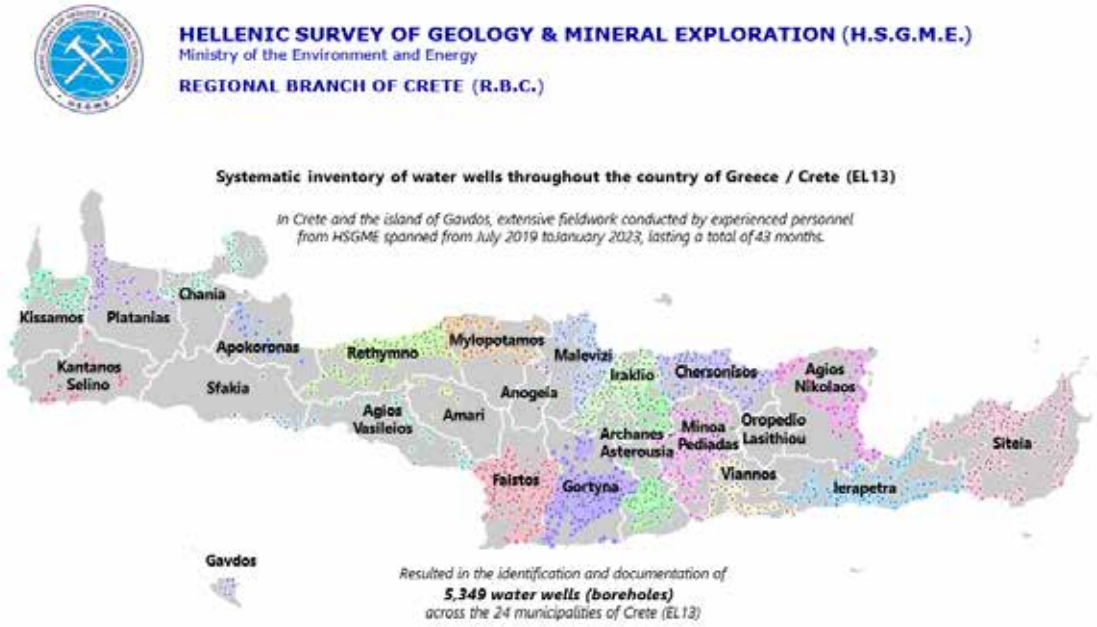

Figure 1. Results of a systematic inventory of water wells (boreholes) conducted across Water District EL13, which identified and documented 5,349 water wells within the 24 municipalities of the region. Different colored dots represent boreholes categorized by their respective municipalities, while white lines delineate municipal boundaries.

Introduction

Since the early 2000s, the European Union has implemented transformative water resource management policies, most notably the Water Framework Directive (Directive 2000/60/EC). Effective from 22 December 2000, this Directive establishes integrated quality, ecological, and quantitative targets for the protection of aquatic ecosystems, aiming to achieve "*good status*" for all water resources through a holistic, basin-scale approach. The Directive expands the definition of a River Basin to include inland surface waters (e.g., rivers, lakes), groundwater, and transitional and coastal ecosystems (e.g., deltas and estuaries). To realize its objectives, the Directive mandates the development and implementation of Management Plans at the River Basin level, as outlined in Article 13 and Annex VII. These plans incorporate Programs of Measures for the Protection and Rehabilitation of Waters, as specified in Article 11 and Annex VI.

In Greece, River Basin Management Plans have been developed in alignment with Directive 2000/60/EC and formalized through Law 3199/2003 and Presidential Decree 51/2007. These plans provide comprehensive details on River Basin Districts, River Basins, and surface and groundwater bodies.

As a complement to the "*Groundwater Monitoring Network of Greece*" (HSGME/RBC, 2019-2023), the Department of Hydrogeology at HSGME initiated the "*Systematic Inventory of Water Wells for All Uses Throughout the Country of*

Greece" (HSGME, 2019-2023). Co-financed under the European Union's Corporate Regional Development Agreement for the 2014–2020 period, this project sought to address critical gaps in groundwater data and understanding. The outcomes of this project directly support the initiatives of the General Directorate of Water within the Ministry of Environment and Energy, strengthening national water policies. These efforts ensure the protection of both the quality and quantity of Greece's water resources, fulfilling obligations under European Union Directives 2000/60/EC, 2006/118/EC, and 91/676/EEC. The project's functionality is integrated with the geospatial database and services system of the National Register of Water Abstraction Points (*in Greek: "EMSY"*). Established in January 2014, EMSY is an electronic register maintained by the General Directorate of Water (formerly the Special Secretariat for Water) in compliance with Greek Law 3882/2010, which was adopted following Directive 2007/2/EC.

Background / Project Overview (EL13)

For Water District EL13, which includes the Island of Crete and the Island of Gavdos, the majority of water needs are met through water wells (boreholes) and the exploitation of groundwater reserves (IGME, 2009). Groundwater management in Crete poses significant challenges, as it requires the collaboration of multiple stakeholders. Various authorities are involved in managing groundwater resources, including municipalities, municipal enterprises for water supply and sewerage, local land reclamation organizations, and the Water Directorate of the Decentralized Administration of Crete, alongside numerous individual stakeholders. This multiplicity of actors complicates coordination efforts and hinders effective management. The widespread prevalence of illegal water wells (boreholes) further exacerbates these challenges, making it increasingly difficult to achieve sustainable groundwater resource management. Despite significant progress made by the Department of Water Management within the Decentralized Administration of Crete in implementing the River Basin Management Plan and its updates, several obstacles persist (General Directorate of Water, 2024).

Between July 2019 and January 2023, extensive fieldwork conducted by experienced HSGME personnel across Crete and the island of Gavdos yielded valuable insights (HSGME/RBC, 2019–2023). This systematic inventory not only documented the distribution and status of water wells (boreholes) but also enhanced understanding of the geological and hydrogeological conditions of the region. These findings establish a robust foundation for future investigations and make a significant contribution to the sustainable management of groundwater resources on the island.

Objectives

This study aims to present aggregate data on the spatial and percentage distribution of water wells by municipality, use, and ownership, derived from a systematic inventory conducted across Water District EL13 (Island of Crete and Island of Gavdos). Site inspections, carried out in collaboration with local authorities—including municipalities, local communities, municipal water and sewerage enterprises, local land reclamation organizations, and the Water Directorate of the Decentralized Administration of Crete—as well as with individual stakeholders. These efforts resulted in the identification and documentation of 5,349 water wells (boreholes) across the 24 municipalities of the region.

Methods

To implement the objectives of the project *"Systematic Inventory of Water Wells for All Uses Throughout the Country of Greece*" (Subproject 1: "*On-site inspections, direct inventory of water wells and completion of inventory forms*") in Crete (Water District EL13), the Regional Branch of Crete, in collaboration with the Hydrogeology Directorate of HSGME, was designated as the responsible department.

The project commenced with organizational meetings at the Water Directorate of the Decentralized Administration of Crete, followed by the coordination efforts of the Regional Branch to conduct on-site visits municipality by municipality. Initial meetings were held with key local stakeholders, including mayors, deputy mayors responsible for water management, presidents and directors of municipal water and sewerage enterprises, presidents of local communities, local water distributors, and presidents and staff of local land reclamation organizations. Following these discussions, field campaigns were organized to carry out the inventory (Figure 5). To guide field inspections, all available datasets from local authorities were collected, compiled into geodatabases, and thoroughly reviewed. These geodatabases served as a critical resource for planning and optimizing fieldwork efforts. For instance, the geodatabase of the Water Directorate of the Decentralized Administration of Crete recorded 3,657 boreholes as of July 2019 and 3,884 boreholes as of October 2021 (Water Directorate of Crete, accessed: July 2019; October 2021; December 2024).

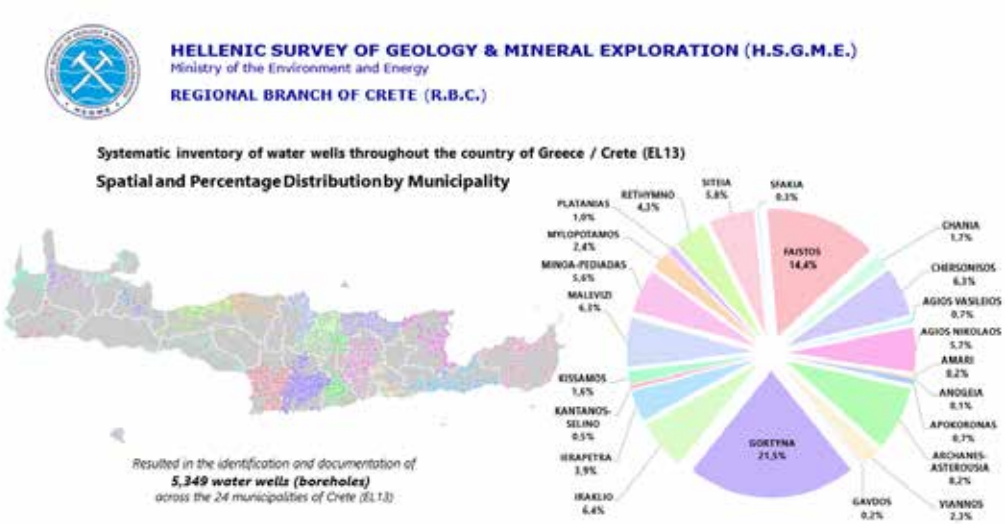

Figure 2. Spatial and Percentage Distribution of Water Wells (Boreholes) in Water District EL13 (Island of Crete and Island of Gavdos). This figure presents the results of a systematic inventory of water wells (boreholes) conducted across Water District EL13, documenting a total of 5,349 wells within the region's 24 municipalities. Colored dots represent boreholes associated with individual municipalities, while white lines delineate municipal boundaries. The accompanying pie chart illustrates the percentage distribution of boreholes by municipality within the district.

Experienced personnel from HSGME were organized into teams of two for field inspections, collaborating with available staff from local authority stakeholders. With their assistance, field inspections were conducted in coordination with individual stakeholders within their respective areas of responsibility.

The on-site inventory of water wells involved completing inventory forms with technical data (e.g., depth, pump specifications), informational details (e.g., ownership, location, coordinates in the Greek Grid), usage information (e.g., irrigation, drinking, period and hours of pumping), and field measurements (e.g., depth of water level, discharge, physicochemical parameters).

All collected data was entered into the project's geodatabase, providing a critical resource for assessing water balances, evaluating the status of the island's groundwater systems, and estimating the pressures exerted on them. This comprehensive data supports the development of appropriate measures aimed at achieving rational and sustainable groundwater management.

As part of the project, Technical Reports on Groundwater Systems within Water District EL13 are being prepared in alignment with the requirements outlined in Greece's River Basin Management Plans.

Results

Aggregate data on the spatial and percentage distribution of water wells (boreholes) by municipality, use, and ownership, derived from a systematic inventory conducted across Water District EL13 (Island of Crete and Island of Gavdos), are presented in Table 1 and Figures 2–4. The inventory resulted in the identification and documentation of **5,349 water wells (boreholes)** across the **24 municipalities** of the region (Table 1; Figures 1 and 2).

The **Municipality of Gortyna** accounts for **21.5%** of all water wells in Crete, followed by the **Municipality of Faistos** with **14.4%** and the **Municipality of Archanes-Asterousia** with **8.2%** (Figure 2). Notably, **52% of all water wells in Crete** are located within the municipalities of Faistos, Gortyna, Archanes-Asterousia, Minoa-Pediadas, and Viannos (Michalakis et al., 2022; HSGME/RBC, 2019–2023). Within the **wider area of the Messara Basin, 46.3%** of all water wells in Crete are concentrated (Michalakis, I., 2024).

Regarding usage, **79.4% of the wells on the Water District EL13 are designated for irrigation**, while **10.5% are used for water supply (drinking water)**. A further **7.6% of the wells are abandoned or no longer in use** (Figure 3).

Ownership data indicate that **68.6% of water wells are privately owned**, followed by **16.4% owned by municipalities**, **9.4% by municipal water and sewerage enterprises**, and **4.6% operated by local land reclamation organizations** (Figure 4).

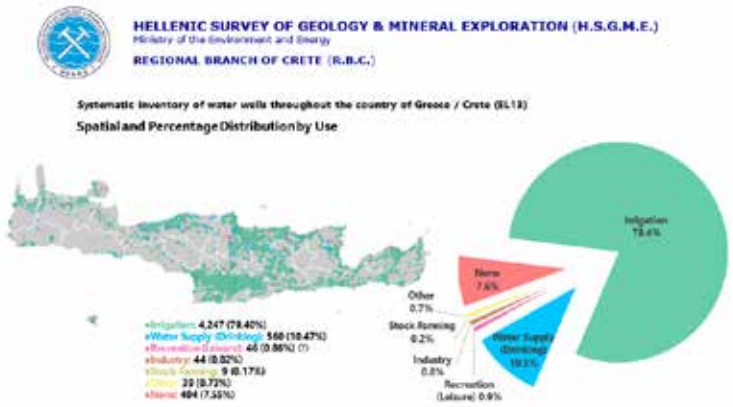

Figure 3. Spatial and Percentage Distribution by Use of Water Wells (Boreholes) in Water District EL13 (Island of Crete and Island of Gavdos) and corresponding pie chart. Different colored dots on the map represent boreholes categorized by specific usage, as detailed in the map legend.

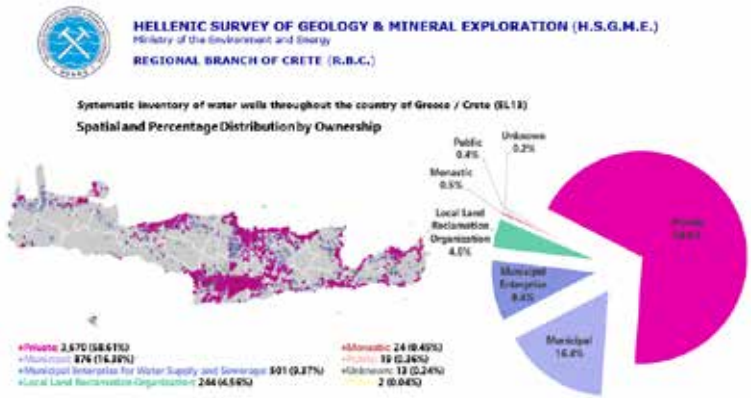

Figure 4. Spatial and Percentage Distribution by Ownership of Water Wells (Boreholes) in Water District EL13 (Island of Crete and Island of Gavdos) and corresponding pie chart. Different colored dots on the map represent boreholes categorized by ownership type, as detailed in the map legend.

Table 1 presents aggregate data by municipality, classified according to the respective main use and ownership of water wells (boreholes). Numeric values indicate the total number of wells, with corresponding percentages (%) shown in parentheses, and are provided for reference.

Table 1. Aggregate data by municipality, main use, and ownership derived from the inventory of water wells (boreholes) conducted across Water District EL13.

		Main Use		Main Ownership			
Municipality	**Total Number of Water Wells (%)**	**Irrigation (%)**	**Water Supply (%)**	**Private (%)**	**Municipal (%)**	**Municipal Enterprises (%)**	**Local Land Reclamation Organization (%)**

Conclusions

This study provides a comprehensive overview of the systematic inventory of water wells conducted across Water District EL13. The identification and documentation of **5,349 water wells (boreholes)** across **24 municipalities** represent a significant milestone in understanding the spatial and functional distribution of groundwater abstraction points. The findings reveal key insights into the distribution and use of water wells. The **wider area of the Messara Basin**, a critical agricultural and hydrogeological region in central-southern Crete, accounts for **2,474 wells** (**46.3% of the island's total**), highlighting the region's significant dependency on groundwater for irrigation.

Irrigation dominates water use, representing **79.4% of all wells**, followed by **water supply** (**10.5%**) and a smaller fraction of wells (**7.6%**) that are abandoned or not in use. Ownership patterns indicate a high prevalence of **private wells** (**68.6%**), highlighting the challenges of regulatory oversight and sustainable resource management.

The geodatabases developed as part of this inventory serve as a vital tool for planning and decision-making. They provide a foundation for assessing water balances, evaluating groundwater pressures, and formulating appropriate management strategies. By integrating technical, informational, and usage data, the inventory supports compliance with Greece's River Basin Management Plans and aligns with the European Union's Water Framework Directive and related policies.

The successful implementation of this project demonstrates the importance of collaboration among stakeholders, including local authorities, municipal enterprises, land reclamation organizations, and individual users. Despite challenges such as the prevalence of illegal wells and the complexity of coordinating multiple actors, this initiative contributes significantly to improving the management and sustainability of Crete's groundwater resources.

Future efforts should focus on strengthening the monitoring of groundwater systems, enforcing regulations on illegal wells, and promoting sustainable water use practices. These actions are crucial to safeguarding groundwater resources and addressing the growing pressures of agricultural demand, climate variability, and population growth in the region.

Figure 5. Random photographs from fieldwork conducted during the systematic inventory across Water District EL13.

Acknowledgements

Fieldwork was conducted by the executive staff—Athanasouli Elpida, Davrados Michalis, Lionakis Ioannis, Papanikolaou Kassiani, Pavlidou Saia, Tsolaki Eleni, Zourmpakis Evangelos, and the first author—from the Regional Branch of Crete and the Department of Hydrogeology of HSGME as part of the project "*Systematic Inventory of Water Wells for All Uses Throughout the Country of Greece"*. The authors express their gratitude to the personnel of local authorities, including mayors, deputy mayors responsible for water management, presidents and directors of municipal water and sewerage enterprises, presidents of local communities, local water distributors, presidents and staff of local land reclamation organizations, as well as the personnel of the Water Directorate of the Decentralized Administration of Crete. The authors also express their sincere gratitude to all individuals who provided their cooperation, particularly during field activities.

Research Highlights

Areas of significant groundwater depression have been identified, alongside potential geohazards linked to land subsidence resulting from excessive groundwater withdrawal and significant level decline. Data from the European Ground Motion Service (EGMS) were analyzed to detect land subsidence induced by groundwater exploitation, with findings subsequently validated through site inspections.

Introduction / Background

In cases of overpumping with significant lowering of the piezometric surface across large aquifers subsidence phenomena are often observed (Zhang et al., 2008; Loupasakis et al., 2014; Raspini et al. 2014; Svigkas et al., 2016; Papoutsis et. al., 2020; Kamali et al., 2021). The Messara Basin, a key agricultural and hydrogeological region in central-southern Crete (Figure 2), is characterized by complex geological formations, intensive agricultural activities, and increasing water demand. Geodetic satellite measurements for the period 2007-2009 indicate a subsidence rate of approximately 2 cm per year in the central part of the Messara Plain (Mertikas et al., 2010).

Groundwater demand has approximately doubled the number of recorded boreholes in the area over the past decades. By 2007, the number of boreholes was estimated at 1,400. Recent data from a systematic inventory of water wells (boreholes) in Greece, documented 2,474 boreholes in the Messara Basin (Figure 1), accounting for 46.3% of all water wells in Crete (H.S.G.M.E./ R.B.C., 2023; Michalakis, 2024).

Figure 1. The Spatial Distribution of 2,474 water wells across the broader area of Messara Basin. Results from Project: Systematic inventory of water wells (boreholes) throughout the country of Greece / Crete (EL13). This comprehensive effort resulted in the identification and documentation of 2,474 boreholes across Messara Basin. This represents 46.3% of all water wells in Crete.

Groundwater levels in the Messara Basin exhibit notable seasonal fluctuations (Michalakis, 2024), primarily driven by overexploitation for irrigation, particularly in the aftermath of a prolonged drought. This unsustainable usage raises significant concerns regarding the sustainability of water resources and heightened the basin's vulnerability to climate-induced stresses. Remote sensing technologies, such as the Copernicus Sentinel satellite program, provide valuable tools for monitoring environmental changes and guiding field inspections (Delgado Blasco et al., 2019). This study outlines the integration of Sentinel data with site inspections to address potential geohazards identifying notable displacements and detect induced land subsidence associated with groundwater over-exploitation.

Objectives

This study presents preliminary results from site inspections conducted using Copernicus ground motion data from EGMS. The results highlight the utility of Sentinel data in enhancing field observations and addressing potential geohazards by identifying notable displacements and detecting induced land subsidence associated with groundwater overexploitation.

Methods

Groundwater levels in the basin exhibit significant seasonal variations, largely due to over-exploitation for irrigation, raising critical sustainability concerns. Effective groundwater management requires systematic data collection and precise utilization of primary data. Changes in groundwater head within the Messara Basin were studied from May 2021 to October 2023, leading to the identification of areas with generalized groundwater depressions (Michalakis et al., 2022; Michalakis, 2024). During this period, field observations were conducted, and local authorities and civilians were engaged to assist in identifying notable displacements in their respective areas, with particular emphasis on those linked to groundwater overexploitation. It is worth noting that deformation phenomena occur in several areas; however, as these areas are under cultivation, such phenomena often go unnoticed due to erosion and plowing or are not given adequate consideration.

Following, mean vertical velocities (weekly measurements) from two datasets (80,014 Persistent Scatterers -PSs-) —ORTHO (Level 3) Vertical for 2016–2021 (spanning 5 January 2016 to 22 December 2021) and 2018–2022 (spanning 6 January 2018 to 23 December 2022)—were analyzed using geostatistical methods to identify regions of significant subsidence (Figure 2). Subsequently, an analysis of the ORTHO (Level 3) Vertical dataset for 2019–2023 (spanning 13 January 2019 to 18 December 2023), obtained from the European Ground Motion Service (EGMS) Explorer (accessed on 30 October 2024), led to the selection of 86 PSs for site inspections (EGMS Data Explorer, 2024).

Finally, targeted site inspections at the narrow areas surrounding the 86 selected EGMS PSs were conducted from 11 to 29 November 2024.

Figure 3 presents a plot of vertical displacements and vertical mean velocities for the 86 PSs selected for site inspections in the Messara Basin. In the plot, vertical displacement values range from +48.10 mm (EGMS_08) to -152.40 mm (EGMS_82), while vertical mean velocities range from +9.8 mm/year to -30.80 mm/year, respectively.

Figure 2. The Spatial Distribution of the Mean Vertical Velocities (weekly measurements spanning from 5 January 2016 to 22 December 2021) from dataset: [ORTHO (Level 3) Vertical for 2016–2021 / 80,014 PSs]

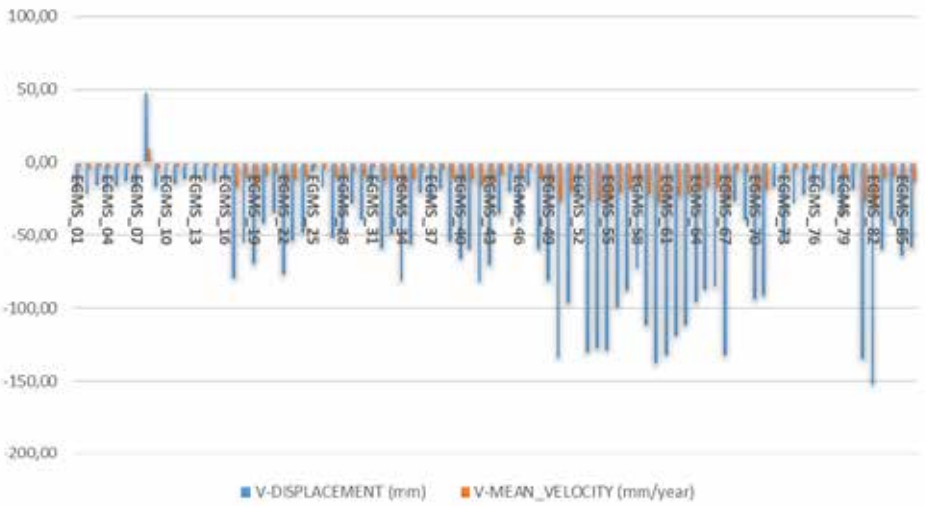

Figure 3. Plot of Vertical Displacements and Vertical Mean Velocities of the 86 PSs selected for site inspections in the Messara Basin.

These values were derived from the ORTHO (Level 3) Vertical dataset for 2019–2023 (spanning 13 January 2019 to 18 December 2023), obtained from the European Ground Motion Service (EGMS) Explorer (accessed on 30 October 2024).

Description and Documentation: An Example

The applied method highlights the utility of Sentinel data in complementing field observations and addressing potential geohazards by identifying displacements and detecting induced land subsidence associated with groundwater overexploitation. Preliminary findings indicate that areas of significant displacement can be identified, while the study of geological and hydrogeological conditions provides a valuable tool for evaluating ongoing geohazards.

An example of the inventory form designed for reporting the findings of the 86 selected sites is presented in figure 3, referring to a Location Southwest of Moires (Kalamiari) (Date of site inspection: 09 December 2024). In Figure 4, embedded Figure 86.1 shows a snapshot from the EGMS Data Explorer, incorporated into the inventory form of EGMS_86.

The reference measurement point (10HQYNAEOU, EGMS_86) is located southwest of Moires, within an olive grove (Figure 4; embedded Figure 86.1). At the reference point and within a radius of ~30m, significant ground ruptures were identified, both within the olive grove and on the paved road to the east. Openings due to pipe-laying phenomena are observed within the olive grove, which are related to underlying deformations (Figure 4; embedded Figure 86.2a). Ground ruptures were observed to the west and at a distance of ~20m, on the eastern margin of the road (Figures 4; embedded Figures 86.2b and 86.2c). Significant deformations and ruptures (Figure 4; embedded Figure 86.2d) are observed over a length of ~70m of the eastern road and are located mainly east and south of the reference point. Two more reference points (EGMS_19 and EGMS_22, shown in figures 5.1 and 5.2) in a short distance gave similar phenomena after site inspections helping to identify an area of high geohazard risk.

Geological Setting. The geological framework of the area is presented in figure 5.2. where **alluvium (al) deposits** comprising unconsolidated sediments such as sands, silts, clays, and gravels deposited by rivers and streams during the Quaternary (thickness up to 20m) overlaying **Pleistocene (Pt) deposits** consisting of marine terraces (typically composed of consolidated beach deposits such as sand, gravel, and occasionally shells) and non-marine clastics including fluviatile beds and fans (consist of coarse-grained materials like sand and gravel).

Hydrolithological Setting.

Alluvium deposits typically form highly permeable and productive aquifer systems where variable yet generally favorable conditions for groundwater storage and movement within these deposits can create a heterogeneous permeability profile. The hydrogeological behavior of alluvial deposits is influenced by the sorting, size distribution, and interbedding of the different sediment types. These factors contribute to a complex and layered aquifer system where hydrological properties can vary significantly over short distances. The hydrogeological properties can vary based on the clast size, sorting, and degree of cementation. This complexity can lead to heterogeneous aquifer properties within short distances, influenced by changes in sediment characteristics and depositional processes (Michalakis et al., 2024).

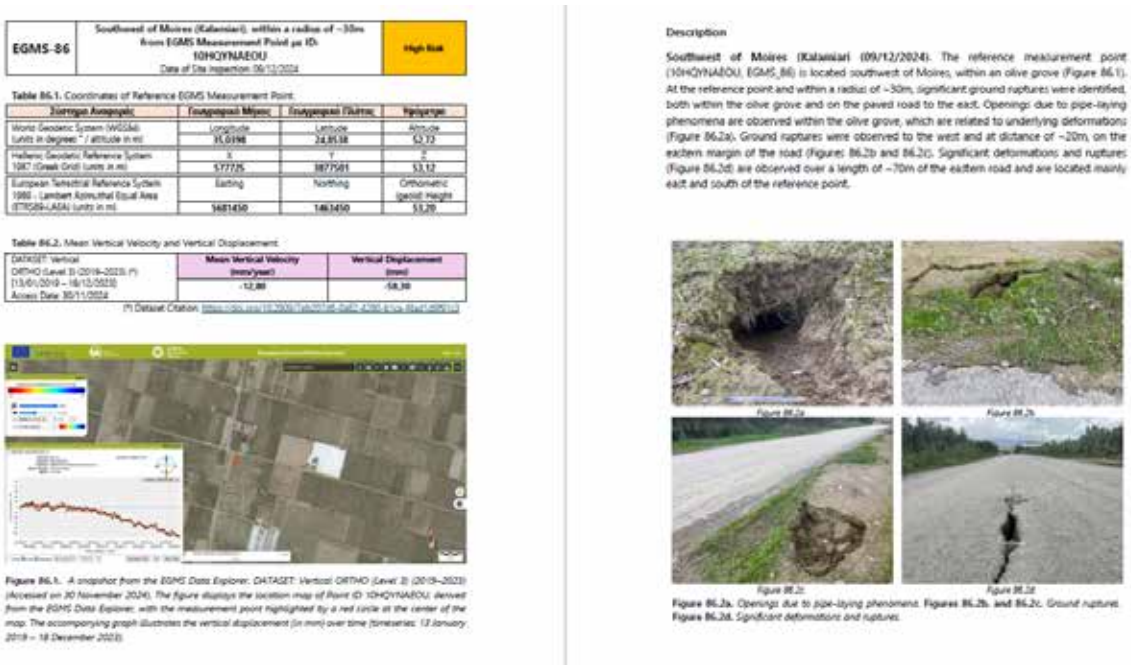

Figure 4. Inventory Form of EGMS Measurement Point: 10HQYNAEOU (EGMS-86).

Pleistocene deposits, presents a stratified aquifer system where the lithological diversity significantly influences hydrogeological properties. Marine terraces, typically composed of consolidated beach deposits such as sand, gravel, and occasionally shells. The degree of cementation varies, but where less consolidated, these terraces often exhibit high porosity and permeability, conducive to effective groundwater storage and flow. The porosity and permeability in marine terraces depend on the degree of lithification. In areas where the terrace deposits are less cemented, they can exhibit high porosity and permeability. Non-marine clastics (fluviatile beds and fans) formed from river and alluvial fan processes, generally consist of coarse-grained materials like sand and gravel. The sorting and layering of these materials can significantly affect their hydrogeological characteristics. Typically, these materials have high porosity due to the loose packing of coarse grains, coupled with high permeability that facilitates effective water infiltration and movement. The hydrogeological properties can vary based on the clast size, sorting, and degree of cementation. The unit exhibits a complex hydrogeological behavior due to the mixture of marine and non-marine depositional environments. This complexity can lead to heterogeneous aquifer properties within short distances, influenced by changes in sediment characteristics and depositional processes. The groundwater flow in these areas is generally robust, especially in regions where the sediments are coarse and well-sorted. The yield from these aquifers can vary depending on local conditions such as sediment depth, degree of consolidation, and the presence of impermeable layers or lenses within the deposits (Michalakis et al., 2024).

Hydrogeological Setting and Deformations

Hydrogeological conditions in the Messara Basin were studied from May 2021 to October 2023, resulting in the identification of areas with generalized groundwater depressions (Michalakis et al., 2022; Michalakis, 2024). Potentiometric data, collected during wet and dry seasons in 2021 and 2023, were derived from an extensive network of 767 measurement points across the basin. These data allowed for the analysis of groundwater head changes, leading to the documentation of significant depressions.

Groundwater overexploitation near the reference measurement point has created a cone of depression, with groundwater levels dropping to negative elevations (below mean sea level). Figure 5.1 illustrates this phenomenon, where the purple-shaded area represents a cone of depression with groundwater head values reaching as low as -31.08 m by the end of the dry season in 2023. Within this zone of excessive groundwater withdrawal (Figures 5.1 and 5.2) lies reference measurement point 10HQYNAEOU (EGMS_86), along with EGMS_19 and EGMS_22, where notable deformations and ruptures were observed.

During the wet season, groundwater levels in alluvial deposits rise to +50 m, influenced by the Geropotamos River located approximately 550 m to the north. However, significant seasonal fluctuations—up to 85 m in vertical water level—are observed in the area, which has an altitude of 53.12 m (EGMS_86). These fluctuations are exacerbated by extensive groundwater overexploitation and occur within highly permeable hydrolithological units that facilitate rapid water infiltration and movement. Embedded Table 86.2 in Figure 3 presents the mean vertical velocity and total vertical displacement of EGMS_86, as derived from the EGMS Data Explorer (accessed on 30 October 2024).

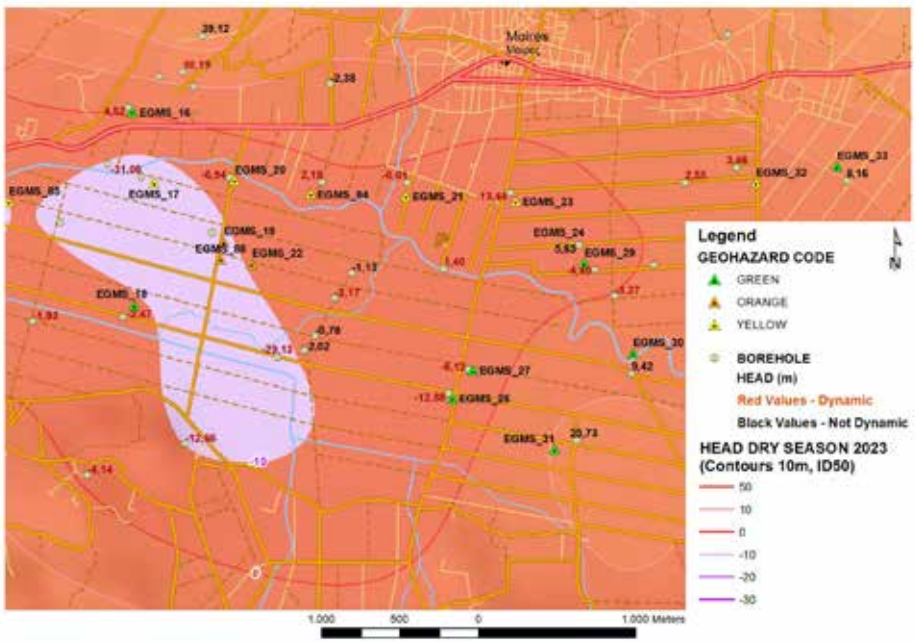

Figure 5.1. Groundwater overexploitation near the reference measurement point has created a cone of depression, with groundwater levels dropping to negative altitude.

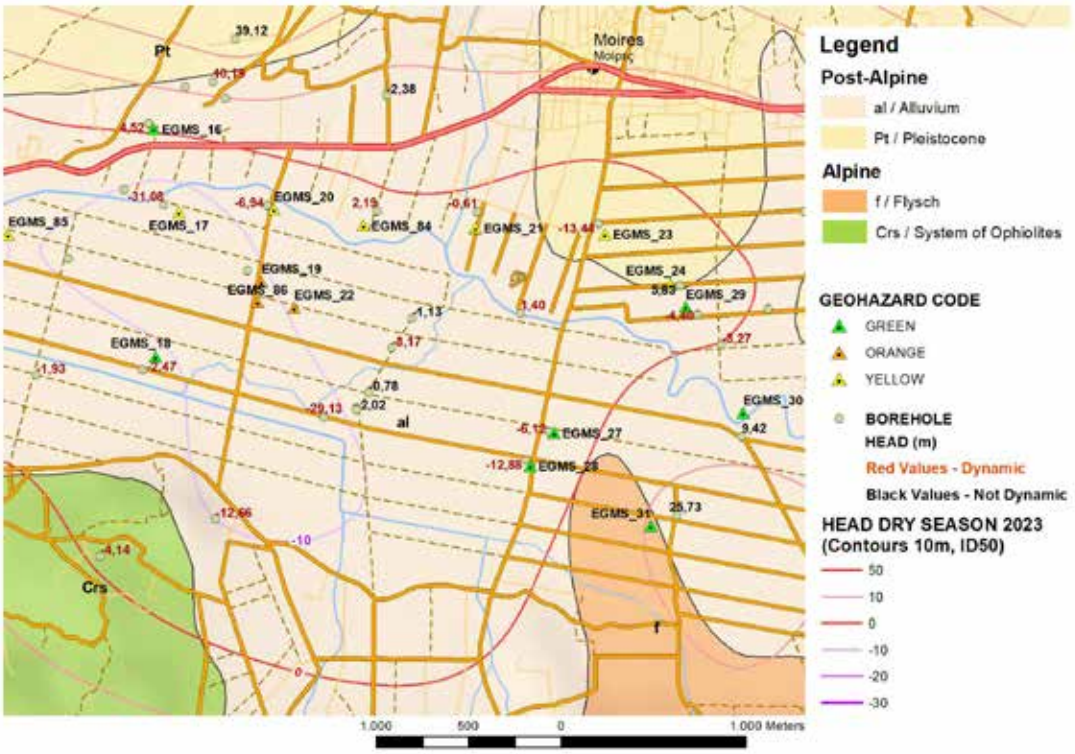

Figure 5.2. The geological framework of the area, illustrating potentiometric contours and head values.

The loose packing of alluvial deposits in the upper layers and the unconsolidated Pleistocene deposits (e.g., sand and gravel) beneath them are particularly affected by these changes. This interaction leads to significant ground ruptures and openings due to pipe-laying phenomena, which are attributed to underlying deformations caused by groundwater-level fluctuations.

It is worth noting that similar phenomena (subsidence - ground movements due to groundwater depletion) occur in other comparable areas; however, because these areas are under cultivation, deformation phenomena often go unnoticed due to erosion and plowing or are not given sufficient consideration. Documenting these areas where such phenomena occur can enhance the understanding of the geological background's response in regions affected by overexploitation and contribute to the assessment of existing or potentially emerging geohazards, ultimately aiding in risk reduction. In addition, it will help in the design of mitigation measures, such as the application of artificial recharge.

Conclusions

Ground movements caused by groundwater decline are an increasingly significant issue worldwide, often due to excessive water extraction and pronounced rainfall seasonality. In agricultural and peri-urban areas, such as the Messara Basin on the island of Crete, these drawdowns are predominantly anthropogenic, with excessive groundwater extraction for agriculture leading to land subsidence. Understanding the geological and hydrogeological conditions of an area, combined with the use of satellite data, offers a critical tool for mitigating risks and minimizing the impacts of potential geohazards. Such integration is particularly valuable for civil engineering applications, including the structural assessment of buildings and infrastructure, detection of differential displacements, evaluation of terrain stability, and other related challenges.

Acknowledgements

Field surveys have been conducted within the framework of the PhD thesis assigned to the first author at the N.T.U.A. We acknowledge the use of data from the European Ground Motion Service (EGMS) Data Explorer in this study. The datasets provided valuable insights for analyzing induced land subsidence and geohazards. We gratefully acknowledge the European Environment Agency (EEA) for maintaining and providing access to the EGMS data, which significantly contributed to the outcomes of this research.

EXTENDED ABSTRACT 211

Application of geochemical indices for heavy metal evaluation in the Pinios Dam, Greece

Michalopoulou M.[1], Depountis N.[1], Zagana E.[1], Avramidis P.[1]

Research Highlights: Application of geochemical indices for the evaluation of sediment and water samples in the Pinios Dam drainage basin in Western Greece

Introduction

Reservoirs are essential for water supply and flood management; yet numerous reservoirs encounter quality challenges caused by heavy metal concentration. This study investigates the extent of heavy metal concentration in the Pinios Dam drainage basin in the Ilia Regional Unit in Western Greece by analyzing sediment and water samples from the dam reservoir as well as water samples from the river tributaries. The main focus is to evaluate heavy metal concentration levels using established geochemical indices. The indices that were used for this purpose include the Geo-Accumulation Index (Igeo), the Contamination Factor (CF), the Pollution Load Index (PLI), and the Heavy Metal Pollution Index (HPI).

Study area

The Pinios Dam is an earth-filled structure characterized by a heterogeneous design, standing 50 meters high and spanning a length of 2,175 meters, with a final crest elevation of 100 meters. Constructed in 1968, the reservoir associated with the dam covers a total surface area of 19.87 km² and it collects surface runoff from a catchment area of 673.41 km². The water that is collected serves dual purposes, supplying both drinking and irrigation needs (Michalopoulou et al., 2024). Geologically, the catchment area is predominantly underlain by Alpine bedrock, which includes formations from the Ionian, Gavrovo-Tripolis, and Pindos geotectonic zones. These formations primarily consist of flysch and limestone. Additionally, the area features Neogene and Quaternary sediments. To provide a detailed representation of the area's geological framework, a geological map was developed using ArcGIS Pro 3.4.0. This map integrates unified data from four geological sheets produced by the Hellenic Survey of Geological and Mineral Exploration and presents the sampling points of this research (Figure 1).

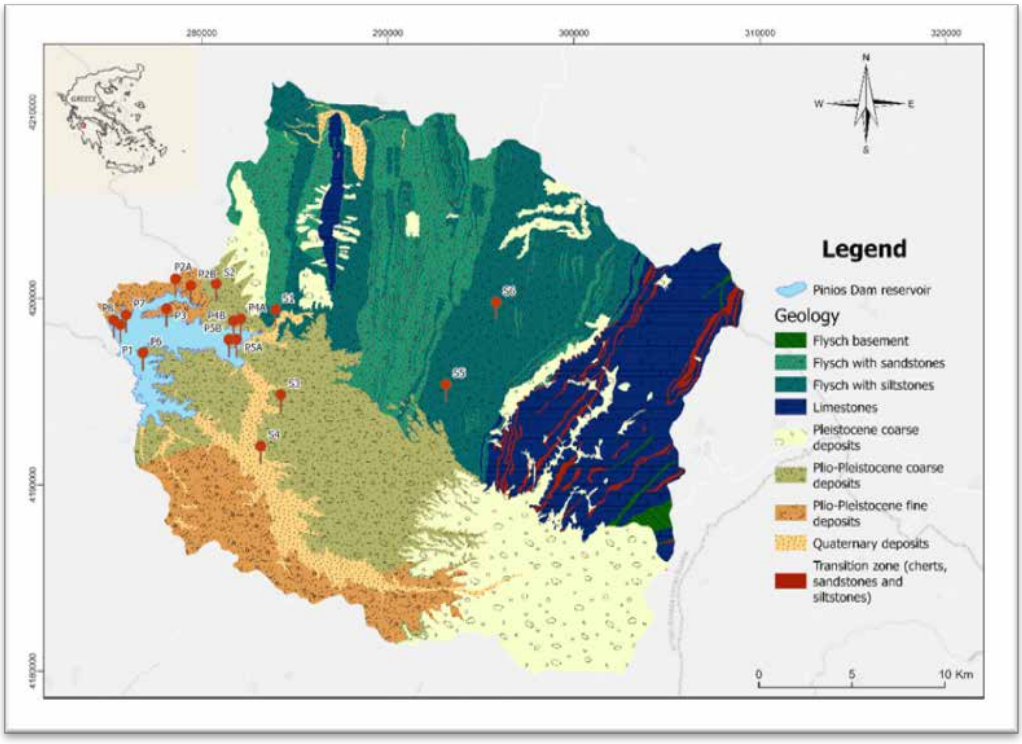

Figure 1. The sampling points and the geological formations of the research area (modified from Michalopoulou et al., 2024).

The surrounding region has experienced high rates of soil erosion and shallow landslide activity in recent decades, largely attributed to the extensive wildfires that have occurred over the past 20 years (Depountis *et al.*, 2020; Lainas *et al.*, 2021; Michalopoulou *et al.*, 2022). These processes have accelerated sediment deposition within the reservoir, significantly influencing the distribution and concentration of heavy metals in the water body and the deposited sediments; thus, altering the geochemical dynamics of the artificial lake.

Methods

Within the research area, monitoring and sampling stations (Figure 1) were established for the analysis of sediments, as well as the incoming and stagnant water. Sediment samples were obtained from the reservoir's bottom using a Van Veen grab sampler at seven stations (P1-P7), covering a collection area of 0.04 m². At locations P3 and P7, in situ measurements were performed during the autumn and winter seasons to record the physicochemical properties of the water column. Both sediment and water samples were transported to the laboratory in a portable refrigerator. Sediment samples were stored at −4 °C to ensure preservation, while water samples were analyzed within 24 hours for nutrient content and acidified for subsequent heavy metal analysis. Regarding the sediment analysis, major elements were analyzed using WD-XRF (Rigaku ZSX PRIMUS II), and the total organic carbon was quantified using the potassium dichromate oxidation method. Fe and Mn in water samples were measured via atomic absorption spectroscopy (Perkin Elmer Pinacle 900). pH, Eh, and other parameters were recorded in situ with a YSI 63 multiparameter probe.

Runoff water sampling was carried out at six sites (S1–S6), representing the tributaries and the main branch of the Pinios River basin. Samples were collected in two polyethylene bottles, one with a capacity of 1 L and the other 100 mL. The 100 mL samples were filtered on-site through a 0.45 μm filter to remove particles, followed by acidification with HNO_3. Following each sampling, water samples were transported to the laboratory for chemical analysis using atomic absorption spectroscopy. The elements analyzed in the sediments are Fe, Mn, Ni, Cr, Pb, Zn, Cu, Co, and Zr. The water samples were analyzed for Fe, Mn and major cations/anions Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}, HCO_3^{-}, SO_4^{2-}, Cl^{-}, NO_3^{-}, NO_2^{-}, PO_4^{3-}, NH_4^{+}.

The Geo-Accumulation Index (Igeo) was used for the assessment of heavy metal enrichment in sediments and soil as suggested by Muller (1969), Sojka *et al.* (2022), Wu *et al.* (2022), and Wang *et al.* (2023) from another similar research. According to Muller (1969), the Igeo index is calculated by the following formula.

$$I_{geo} = \log_2\left(\frac{C_n}{K * B_n}\right), \quad (1)$$

The Cn value represents the measured heavy metal concentrations of the sediment samples (mg/kg), the K coefficient is typically equal to 1.5 and demonstrates the adjustment of the standard variation of heavy-metal concentrations during diagenesis (Wu *et al.*, 2022) and the Bn is the background concentrations of each heavy metal (mg/kg) displaying the composition of the upper continental crust (Taylor *et al.*, 1985; McLennan, 2001). The classes of the Igeo index describing the level of contamination are the following: Igeo ≤ 0: uncontaminated, 0 < Igeo ≤ 1: uncontaminated to moderately contaminated, 1 < Igeo ≤ 2: Moderately contaminated, 2 < Igeo ≤ 3: Moderately to heavily contaminated, 3 < Igeo ≤ 4: Heavily contaminated, 4 < Igeo ≤ 5: Heavily to extremely contaminated and Igeo > 5: Extremely contaminated sediment sample.

The Contamination Factor (CF) is an index proposed by Hakanson (1980) and is widely used for the evaluation of the contamination level of sediments by metals and it is calculated by dividing the measured heavy metal concentration (C_{metal}) with their corresponding background value ($C_{background}$). CF values below 1 show low contamination, values between 1 and 3 show moderate contamination, values between 3 and 6 indicate considerable contamination and values higher than 6 show very high contamination.

$$CF = \frac{C_{metal}}{C_{background}} \quad (2)$$

The Pollution Load Index (PLI) is another index suggested by Tomlinson *et al.* (1980), that intends to evaluate the degree of heavy metal enrichment in sediment samples, and it is calculated by the following formula (Tomlinson *et al.*, 1980).

$$PLI = \sqrt[n]{CF_1 \times CF_2 \times \cdots \times CF_n} \quad (3)$$

The CF component refers to the calculated contamination factor for each element mentioned above. The PLI is

estimated as the n root of the n contamination factors multiplied together. The classifications of the PLI values are the following: no pollution for PLI ≤1, moderate pollution for 1 <PLI ≤2, strong pollution for 2 <PLI ≤3, and extremely strong pollution for PLI ≥3.

The Heavy Metal Pollution Index (HPI) is suggested by Mohan *et al.* (1996) for the assessment of the water quality. In this study, HPI is used for the examination of lake and stream surface water quality concerning Fe and Mn concentrations. The formulas for the estimation of this index are presented below (Mohan *et al.*, 1996; Moldovan *et al.*, 2022; Sur *et al.*, 2022).

$$Q_i = \frac{M_i}{S_i} \times 100 \quad (4)$$

$$W_i = \frac{1}{S_i} \quad (5)$$

$$HPI = \frac{\sum_{i=1}^{n} W_i Q_i}{\sum_{i=1}^{n} W_i} \quad (6)$$

The Q_i refers to the sub index of the *i*th parameter, the W_i is the unit weightage of the *i*th parameter, the n is the number of the examined heavy metals, the Si demonstrates the standard permissible values of the examined heavy metals, and the Mi presents the measured heavy metal concentrations of the water samples. Concerning the Si values for Fe and Mn, the European Directive 2020/2184 on water quality was assessed. When the HPI is less than 100, it indicates low levels of heavy metal concentrations; when it is estimated to be more than 100, it indicates that the water is unsafe for consumption and can have adverse health implications.

Results

The indices that were chosen for the pollution assessment are Igeo, CF, PLI for sediments and HPI for water samples. The values of Igeo for all sampling sites are shown in Figure 2. For most heavy metal elements, the Igeo values are calculated below 1 in every station which means that the samples are practically uncontaminated. Igeo values above unity indicate moderate heavy metal enrichment and were calculated for Ni in all stations (range: 1.02-1.44) except P5 (0.67), and for Cr only in station P2 (1.05). The average Igeo values were ranked as: Ni> Cr> Pb> Zn> Cu> Co> Zr. The Igeo values suggest a heterogeneous distribution of heavy metal enrichment, which is related to natural geological processes as the metal concentrations could be influenced by natural mineral deposits, or even historical land use patterns.

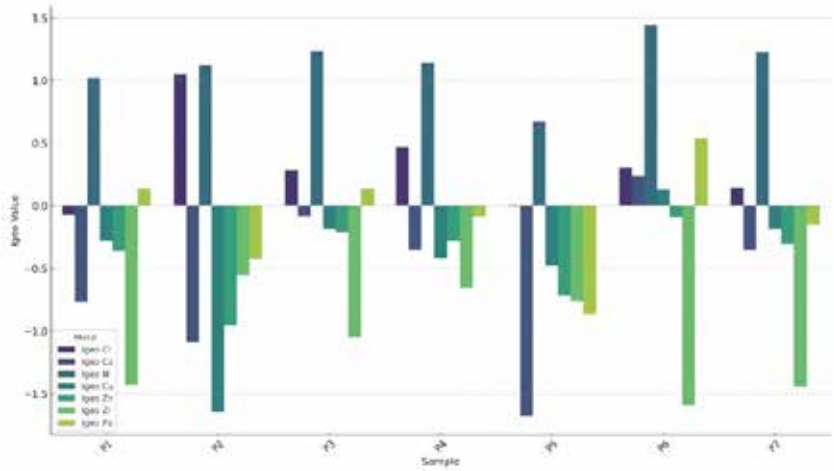

Figure 2. Bar chart of the Igeo values of the examined heavy metals for each station.

The Contamination Factor (CF) values for heavy metals offer insight into the degree of heavy metal enrichment in the examined samples. The ranges of the CF values for Zr, Co, Zn, Cu, Pb, Cr and Ni are 0.50 to 1.02, 0.47 to 1.76, 0.77 to 1.41, 0.48 to 1.64, 0.82 to 2.18, 1.43 to 3.11 and 2.39 to 4.07, respectively. Average CF values for all metals were ordered as presented in the following sequence Ni>Cr>Pb>Cu>Zn>Co>Zr. Low to moderate contamination based

on CF values was calculated for Cu, Zn, Pb, Zr, Co and Cr. The CF values for Ni showed moderate to considerable contamination with a minimum value of 2.39 and a maximum value equal to 4.07. The CF concentrations for all samples indicate varying degrees of heavy metal enrichment, with certain metals like Ni showing consistently higher levels across all samples reflecting mainly natural geological variations (Figure 3).

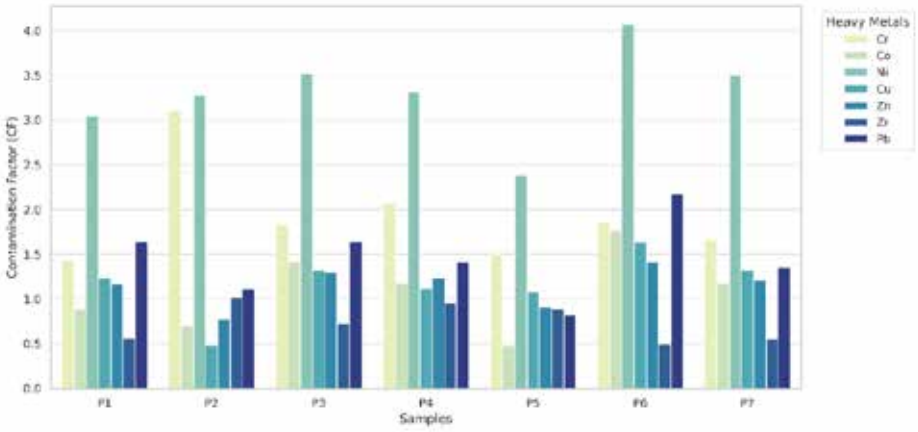

Figure 3. Bar chart of the CF values of the examined heavy metals for each station.

The Pollution Load Index (PLI) for heavy metals offers insight into the degree of contamination in each of the reservoir stations where samples were collected. PLI values below 1 show negligible concentrations while values greater than 1 suggest significant concentrations. The calculated PLI values range between 1.03 to 1.65, indicating moderate degrees of heavy metal enrichment across the stations. The bar graph below visualizes the PLI values across the different stations with the red dashed line representing the PLI threshold (Figure 4).

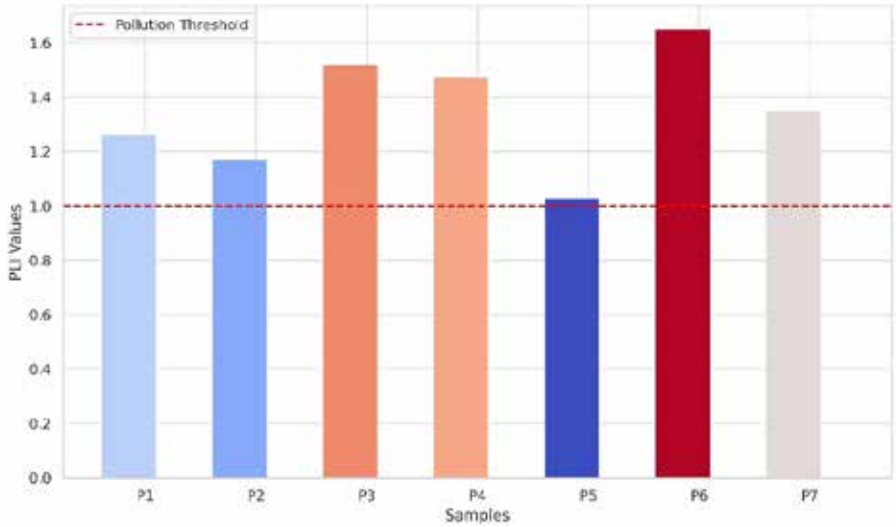

Figure 4. Bar chart of the PLI values of the examined heavy metals for each station.

The Heavy-Metal Pollution Index (HPI) is a vital index for evaluating heavy metal concentrations in water sources as it assesses several heavy metals in the water and their combined effects on water quality in a thorough manner. Each heavy metal is given a weighting factor according to its toxicity and possible health effect in order to calculate the HPI (Badeenezhad *et al.*, 2023). The HPI index was calculated for lake and stream samples for different periods of time. The bar charts for each type of sample are presented in Figure 5. The results showed that the surface lake water samples exceed the threshold of 100 in 22/02/2019 in stations P1, P2, P5, P6, P7 and P8, where in 09/10/2018 the HPI value is considerably high mainly because of the high measured concentration of Mn (226 μg/l). This is likely due to seasonal redox cycling and stratification, which influence metal mobility in the hypolimnion.

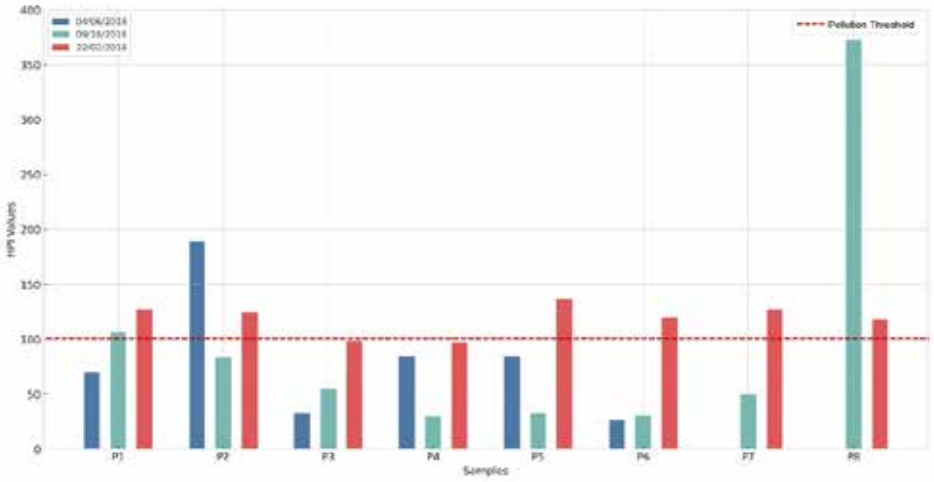

Figure 5. Bar chart of the HPI values of the lake samples for different dates.

Concerning the stream water samples (Figure 6), stations S2, S3, S4 and S6 presented HPI values above the threshold 100. The S2 station is the one with the highest values which exceeded the threshold in almost all samples except for the ones that were taken on 29/11/2018 and at 22/02/2019.

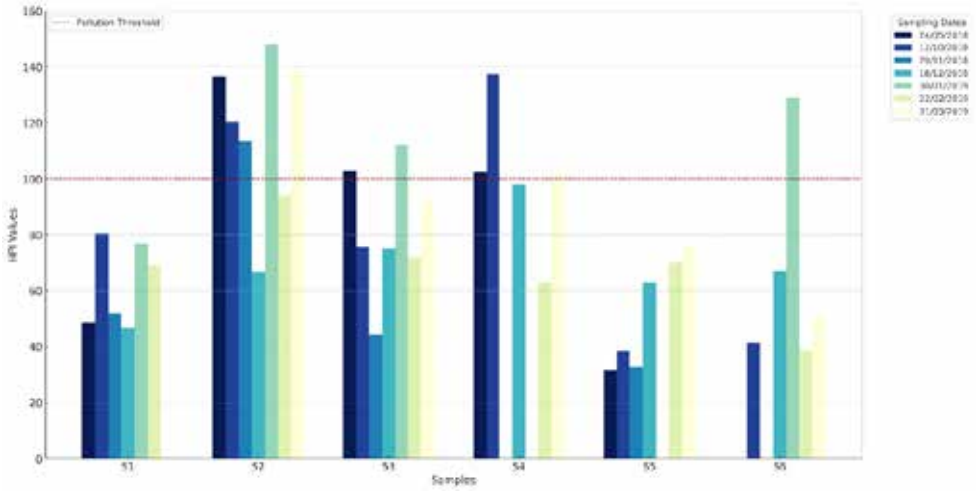

Figure 6. Bar chart of the HPI values of the stream samples for different dates.

Discussion & Conclusions

The application of geochemical indices in the Pinios Dam drainage basin provided valuable insights into the extent and distribution of heavy metal enrichment in sediments and concentrations in water. Regarding the evaluation of sediments, the Igeo values indicate that most heavy metals in the sediment samples are within uncontaminated to moderately contaminated levels, with exceptions observed for Ni and Cr in specific stations. The CF values further suggest low to moderate contamination for most metals, with Ni showing moderate to considerable concentrations, likely due to natural enrichment. The PLI values, ranging from 1.03 to 1.65, point to moderate pollution levels in the sediments across the study area. The examination of the water quality was based on the HPI index which reveals that lake and stream water samples frequently exceed the pollution threshold, primarily due to elevated Fe and Mn concentrations. Temporal variations suggest that certain periods are more prone to higher Fe and Mn concentrations, potentially due to hydrological or seasonal factors. More specifically, in this case, seasonal stratification plays a crucial role in shaping the distribution and mobility of Fe and Mn within the water column of the reservoir, as seasonal fluctuations in their concentrations were evident, with higher levels of these elements observed in the hypolimnion during the autumn/dry season (Michalopoulou *et al.,* 2024).The observed heavy metal indices strongly reflect the strong influence of natural geological processes, such as weathering of metal-rich formations, erosion,

and sediment deposition. These processes dominate the geochemical dynamics of the study area as the observed metal enrichment in the examined sediments originated from natural processes as well as the high concentration of organic carbon and the clayey composition of the fine sediments. So, the geoaccumulation in sediments occurs due to the ability of organic matter and clay minerals to adsorb trace element cations. Anthropogenic activities, such as agriculture, appear to have a secondary role, as suggested by the localized and relatively moderate contamination levels for most metals, and needs further investigation to better quantify their impact. Evaluating pollution levels using multiple indices for the same region can yield varying pollution classifications and lead to different interpretations as these discrepancies arise from the distinct mathematical formulations of each index (Karaouzas et al., 2021). Thus, to ensure effective management, it is essential to prioritize continuous monitoring and utilize modeling techniques to better understand the long-term behavior of metals in the system and to mitigate the potential environmental impacts of metal enrichment.

EXTENDED ABSTRACT 212

The impact of aquaculture units on Copper (Cu) concentrations in marine sediments

Michalopoulou S.[1], Faulwetter S.[1], Christodoulopoulos D.[1], Ramfos A.[2], Avramidis P.[1]
(1) Department of Geology, University of Patras, Greece, mich.sofi6@gmail.com (2) Department of Biology, University of Patras, Greece

Introduction / Background

Copper (Cu) is a trace element commonly found in various rocks and minerals, well known for its antimicrobial properties (Wang et al. 2022). Due to these properties, copper is widely used in aquaculture nets to control biofouling (e.g. Nikolaou et al. 2014). More specifically, it is applied in the form of copper sulfate (CuSO□), which dissolves in water and eventually settles on the seabed. However, at elevated concentrations, copper becomes toxic, particularly in marine sediments where the accumulation of heavy metals is significantly elevated and therefore poses a serious threat to aquatic organisms (Emenike et al. 2022). The effects of fish farm operations on copper concentrations have been the focus of several studies worldwide (e.g. Dean et al. 2007) but in Greece, research has focused mainly on individual fish farms (e.g. Farmaki et al. 2014), and overall knowledge on copper concentrations, their spatial distributions and their accumulation processes in the sediment near fish farms in Greece is limited.

Objectives

While the fate and consequences of organic wastes for the benthic ecosystem are relatively well understood worldwide, less attention has been given to metallic wastes from fish farms and to the changes in marine sediments from copper concentrations. Therefore, the main objectives of our study are:

- To determine the impact of copper originating from marine fish farms on marine sediments
- To examine which environmental and farm parameters influence the copper concentration in marine sediments in different regions of Greece.
- To determine the spatial extent of the impact of fish farms of copper concentration in the sediment
-

Methods

We examined the impact of aquaculture activities across four different regions: Aegean Sea, Corinthian Gulf, Euboea and Ionian Sea (Fig. 1). Sediments were collected from 32 fish farms at 50 m distance from the cages, in accordance with the Greek legislation, as well as from reference stations. In addition, we used a dataset assembled between 2020 and 2023 that included samples collected at distances of approximately 0, 25, 50 and 100 m from the cages, as well as reference samples (Fig. 1). Sediment samples were analyzed for total organic carbon (TOC) and total nitrogen (TN) using a Shimadzu TOC-VCSH TOC/TN analyzer. Total phosphorus (TP) was measured with a Hach photometer according to the APHA 2005-4500-P method. Sediment grain size was determined through dry sieving for coarser materials and with a Malvern Mastersizer 2000 Hydro for the finer fractions. Heavy metal content in the sediment was determined (Cu, Mn, Pb, Zn, Fe) using a Bruker Handheld X-ray Fluorescence Analyzer (Titan S1).
For the dataset from 2024, we assembled additional information on the surface area of the farm, the geomorphology of the coastline (farm located within open or closed embayment) and the distance from the coast.
To test the effects of various environmental parameters on the copper concentration in marine sediments two different analyses were performed, using a general linear model (GLM) with a gamma distribution and inverse link function. For the dataset from 2020-2023, the model included the distance from the farm, depth of the seafloor, percentage of sand, sediment type and geographical region as explanatory variables. For the dataset from 2024, the model included the distance from the farm, depth of the seafloor, percentage of mud, sediment type, geographical region, surface area of the farm, distance from the coast, and bay type (open or enclosed) as explanatory variables. The significance level for all tests was set to α=0.05 and all analysis were performed in R (R Core Team 2024).
Two geochemical indices- Contamination Factor (CF), and the Geo-Accumulation Index (Igeo)- were calculated to identify the enrichment or depletion of metal distribution in sediment samples. The calculation of the CF values contacted using the following equation:

$C_F = \bar{c}_s / C_b$

where the $\bar{c}_s$ represents the mean copper concentration from positions (0, 25, 50, 100m) around the cages and C_b is the background concentration from reference data for each region. The Igeo was calculated using the following equation:

$Igeo=\log_2(Cs /1.5\times Cb)$

where the $\overline{c_s}\overline{c_s}$ represents the mean copper concentration from positions (0, 25, 50, 100m) around the cages, C_b is the background concentration of the same metal in an uncontaminated environment and the factor 1.5 is used as a correction factor to account for natural variability in background levels.

Figure 1. Sampling stations.

Results

The results of the analysis indicated a decrease in copper concentrations with increasing distance from the fish cages (Fig.3a,b). Specifically, the highest concentrations of copper were found directly beneath and around the fish farm cages, but significantly elevated concentration (in comparison to the reference stations) were still found at distances of up to 100 m from the farms (Fig. 2). The dataset from 2024 which included only stations from 50 m distance as well as reference stations showed likewise significantly elevated concentrations at 50 m distance compared to the reference stations.

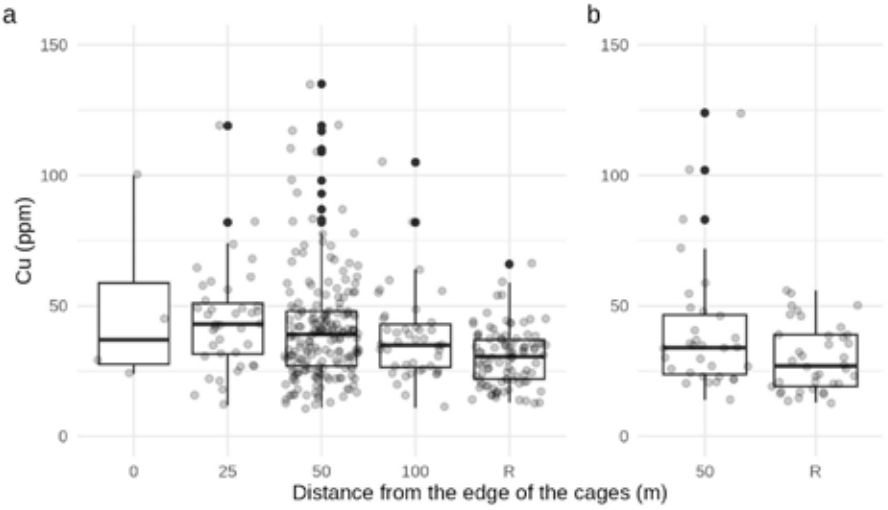

Figure 2. Copper concentration for different distances from the farm distance from the farm. R = Reference station. a) Dataset of 2020-2023, b) Dataset of 2024.

The sediment type was also associated with copper absorption, as finer-grained sediments exhibited a higher capacity for copper absorption in both datasets (Fig. 3). This correlation was weak but statistically significant.

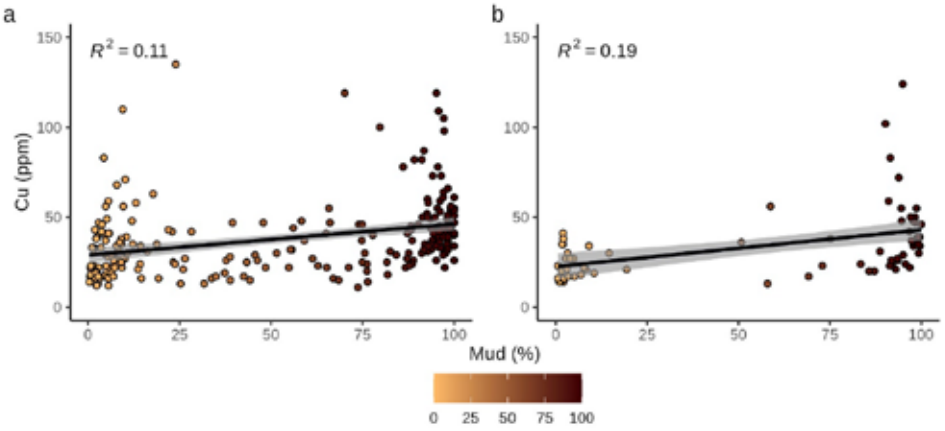

Figure 3. Copper concentration vs percentage of mud in the sediment. a) Dataset of 2020-2023, b) Dataset of 2024.

Additionally, there was an association between copper (Cu) concentration and the geographical region (Fig. 4) Copper concentrations were notably higher in the Ionian region compared to other regions. The Ionian exhibited the highest copper concentrations across all distances from the farm, including reference samples that reflected the natural copper levels of the area. The general pattern of decreasing copper concentrations with increasing distance from the cages was consistent across most regions. However, slight exceptions were observed in regions like Euboea and the Ionian Sea, likely due to a limited number of samples at certain distances.

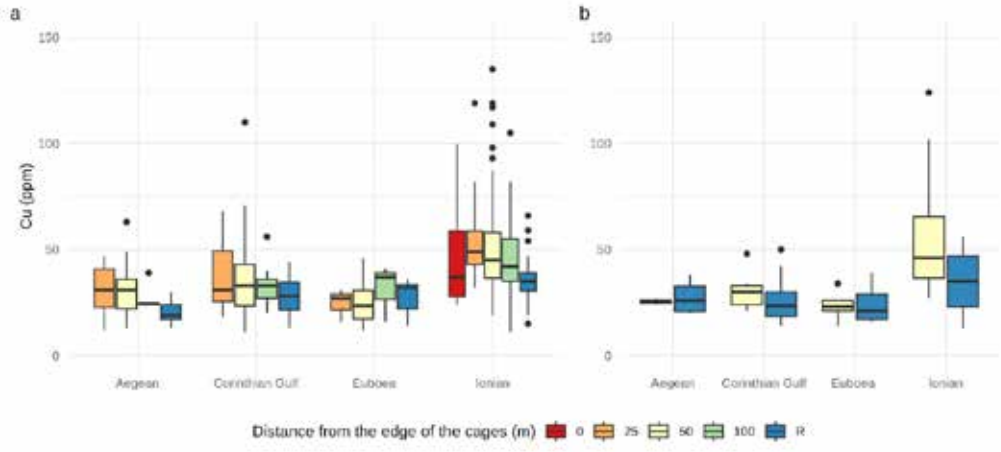

Figure 4. Copper concentration at different distances from the farm, across different regions of Greece. R = Reference station. a) Dataset of 2020-2023, b) Dataset of 2024.

The other variables included in the statistical models (depth of the sea floor, surface area of the farm, the distance from the coast and the bay type (open or enclosed)) did not show any statistically significant effects on copper concentrations.

Overall, the dataset for 2024 confirmed the results of the 2020-2023 dataset. Similar factors were identified to play an important role for copper concentrations in marine sediments.

The contamination factor (CF) provides insight into the extent of pollution in each region. As shown in Table 1, all regions exhibit moderate contamination ($1 \leq CF < 3$), except for Euboea, which falls slightly below this threshold (CF = 0.97), indicating low contamination. Among the regions, the Ionian Sea displays the highest CF value (1.46), suggesting a relatively greater pollutant concentration compared to its natural background levels.

The geoaccumulation index (Igeo) results suggest that all regions are classified as uncontaminated (Igeo<0). The lowest Igeo value was recorded in Euboea (-0,62), significantly lower than the other regions, indicating a natural background concentration very close to or even higher than the sample concentration. The Ionian Sea had the highest Igeo value (-0.04) but still remained within the uncontaminated category.

Table 1. Contamination Factor (CF) and Geoaccumulation Index (Igeo) in Four Study Areas

Region	Sample Concentration (Cs) ppm	Background Concentration (Cb) ppm	CF	Igeo
Aegean	29,4	21,57	1,36	-0,14
Corinthian Gulf	34,81	27,61	1,26	-0,25
Euboea	25,55	26,25	0,97	-0,62
Ionian	51,34	35,13	1,46	-0,04

Conclusions

The present study shows that the determining factors for copper concentration are related to certain individual characteristics of the environment of each farm, such as sediment type and the geographical region. Findings of the present study are of great interest as it highlights that copper concentration is not only determined by the aquaculture activities but also by local environmental conditions.

In both datasets, 2020-2023 and 2024, the results of the analysis indicated that the highest copper concentrations were found directly beneath and around the fish farm cages, within a range of at least 100 m from the cages (no distances further than that were examined). Greek legislation mandates regular environmental monitoring at a distance of 50m from the cages, and while no thresholds or allowed limits for copper concentrations exist in Greece, it is implied that the environmental impact of the farms should overall be limited to this distance. The elevated concentrations found here indicate an effect of the farm on the surrounding marine environment and highlights the impact of feed and faecal inputs as well as the footprint of antifouling products in aquaculture. The spatial extent found in this study is in line with the literature, where effects have been found up to several hundred meters (e.g. Farmaki *et al.* 2014).

The correlation between sediment type and copper concentration in both datasets indicated a weak but significant association, with finer-grained sediments exhibiting a higher capacity for copper absorption. This can be attributed to the solid physio-chemical properties, as smaller particles provide larger surface area per unit mass, facilitating greater adsorption of copper ions.

The spatial differences in copper concentration, particularly in the Ionian region, may be linked to the natural copper concentrations of the area and the geological features, such as inflowing river waters, seasonal variations, hydrodynamic conditions, the rather sheltered conditions of many of the farms and sediment type. In addition, the Ionian region hosts a high number of large fish farms, and cumulative and far-field effects that could even affect the reference stations might likewise play a role and are in need of investigation.

Copper thresholds in marine sediments are crucial for assessing the environmental impacts of aquaculture activities. These thresholds can vary depending on factors such as sediment characteristics, the local species, and environmental conditions. As no copper thresholds have been established by the National or EU Legislation for marine sediments, as well as with SQGs recommended by the Canadian Council of Minister of the Environment (Farmaki et al., 2014), direct comparison of our findings is rather difficult. We found that mean copper concentrations near the cages (42.67 ppm) including extreme values, exceed the Canadian guidelines, set at 18.7 ppm and remain below the Probable Effects Level (PEL=108 ppm). While levels below the PEL suggest that severe biological effects are unlikely, exceeding the ISQGs indicates potential risks to benthic organisms, particularly with prolonged exposure. Additionally, the mean copper concentration in Greece is below 65 ppm, aligning with the threshold set by the Australian & New Zealand Guidelines for Fresh & Marine Water Quality. These findings underscore the need for regular monitoring and targeted mitigation measures.

Other studies in the Mediterranean Sea have found that there is a definite enrichment for copper under the cages, up to 28 ppm in Gulluk Bay in the southeastern Aegean Sea (Dalman et al., 2006). In E. Aegean Sea, Balci Küçüksezgin (1994) found copper concentrations from 8 to 29 ppm and lower copper levels of 15 ppm have been reported in the Bay of Cádiz in Spain, by Mendiguchía et al. (2006) . Outside the Mediterranean, significantly higher copper concentrations were documented in areas with intense industrial activity, such as the mining and smelting region of Rouyn-Noranda, Quebec in Canada (216–2984 ppm) (Borgmann et al., 2004). According to another Canadian study (Brooks and Mahnken, 2003) that compared surface sediment samples from salmon farms that (a) were using copper anti-foulant products, (b) used no copper-based anti-foulant and (c) from reference stations remote from fish farms, concluded that sediment copper levels were higher at farms using copper based anti-foulants.

Overall, this study is an important contribution to the understanding of the impact of fish farms on copper concentrations in the marine sediments and the results should be taken into account for designing environmental monitoring

programs and adopting sustainable farming practices.

EXTENDED ABSTRACT 213

Spatiotemporal diffusion variability in seismic swarms

Michas G.[1]
(1) Institute of Geodynamics, National Observatory of Athens, Athens, Greece, gmichas@noa.gr

Research Highlights

- The spatiotemporal diffusion properties of seismic swarms can well be reproduced with the Continuous Time Random Walk (CTRW) model and the fractional diffusion equation
- The results show intrinsic variability in earthquake diffusion that may highlight the physical mechanisms at play

Introduction

Seismic swarms are characterized by intense seismic activity strongly clustered in time and space and without the occurrence of a major event that can be considered as the mainshock. Such intense seismic activity is most commonly associated with external aseismic factors, as pore-fluid pressure diffusion, aseismic creep, or magmatic intrusion that can perturb the regional stresses locally triggering the observed seismicity (Vidale & Shearer, 2006). These factors can control the spatiotemporal evolution of seismic swarms, frequently exhibiting spatial expansion and migration of event hypocenters with time (Michas *et al.*, 2021). This phenomenon, termed as earthquake diffusion, can be highly anisotropic and complex, with earthquakes occurring preferentially along fractures and zones of weakness within the heterogeneous crust, presenting anisotropic diffusivities that may locally vary over several orders of magnitude (Michas & Vallianatos, 2018a). The efficient modelling of the complex spatiotemporal evolution of seismic swarms, thus, represents a major challenge.

Herein, we apply a stochastic framework based on the well-established Continuous Time Random Walk (CTRW) model, to map the spatiotemporal evolution of seismic swarms. The CTRW model is a well-established stochastic framework for modelling anomalous diffusion phenomena in complex heterogeneous media (Berkowitz *et al.*, 2006), including fluid flow in fault zones (O'Brien *et al.*, 2003; Brixel *et al.*, 2020) and seismicity (Sotolongo-Costa *et al.*, 2000; Helmstetter & Sornette, 2002; Michas & Vallianatos, 2018a; 2024) among others. The term "anomalous" is used to signify the deviation of the triggered earthquake diffusion from linear diffusion equations and normal (Gaussian) diffusion. Within this context, earthquake occurrence is considered as a point- process in space and time, with jump lengths and waiting times between successive earthquakes drawn from a joint probability density function. The spatiotemporal evolution of seismicity is then described with an appropriate master equation and the time-fractional diffusion equation (TFDE). The applicability of the model is herein demonstrated for the 2014 Long Valley Caldera (California) seismic swarm that has been associated with pore-fluid pressure diffusion at depth (Shelly *et al.*, 2016) and the results are compared with seismic swarms that have occurred in the Corinth Rift (Greece) (Michas & Vallianatos, 2018a; Michas *et al.*, 2021; 2022) and elsewhere, including injection-induced seismicity (Michas & Vallianatos, 2024) and the 2025 seismic crisis in the offshore area between Santorini and Amorgos.

Methods

Within the CTRW context, we consider seismicity as a point-process in time and space, marked by the magnitude of the event. Starting from an origin, seismicity undergoes a random walk in space and time, where the hypocenter of each new event is the new position of the random walk that occurs after waiting some time τ in the previous position. This process can be described with the joint probability density $\psi(x, t)$, which, in the case of seismicity, expresses the probability of an earthquake to occur at some position x after some time t (Michas & Vallianatos, 2018a). By further considering that jump lengths and waiting times between the successive earthquakes are independent random variables, the probability densities of jump lengths $\lambda(x)$ and waiting times $\varphi(t)$ can be deduced from $\psi(x, t)$. In this case, finite or divergent moments of $\lambda(x)$ and $\varphi(t)$ determine the type of the diffusive process. If both are finite, then the random walk corresponds to the well-known Brownian motion (normal diffusion). If, however, $\lambda(x)$ and $\varphi(t)$ present broad distributions with power-law scaling behavior that signifies long-range interactions, then anomalous diffusion arises (e.g., Metzler & Klafter, 2000). In this case, the mean squared distance (MSD) $\langle x^2(t) \rangle$ of seismicity deviates from its linear growth with time t, a function that characterizes normal diffusion. Instead, for various complex systems that present anomalous diffusion, MSD frequently takes the mathematical form:

$$\langle x^2(t) \rangle \propto t^a. \quad (1)$$

The latter equation manifests the power-law growth of the MSD with time, with the diffusion exponent a characterizing

the various domains of anomalous diffusion. Thereby, for $a > 1$ we get superdiffusion, for $0 < a < 1$ subdiffusion, while for $a = 1$ normal (Gaussian) diffusion is recovered.
In the case of seismicity, the diffusion exponent a can provide a proxy for the rate of triggered earthquake diffusion (McKernon & Main, 2005). The MSD is estimated from an origin that is considered to be the mean position of the first ten events in the beginning of each seismic sequence. Then, $x(t)$ is the 3D Euclidean distance between each event and the origin. The MSD is then calculated from the following equation (Michas & Vallianatos, 2018a):

$$\langle x^2(t)\rangle = \frac{1}{N}\sum_{n=1}^{N} x_n^2(t), \quad (2)$$

where N is the total number of events and $x_n(t)$ the distance of the nth event from the origin that have occurred at time t.
In addition, subdiffusion in terms of the probability density function (pdf) $P(x,t)$ to find the variable under observation (e.g., an earthquake) at some position x after some time t, is interchangeable with the time-fractional diffusion equation (TFDE) (Metzler & Klafter, 2000):

$$\frac{\partial}{\partial t}P(x,t) = {}_0D_t^{1-a} K_a \frac{\partial^2}{\partial x^2}P(x,t), \quad (3)$$

where K_a is the generalized diffusion coefficient and ${}_0D_t^{1-a}$ is the Riemann – Liouville fractional operator of order $1 - a$ ($0 < a < 1$) applied to $P(x,t)$. The standard approach to find the position of the propagator $P(x,t)$ is the Fourier-in-space Laplace-in-time transform (Metzler & Klafter, 2000). In terms of $F(x,t)$, i.e. the pdf of the number of earthquake events having just occurred at some position x after some time t, the solution of the TFDE can be found by using the Riemann – Liouville derivation and in terms of the Fox hypergeometric functions, providing the asymptotic behavior of $F(x,t)$ for large x (Helmstetter & Sornette, 2002; Michas & Vallianatos, 2024):

$$F(x,t) \sim \frac{(\tau')^{-a}}{\sqrt{K_a}t^{1-(a/2)}}\left(\frac{|x|}{\sqrt{K_a t^a}}\right)^{d(1-a)/(2-a)} \times \exp\left[-\left(1-\frac{a}{2}\right)\left(\frac{a}{2}\right)^{a/(2-a)}\left(\frac{|x|}{\sqrt{K_a t^a}}\right)^{2/(2-a)}\right], \quad (4)$$

where $\tau' = T\left(\Gamma(1-a)\right)^{1/a}$ ($a < 1$) and d the spatial dimensions. The latter equation manifests a power-law increase of the earthquake density for short distances from the origin and an exponential decay of seismicity as distance increases.

Results

First, we consider the probability distribution of waiting times τ between the successive events with magnitude $M \geq -0.4$ for the 2014 Long Valley Caldera seismic swarm (Shelly *et al*., 2016). The probability density $p(\tau)$ is calculated by counting the number of τ that fall into logarithmically spaced bins and then normalized by the bin width and by the total number of counts (Michas & Vallianatos, 2018b). In Fig. 1b the probability density $p(\tau)$ is shown that presents asymptotic power-law behavior with exponent -1.51. For comparison, the probability density $p(\tau)$ of the waiting times τ ($M \geq 0$) for the 2020 Perachora (Corinth Rift) seismic swarm (Michas *et al*., 2022) is shown in Fig. 1a, using a seismic catalogue enriched more than thirty-fold with template-matching (Kapetanidis *et al*., 2023). In this case, $p(\tau)$ shows an almost flat regime for short τ and a rapid decay for larger τ, exhibiting a bimodal behavior. This trend is approximated with the q-generalized gamma function (Michas & Vallianatos, 2018b):

$$f(\tau) = C\left(\frac{\tau}{\tau_0}\right)^{\gamma-1}\exp_q\left(-\frac{\tau}{\tau_0}\right), \quad (5)$$

where C is a normalization constant, τ_0 a positive scaling parameter and γ the scaling exponent. The last term in the right-hand side is the q-exponential function:

$$\exp_q(x) = [1 + (1-q)x]^{1/(1-q)}. \quad (6)$$

For $q > 1$, the q-exponential function exhibits asymptotic power-law behavior, while in the limit of $q \to 1$ it exactly recovers the exponential function and the q-generalized gamma the ordinary gamma function, respectively (Michas & Vallianatos, 2018b).

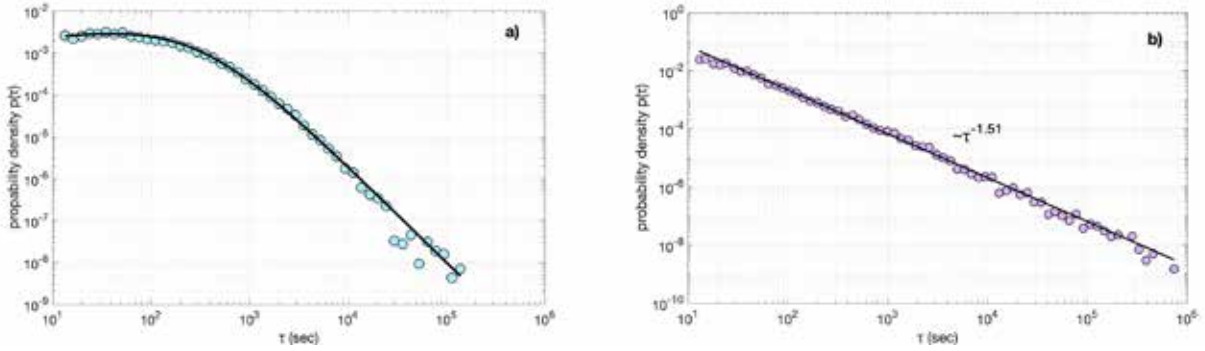

Figure 1. a) Probability density $p(\tau)$ of the waiting times τ (symbols) for the 2020 Perachora swarm according to a template matching catalogue. The solid line represents the q-generalized gamma function fitted to the data, with parameter values C = 0.0012, γ = 1.33, τ_0 = 105.37 and q = 1.38. b) Probability density $p(\tau)$ of the waiting times τ (symbols) for the Long Valley Caldera swarm. The solid line represents a power-law function fitted to the data.

As observed in Fig. 1a, the q-generalized gamma function fits rather well the normalized probability density $p(\tau)$ for the 2020 Perachora swarm, indicating clustering effects in the long-term occurrence of seismicity at breaking asperities that interact with each other. Similar scaling behavior was found for multiplet families during the Perachora swarm (Kapetanidis *et al*., 2023), for the Agios Ioannis seismic swarm that occurred in the western Corinth rift in 2001 (Michas & Vallianatos, 2018a), as well as for injection-induced seismicity in Enhanced Geothermal Systems (Michas & Vallianatos, 2024; Michas, 2025).

Next, the mean squared distance (MSD) $\overline{\langle x^2(t)\rangle}\overline{\langle x^2(t)\rangle}$ of seismicity, as estimated from Eq. 2, is analyzed. For the 2014 Long Valley Caldera swarm, the MSD scales according to Eq. 1 (R^2=0.97), for a diffusion exponent a=0.34 ±0.03 (Fig.2b), showing subdiffusion. The 2020 Perachora swarm presents the higher diffusion exponent of a=0.89 ±0.06 (R^2=0.98), still lower than unity, indicating once more subdiffusion of seismicity (Michas *et al*., 2022). Similar behavior and subdiffusion have also been found for other seismic swarms in the western Corinth rift (Michas *et al*., 2021) and for injection-induced seismicity during hydraulic stimulations in EGS (Michas & Vallianatos, 2024; Michas, 2025). However, diffusion exponents higher than unity and superdiffusion have also been found in seismic sequences and injection-induced seismicity, as for the 2006 hydraulic stimulation in Basel (Michas, 2025) and the 2025 seismic sequence in Anydros, in the Santorini-Amorgos tectonic zone, where a rapid diffusive regime with diffusion exponent >3 is encountered during the first days of intense activity. Such diffusion exponents, close to or even greater than unity, are consistent with pore-fluid pressure diffusion phenomena in fractured media and fault zones (Berkowitz *et al*., 2006; O'Brien *et al*., 2003), implying fluid diffusion as the dominant triggering mechanism. In addition, aftershock sequences associated with stress transfer effects show considerably lower diffusion exponents, generally lower than 0.1 (Huc & Main, 2003; Helmstetter *et al*., 2003; Michas *et al*., 2021), suggesting that diffusion variability may be used to infer the main triggering mechanism of seismicity.

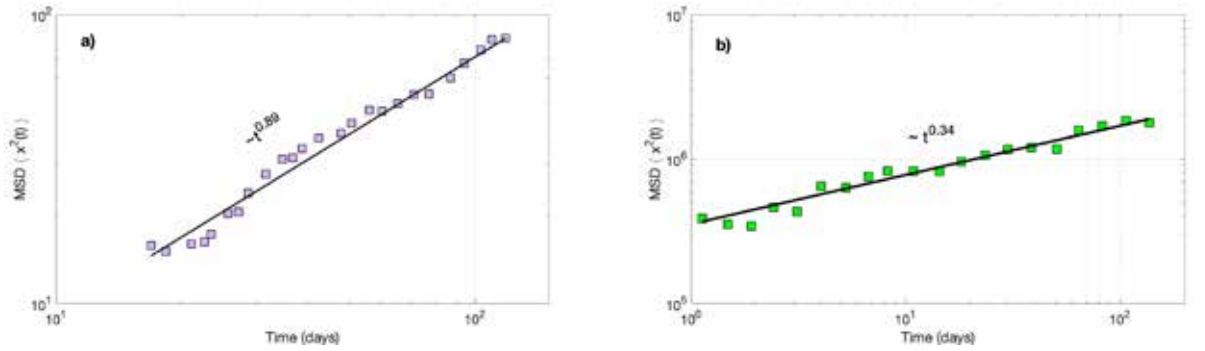

Figure 2. Mean squared distance (MSD) of seismicity with time for a) the Perachora (modified from Michas *et al*., 2022) and b) the Long Valley Caldera seismic swarms (filled squares). Solid lines represent the best-fitting solutions according to Eq. 1 for the diffusion exponents shown in the image.

Furthermore, as discussed previously, the subdiffusive regime of the CTRW model is interchangeable with the time-

fractional diffusion equation (TFDE). Fig. 3 shows the application of its asymptotic solution (Eq. 4) to the observed concentration profiles of seismicity for the Long Valley Caldera swarm for two time periods. In practice, the concentration profile shows the histogram of the absolute 3D distances between each event (for $M \geq M_c$) and the origin. Then, $F(x,t)$ is normalized such that $\int dx F(x,t) = 1$. $F(x,t)$ shows a peak closer to the origin and a tail that stretches towards greater distances. For comparison, the concentration profiles of seismicity for the 2001 Agios Ioannis swarm (Corinth Rift) (Michas & Vallianatos, 2018a) is also shown in Fig. 3 for two time periods. The model successfully captures the main features of earthquake occurrence regarding the peak of concentration close to the origin, the narrowing down and broadening of the peak with time and the stretched relaxation of seismicity with distance.

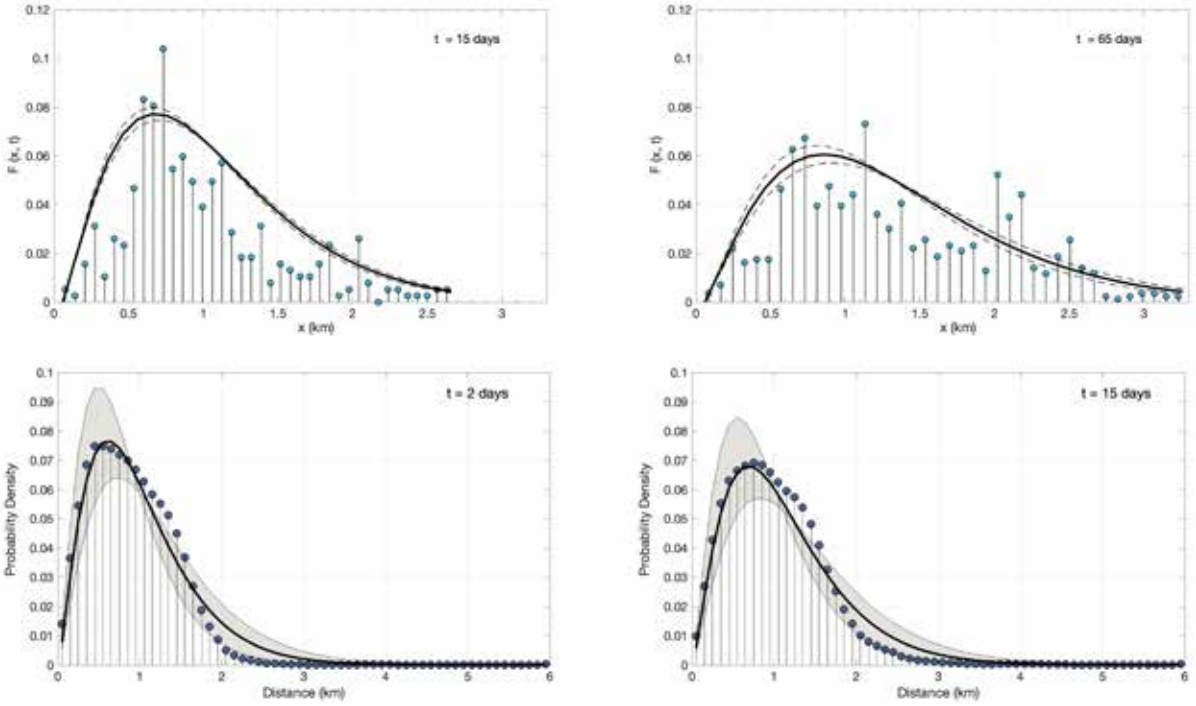

Figure 3. Concertation profiles of seismicity for two time periods, for the 2001 Agios Ioannis seismic swarm (top) (modified from Michas & Vallianatos, 2018a) and the 2014 Long Valley Caldera swarm (bottom). The solid line and the shaded area, or the dashed lines, indicate the asymptotic solution of the TFDE (Eq. 4) and the corresponding confidence intervals, respectively.

Conclusions

Statistical analysis of the studied cases in the light of the CTRW model shows that the mean squared distance of event hypocenters from an origin departs from its linear growth with time, while the temporal occurrence of seismicity exhibits broad waiting times distributions with asymptotic power-law behavior, indicating long-term inter-erathquake interactions. Such properties are intrinsic characteristics of anomalous earthquake diffusion. In such cases, the asymptotic solution of the TFDE can successfully capture the main features of earthquake progression in time and space, showing a peak of event concentration close to the initial source of the stress perturbation and a stretched relaxation of seismicity with distance. Furthermore, the spatiotemporal diffusion variability encountered in various seismic swarms, as well as in injection-induced seismic sequences associated with hydraulic stimulations in EGS, may highlight the main triggering mechanims at play, showing higher diffusion exponents for fluid-related sequences. Overall, the results demonstrate that the CTRW model and the TFDE can efficiently be used to decipher the complex spatiotemporal evolution of seismicity.

EXTENDED ABSTRACT 214

Hellenic Landslide Platform (He.L.P.): A Geospatial Landslide Inventory for Western Greece.

Misiri Z.[1], Lainas S.[1], Depountis N.[1]
(1) University of Patras, Department of Geology, Patra, Greece, geo07060@ac.upatras.gr

Research Highlights: **Development of a comprehensive landslide inventory for Western Greece**

Introduction

Landslides pose a significant risk to communities, infrastructures, and the natural environment throughout Europe and worldwide. Driven by complex geological settings, increasing urban development, and infrastructure expansion, as well as the occurrence of extreme climatic events, landslides are becoming more frequent and severe. This presents a growing hazard for both human activities and economic assets.

Landslides are widely spatially distributed across Europe, with their occurrence influenced by various topographic and geo-environmental factors, often dictated by each Country's unique geological, geomorphological, and environmental conditions. In Greece, landslides are predominantly associated with mountainous and hilly areas, road network, coastal regions, and riverbanks. Specific site conditions, such as lithology, hydrology, hydrogeology, active tectonics, as well as slope gradient and directionn, are critical in determining landslide susceptibility, hazard and risk status.

The complex geological and tectonic settings in Greece contribute to the complexity and variety of landslide types observed. The classification of landslides in the country generally follows established international standards, including those by Varnes (1978), Cruden *et al.* (1996), and Hungr *et al.* (2014). These classifications are based on the type of movement and the material involved. According to these classifications, the most identified landslide types in Greece include earth slides (rotational and translational), earth flows, debris flows, rockfalls, rockslides, and complex landslides.

While the aforementioned conditions predispose areas to landslides, external triggers serve as the immediate causes of landslide activation. In Greece, the most frequent triggers are related to increasingly extreme weather events, such as intense or prolonged rainfalls, often associated with floods. Other natural triggers include earthquakes, as well as natural erosion along coastlines and riverbanks. Human activities also significantly contribute to landslide initiation, as any interference with a slope influences its equilibrium.

Given for certain that landslides triggered by extreme rainfall events will increase in the future due to climate change, there is an urgent need for landslide recording, enhanced monitoring, risk assessment, and predictive capabilities in affected areas to protect communities, infrastructures, and preserve human activities.

To address this, landslide inventories and susceptibility maps have been developed in many countries worldwide, including at small-scale European and Global levels. A European Landslide Susceptibility Map (ELSUS v2) developed by Günther *et al.* (2014) and Wilde *et al.* (2018) is already available at the European Soil Data Centre (ESDAC) web page. Furthermore, a Global Landslide Catalog (GLC), published in 2019, which includes NASA's landslide datasets and other reports contributed by scientists, is available on-line, but should be updated in the future and with other available landslide datasets.

According to the definition given by Fell *et. al.* (2008) a landslide inventory is an inventory of the location, classification, volume, activity and date of occurrence of landsliding. So far in Greece there is no web application with the of landslide inventory in Greece. However, a national landslide inventory is under construction by the Hellenic Survey of Geology and Mineral Exploration (H.S.G.M.E.), which is the competent authority for the identification, recording, investigation and study of geohazards, as well as for the preparation of susceptibility, hazard and risk maps.

The presented in this work Landslide Inventory Platform named as He.L.P. (Hellenic Landslide Platform) is a first attempt to publish a web-based GIS platform that provides information on landslide phenomena which have been recorded over time in the geographic territory of Western Greece, as defined by the administrative regions of Western Greece, Epirus, and Ionian Islands.

The aim of the platform is to manage geographic information from multiple sources that can be applied to administrative departments and agencies, scientific and general applications, with the management of the volume of information having multiple feed points.

Presentation of the platform

The design and development of HeLP (Hellenic Landslide Platform) (Figure 1) is the achievement of many years of effort by all the members of the Laboratory of Engineering Geology of University of Patras (Professors, PhDs,

Postgraduate students) and was prepared after years of collection, processing and analysis of data from landslide surveys and studies performed by the Laboratory members, satellite images, historical records, as well as studies from Public Authorities, Organizations, Institutes, as well as Technical and Engineering Consulting Companies. Moreover, the possibility for continuous completion and updating with additional records, gives the Platform a "dynamic" character with the prospect of its expansion throughout Greece.

Figure 1: The HeLP (Hellenic Landslide Platform) developed by the EnGeo lab. The red dots represent the landslide events

The Platform draws all its data from geographic databases maintained by the Laboratory of Engineering Geology. In this way, the end user has at his disposal the satellite image of the area with information such as, inventory code, geographical location based on the administrative division of Greece, coordinates in GGRS87, type of landslide and a Landslide Inventory Form (LIF) as a pdf sheet.
In a more advanced process, the platform can display various lists of layers concerning a) the administrative boundaries of a region or a municipality, b) the elevation, c) geological data (engineering-geological units, etc), d) the land use patterns, e) boreholes, f) information on geotechnical monitoring, etc. (Figure 2)

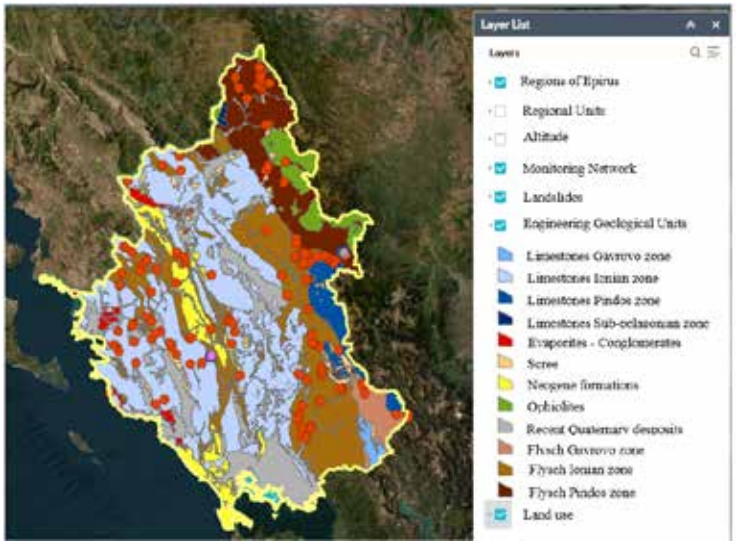

Figure 2. Display of He.L.P. (https://gis.geodory.gr/) for the Region of Epirus. The red dots represent landslide events.

The platform presently includes 1176 landslides. The detailed inventory and the corresponding descriptive data are stored in a database, separately from the graphical part of the inventory map in the form of tables, which allows the visualization of queries and analysing.

The main requirement for predicting future landslides is a well-documented Landslide Inventory Form (LIF). LIF has as its main purpose the recording of all landslides under a common code to achieve an objective in comparison between them and to make it easier to register a new landslide. The design of LIF, used in the He.L.P. platform, was based on the landslide report (WP/WLI, 1990), summary (WP/WLI, 1991), activity (WP/WLI, 1993), landslide causes (WP/WLI, 1994), and rate of movements (WP/WLI, 1995) as well as on corresponding forms of international organizations (United States Geological Survey) and the experience of the Laboratory's staff in the field of landslides. The presented LIF (Figure 3) provides all the necessary information in a condensed form so that it can be easy to rapidly assess the possible risk of each landslide to the natural and man-made environment. It includes seventeen (17) basic fields of information, some of which are subdivided into other categories, as described below.

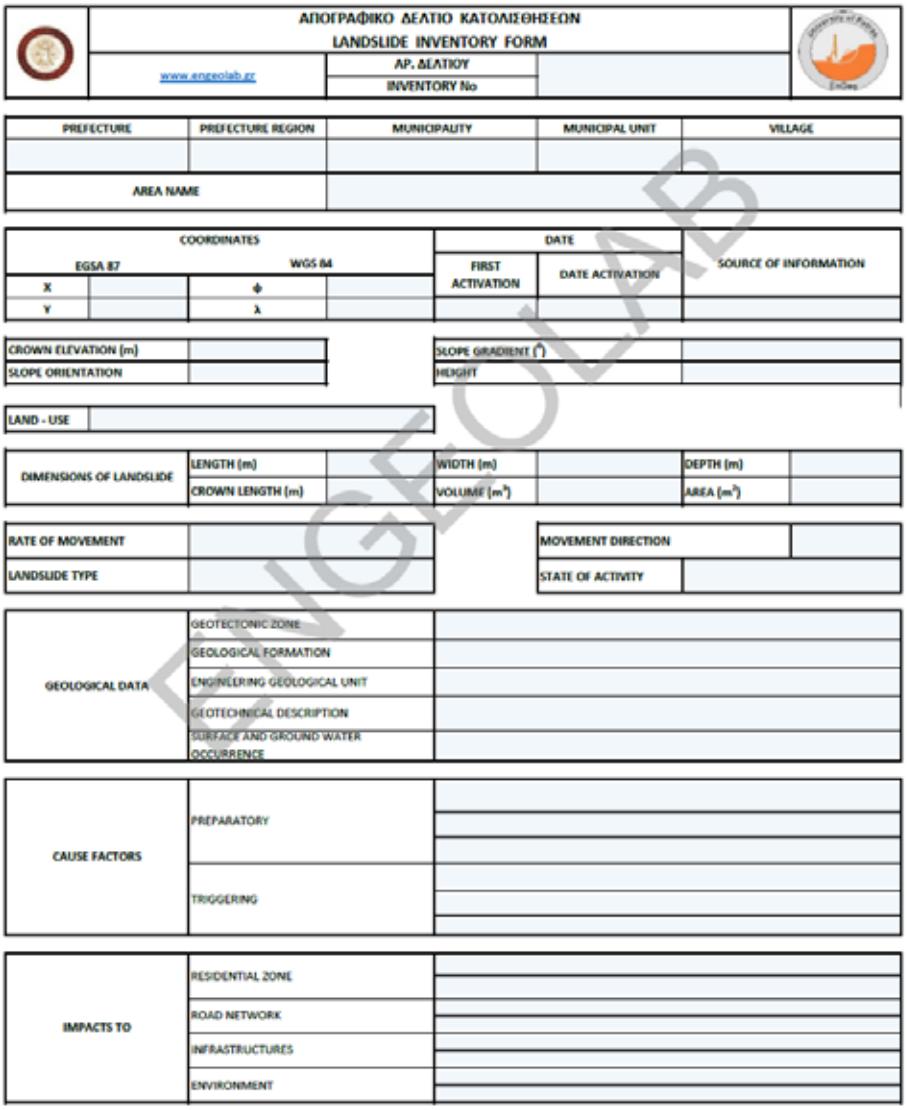

Figure 3. The Landslide Inventory Form used in the He.L.P. platform

Land use classification was based on the Corine Land Cover 2018 project, which is part of the Pan-European Land Use Database and includes residential areas, cultivated areas, forest areas, wetlands and fire-affected areas.

Landslide type was indicated according to the classification of Varnes (1978), whose main criteria are the type of movement and the type of material (Figure 4).

TYPE OF MOVEMENT		TYPE OF MATERIAL		
		BEDROCK	ENGINEERING SOILS	
			Predominantly coarse	Predominantly fine
FALLS		Rock fall	Debris fall	Earth fall
TOPPLES		Rock topple	Debris topple	Earth topple
SLIDES	ROTATIONAL	Rock slide	Debris slide	Earth slide
	TRANSLATIONAL			
LATERAL SPREADS		Rock spread	Debris spread	Earth spread
FLOWS		Rock flow (deep creep)	Debris flow (soil creep)	Earth flow
COMPLEX		Combination of two or more principal types of movement		

Figure 4: Classification of landslides according to Varnes (1978)

The geological data are a decisive factor for the likelihood of a landslide occurrence. In the LIF Geotectonic Zone refers to the Geotectonic Zones of Greece, for example Ionian, Sub-pelagonian, Pelagonian, Paxon zone, while the Engineering Geological Unit describes the lithology, and the properties of the materials involved in the movement.
The landslide causal factors are divided into preparatory and triggering factors (Varnes 1978). A preparatory factor can act for years preparing the conditions for the occurrence of a landslide, while a triggering is the factor that under certain conditions can shift the slope from a marginally stable to an actively unstable state. Some of the preparatory factors are surface erosion, annual or seasonal rainfall, slope and tectonics, while triggering factors are earthquakes, volcanic action, and intense or prolonged rainfall.
Landslides have various effects on both the natural and human environment. Effects can be quantitative or qualitative, extensive or not. Table 1 lists examples of the landslide impacts in Residential Zones, Road Network, Infrastructures and the Environment.

Table 1. Impacts of landslides

IMPACTS	RESIDENTIAL ZONE	Damage to buildings
	ROAD NETWORK	Failure of embankments
	INFRASTRUCTURES	Failure of public service networks
	ENVIRONMENT	Loss of arable land

Conclusions

Landslides are a major geohazard, as they are widespread and rank high on the list of natural disasters. In Greece, their occurrence is frequent and controlled mainly by geomorphology, geological structure, seismicity and rainfall. Therefore, their recording is of utmost importance and aims to process their data for scientific and civil protection purposes.
The grouping of the most important parameters describing landslides from a huge number of different information sources created the need for the creation of the presented in this paper Hellenic Landslide Platform names as He.L.P., and the creation of a Landslide Inventory Form (LIF) for each landslide. The design of the Landslide Inventory Form as well as the selection and grouping of its parameters (geological conditions, type of landslides, causative factors, etc.) was made according to the current International Standards and guidelines for landslide recording.
The main objective of this work is the presentation of He.L.P., which is a web-based GIS platform, and by today includes 1176 landslides that have occurred in the regions of Western Greece, Epirus, and Ionian Islands. The simplicity of the platform as well as its accompanying LIF, gives to the Platform a “dynamic” character of continuous completion and updating with additional landslide records, with the prospect of its expansion throughout Greece.

Introduction

The present study examines the depositional processes as well as the sedimentary microfacies types of the Paleocene-early Eocene carbonates of the Gardiki section, situated in Epirus region (western Ionian basin, Paramythia, Greece). This study defines the Paleocene-early Eocene depositional evolution of the area, based mainly on litho-stratigraphic characteristics in the external Ionian domain, which is regarded as a significant hydrocarbon prolific basin in western Greece. This work was accomplished by an extensive sedimentological analysis of the carbonate succession, alongside a synthetic paleoenvironmental reconstruction of the study area. Furthermore, the results provide valuable insights into regional geology and contribute to a deeper understanding of the Ionian basin in western Greece.

Study area

The study area is situated in the Ionian zone, a key element of the fold-and-thrust belt of the External Hellenides orogenic belt in western Greece. The External Hellinides are divided into three tectonostratigraphic zones, namely the pre-Apulian, Ionian, and Gavrovo-Tripoli tectono-stratigraphic zones. At a regional scale, this Alpine belt records the initiation, development, and final destruction of the southeastern margin of the Tethys Ocean and the consequent continent-to-continent collision between the Apulian and the Pelagonian micro-continents to the east. On a local scale, the various sub-basins of the Hellenic Tethys margin have been inverted to produce the main Hellenic thrust sheet folded zones. The Ionian zone, bounded westwards by the Ionian thrust and eastwards by the Gavrovo thrust, extends from Albania to the north most of the Epirus region and parts of the Ionian islands and continues southwards to Central Greece, Crete, and the Dodecanese. According to Auboin (1959) and IGRS-IFP (1966), the Ionian zone is subdivided into the Internal, Middle and External sub-basins (Figure 1a).

Materials and methods

A total of 126 samples were systematically collected from Gardiki area (lat: 39°20′22,08′′ N, long: 20°33′5,63′′ E) (Figure 1b), covering the Paleocene-early Eocene carbonate formations. The fieldwork included detailed logging, measurements and sampling, along with additional observations made on the litho-stratigraphic properties of the limestones, such as colour, lithological and textural variations, bed thickness, syn- and post-depositional features etc. Sampling resolution varied along the section, influenced by outcrop conditions, thickness and the lateral extend of each carbonate unit.

All samples undergone microfacies analysis, focusing mainly on lithofacies and biofacies, to ascertain their age and depositional environment. Thin sections were prepared at the Hellenic Survey of Geology and Mineral Exploration (H.S.G.M.E.) and examined biostratigraphically and sedimentologically using a polarized LEICA DM LP microscope, with photographs captured via an OLYMPUS UC30 microscope digital camera.

The microfacies description and textural characters analysis of the limestones were defined according to Dunham (1962) classification scheme, which was later modified by Embry and Klovan (1971) and Flügel (2004), based on the Standard Microfacies Types (SMF) in the Facies Zone (FZ) of the rimmed carbonate platform model. Depositional paleoenvironments were reconstructed by analyzing sedimentological characteristics observed during the fieldwork and interpreted sedimentary facies analysis. This analysis was supplemented by comparing additional data from existing time-equivalent sections of the same formation known from the literature.

Finally, the basic geological information was provided by the geological map (PARAMYTHIA SHEET 1:50.000) of the Hellenic Survey of Geology and Mineral Exploration (H.S.G.M.E.).

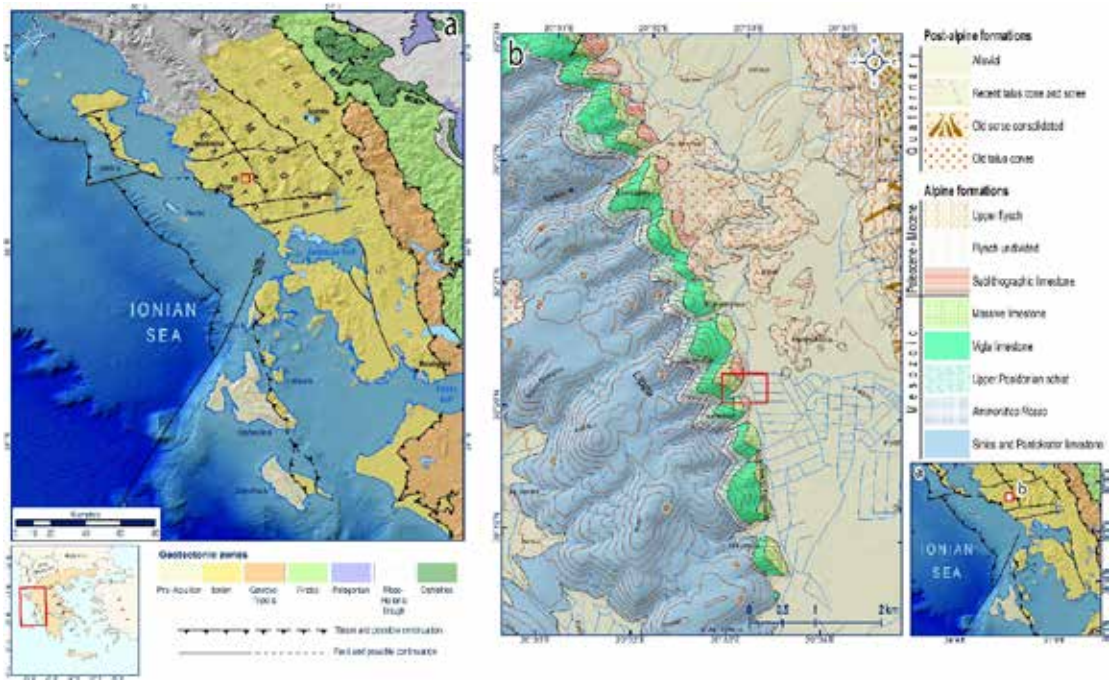

Figure 1(a,b). a) Geological map of the External Hellinides in NW Greece, illustrating the principal tectono-stratigraphic zones: Pre-Apulian, Ionian, Gavrovo, Pindos. b) Geological map of the study area. The red square shows the location of the study area. Legend interpretations are presented in the inset.

Biostratigraphy

The biostratigraphic analysis based on planktonic foraminifera presented in Table 1, revealed that the study part of Gardiki section covers the Paleocene-early Eocene time span based on the existence of *Morozovella* sp., *Operculina* sp., *Miscellanea* sp., *Melobesia* sp., Globorotaliidae and Globigerinidae. In addition, the appearance of radiolarians, rudist fragments, Dasycladacea algae, Siderolites spicules, Globotruncanidae, *Orbitoides* fragments, Miliolidae, *Idalina sp.*, supports their transportation form the underlying Upper Cretaceous Senonian limestones.
The age determination is in partial accordance with the geological map (PARAMYTHIA SHEET 1:50.000) concerning the Ionian rock exposures in Epirus area.

Sedimentary Microfacies Analysis

The key textural and compositional attributes, along with the sedimentary features of the identified microfacies are outlined in Table 1, corresponding to various depositional environments or facies zones. More specifically, within the studied carbonate succession, we observed 4 distinct sedimentary microfacies (Figure 2), which correspond to environments ranging from the upper part of the slope to the deep shelf. They mostly include in-situ wackestone-packstone lithofacies enriched in keeled planktonic foraminifera of Paleocene age, accompanied by faunal fragments indicative of shallower conditions due to their erosion and transportation by turbiditic currents along the slope, e.g., from the nearby platform to the basin. Within these deposits, the presence of bioclasts like the pelagic Globotruncanids in the micritic matrix of the basal samples was interpreted that they have been transferred from the underlying Upper Cretaceous strata. In the Ionian zone, such “clastic limestones” are usually alternated with sub-lithographic pelagic limestones reflected mostly by bioclastic mudstone facies (Kontakiotis *et al.*, 2020; Bourli *et al*., 2021; Moforis *et al.*, 2022).
More explicitly, the lower part of the succession was characterized by alterations of a pelagic biomicrite mudstone mostly with planktonic foraminifera and more rarely radiolarian (SMF 2-3) with a bioclastic biomicrite wackestone-packstone with abundant planktonic foraminifera (SMF 3-4), reflecting deposition in a low energy, relatively deep environment such as the toe of slope (FZ3) and/or the deep shelf (FZ2). A microbreccia bioclastic rudstone enriched in planktonic foraminifera along with fragments of shallow water fauna (benthic foraminifera, rudists, echinoderms and algae) (SMF 5), represents deep slope depositional conditions (FZ 4). A biomicrite packstone-grainstone (SMF 5) with mixed fauna and reworked lithoclasts was also observed and could be considered as indicative of a medium to high energy environment in the upper part of the slope close enough to the platform.

Samples	Description of Microfacies Analysis	Facies Zone	Lithology	Age
K69-K126	Biomicrite packstone-grainstone (SMF 5)	Slope (FZ 4)	Turbiditic limestone	Paleocene-early Eocene
	Biomicrite mudstone (SMF 2-3)	Deep shelf (FZ 2)		
K60-K68	Bioclastic rudstone (SMF 5)	Slope (FZ 4)	Micro-brecciated limestones	Paleocene
K1-K59	Bioclastic biomicrite wackestone-packstone (SMF 3-4)	Toe of slope (FZ 3) and/or Deep shelf (FZ 2)	Turbiditic limestone	Paleocene
	Biomicrite mudstone (SMF 2-3)			

Table 1. Description of microfacies analysis of samples from Gardiki section (Epirus, western Greece).

Research Highlights

Acquisition analysis of widely available geospatial information to assess the state and dynamics of island beaches.

Introduction

Assessing the state and dynamics of sandy shorelines (beaches) is vital for developing efficient management strategies (e.g. Karditsa *et al*., 2024; Chalazas *et al*., 2024), with the approaches used depending on their spatio-temporal scales and the available information and resources. In regional (island) scales, the extensive scope of studies and the high potential costs of adaptation (Narayan *et al*., 2016) may require prioritization of responses and efficient allocation of the (mostly) limited resources. This requires, among others, information of the geospatial characteristics and their interrelationships which may provide much needed information and identify potential controls of beach dynamics. Therefore, the objective of this short contribution is to present an approach that could acquire such information at a regional (island) scale on the basis of widely available geospatial data; the approach is demonstrated for the island of Kos, South Aegean Sea, Greece (Fig.1).

Study area

Kos has an area of about 295 km^2, a coastline length of 112 km and a resident population of about 37,100. Kos is a highly touristic island: in 2023, 1.3 million passengers arrived at the island of Kos. There are > 57,000 hotel beds in Kos, tourism density and intensity being very high (28,917 tourist nights/km^2). Most of this infrastructure and the tourist activities are associated with the island's beaches, as Kos is a global tourist destination for Sea-Sand-Sun - 3S tourism (SETE, 2024). Kos coast is microtidal (0.1 m astronomical tidal range). In the north NNW waves dominate with the largest waves showing heights Hs of 3.8 m and periods Tp of 7.5 s. Energetic waves occasionally impinge on western and southern coasts, with the largest waves having heights of 4–5 m and periods of 9–10 s (Monioudi *et al*., 2025). Kos is a part of the easternmost South Aegean volcanic arc. Its northeastern part is mostly formed on Plio-Quaternary sediments, whereas its southeastern highlands are made mostly of alpine and pre-alpine metamorphics and some Miocene volcanics (Pe-Piper *et al*., 2024). Following a hiatus, volcanism, resumed 3 million years ago (mostly) in the island's west; the large eruption of the Kos Plateau Tuff volcano (161 ka BP) deposited pyroclastics up to 15 m thick that covered most of the western Kos and the adjacent islands (Piper and Pe-Piper, 2020). Most large/wide beaches are found in the low-relief, sedimentary northeastern Kos (Fig. 1), indicating a potential geological control.

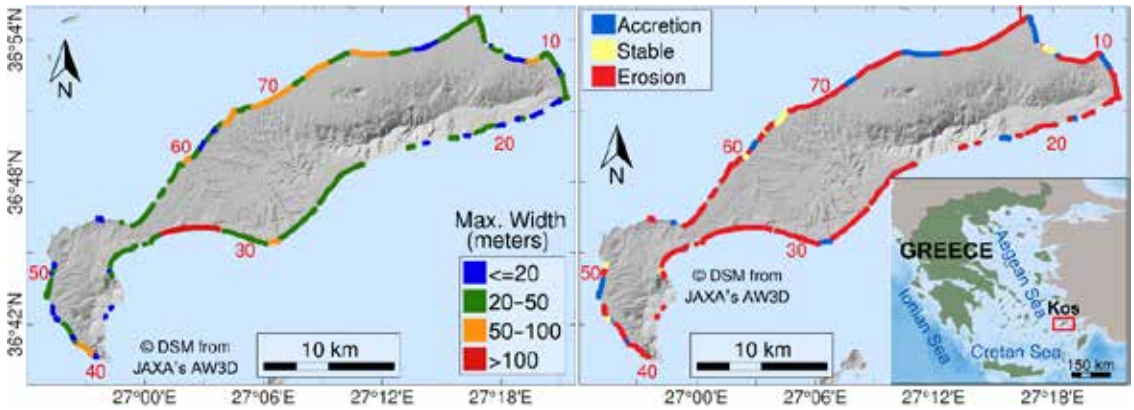

Figure 1. Kos: Beach maximum width (BMW) and long-term beach erosion trends. Numbers refer to the ID of the 78 beaches of Kos (after Monioudi *et al*., 2025).

Methods

The compiled inventory of the Kos beaches provides information on the dimensions, sediment types and the presence of outflowing streams, coastal defenses or artificial and natural features. Using satellite images available in the Google Earth Pro application, subaerial (dry) beaches were digitized as polygons based on clearly visible boundaries: natural features like vegetated dunes or cliffs and permanent artificial structures such as embankments, seawalls, or buildings and the shoreline define the landward and seaward limits, respectively. To ensure consistency, all digitization was conducted by a single analyst adhering to strict delimitation rules. The database was constructed through the digitization of beach polygons from selected images obtained in the period 2003–2021, which allowed an estimation of the recent historical changes. The beach (CNES/Airbus and Maxar) imagery has a spatial resolution about 0.5 m, but its results are constrained by the image accuracy; comparison of satellite images with concurrent RTK-DGPS ground observations showed an RMSE of about 2 m. Moreover, although tidal effects on the shoreline position are very small care was taken to analyze satellite images from the same season and under low hydrodynamic conditions; however as the available images along the islands' coasts have been collected at different times and under different preceding hydrodynamic conditions, recorded beach dimensions may not represent synoptic conditions at the island scale. Such limitations, however, cannot be avoided in the analysis of (historical) satellite imagery at large spatial scales (Monioudi *et al*., 2023). Following these procedures, the characteristics of 78 (Kos) beaches (Fig. 1) were identified, recorded and compared.

Results

The majority of beaches (53%) were found to have maximum widths (BMWs) of 20-50 m, 35% had widths < 20 m and 10 beaches had widths > 50 m (Fig. 1); the average maximum width was found to be 31 m. Despite the higher wave energy of the north- and west-facing beaches, a clear trend was observed in the development of northwest-facing beaches (303.75°- 348.75°). Fewer beaches were found to develop with southeast (16%) and south (12%) orientations, with the remaining beaches exhibiting other orientations (Fig. 2). This supports the hypothesis that the development of the Kos beaches is not controlled by the hydrodynamics, but is mainly subject to geological controls.

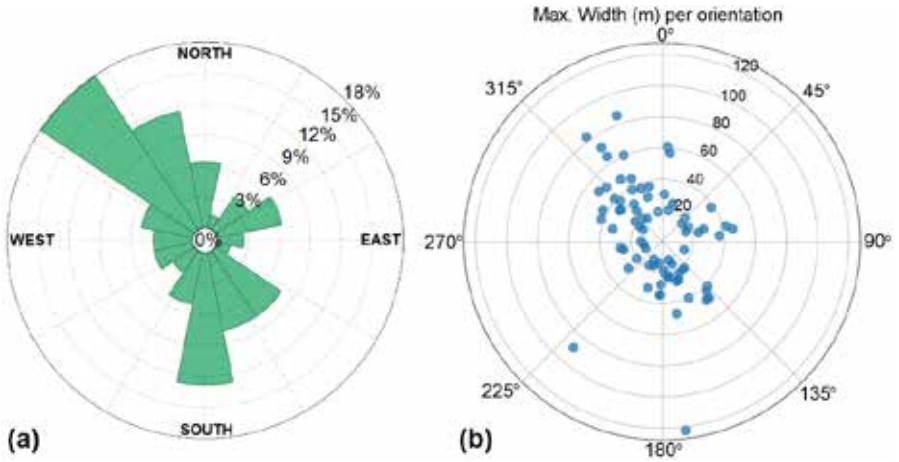

Figure 2. (a) Distribution of the Kos beach orientation. (b) Rose diagram of the beach maximum widths.

The relationship between orientation and the BMWs was further investigated using Angular-Linear correlation (Mardia, 1976; Zar, 2014) was used. This statistical test assesses the null hypothesis H_0 of no correlation between the two variables against the alternative hypothesis H_1 of a significant correlation. The results showed an $R^2 = 0.0327$ and $p = 0.279$, suggesting rejection of the H_0 hypothesis as $p > 0.05$; thus, there is no statistically significant correlation between the two variables.

There are outflowing streams in many Kos beaches (49%), indicating (potential) terrestrial sediment supply. Comparison of the BMWs with the occurrence of streams, shows that stream presence affects the beach size. In 2021, beaches with streams were found to have an average maximum width of 40.4 m which was almost double the

width of beaches without streams (22.8 m). In order to examine the potential correlation between stream presence and BMWs it was checked whether the BMWs follow a normal distribution. Using the Shapiro-Wilk regularity test (Shapino and Wilk, 1965), it was found that the BMWs do not show 'normality' in terms of distribution (the Shapiro-Wilk regularity control gave W = 0.772, p <0.001); thus, the non-parametric Mann-Whitney test was used. Its result showed that these two types of beaches differ (U = 307.5, p <0.001), i.e., there is a correlation between beaches without streams and smaller BMWs with a median width of 22 m (Fig. 3a).

Regarding beach sediments, the majority of Kos beaches (53%) form on sandy sediments, whereas 32 % of the beaches on mixed sediments (gravels/sands) and 15% on pebbles. Comparison of the BMWs with the different sediment types showed good correlations; sandy beaches had an average BMW of 40.8 m (standard deviation 20), i.e. they are significantly wider than mixed sediment beaches and pebble beaches which showed average BMWs of 23.4 m (10.8 standard deviation) and 16 m (7.3 standard deviation), respectively. Even when the mixed sediment and pebble beaches were grouped together, their comparison with the sandy beaches showed a clear difference. Sandy beaches were found to have significantly greater BMWs (40.8 m) compared to the grouped mixed sediment/pebble beaches (21 m). It appears that the coarse sediment beaches attain BMWs 10-25 m, whereas the sand beach BMWs 30-50 m and 50-80 m (Fig. 3b).

In addition, it appears that about 60% of sandy beaches are also associated with outflowing streams, compared with those beaches forming on mixed sediments (45%) and pebbles (17%). To check this hypothesis the non-parametric Kruskal-Wallis test was used (the BMWs do not follow a normal distribution). The test checked the hypotheses: H_0, no correlation between the BMWs and the local sediment; and H_1, correlation between BMWs and the local sediments. The test showed that there is a clear difference between the maximum widths of beaches forming on sand and those forming on mixed/coarse sediments (H_1 = 25.911, p < 0.001). Beaches forming on pebbles have a median BMW of 14.9 m, whereas those formed on mixed sediments and sands 22.6 m and 40.5 m, respectively. A Kruskal-Wallis test (Kruskal and Wallis, 1952) was also applied in the case that beaches divided into two classes: those with sand sediments and those with mixed sediments and pebbles. The test showed a clear difference between these beach classes (H_1 = 25.090, p <0.001).

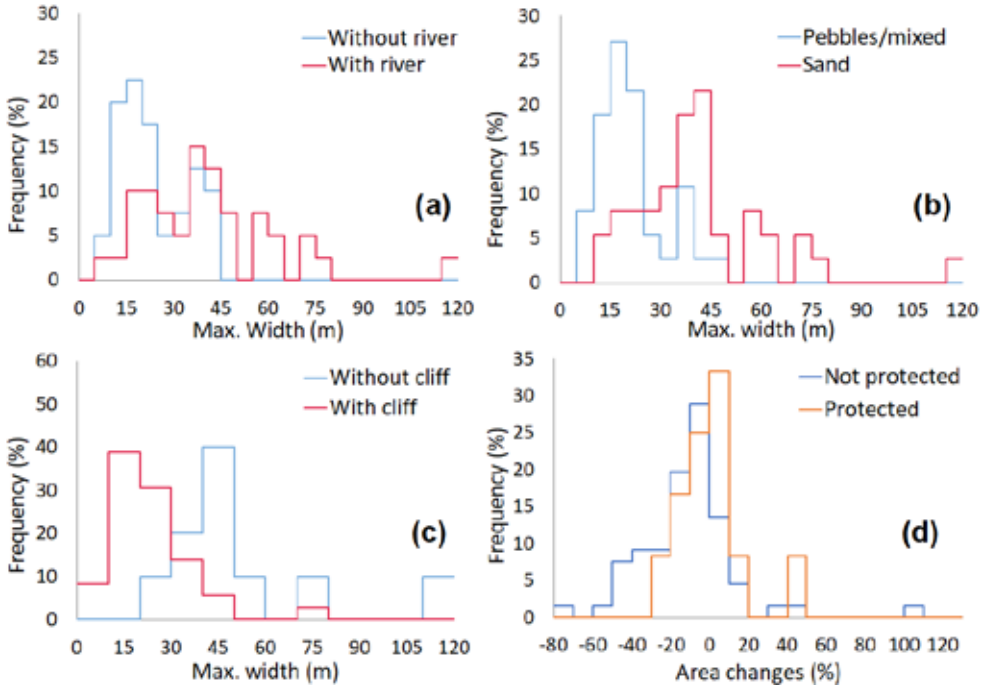

Figure 3. (a) Beach maximum widths (BMW) and the presence of beach streams (5 m steps), (b) BMWs and sediment texture (2 categories), (c) BMWs with the presence of backshore cliffs (10 m steps) excluding beaches with backshore infrastructure, and (d) Histogram of frequencies of areal changes.

A total of 50% of the island's beaches are characterized by the presence of backshore coastal cliffs. An initial investigation of the potential correlation with the BMWs did not reveal a significant relationship. However, as the presence of infrastructure/assets along the immediate backshore might affect the BMWs and other beach dimensions due to e.g., reduction/interruption of the land sediment supply and, thus, the correlation. Excluding beaches where there are backshore infrastructure/assets (about 50% of the total), a significant relationship is apparent (Fig. 3c). Many beaches with cliffs show BMWs of 10-20 m (and up to 30-50 m), whereas the beaches without cliffs attain obviously greater BMWs. The relationship was tested using the Mann-Whitney method excluding beaches with backshore infrastructure/assets. It appears that there is a statistically significant relationship ($U = 34$, $p < 0.001$). Those beaches without a backshore cliff are larger (a median BMW of 46 m) than those with a backshore cliff (median of 22 m). It seems that the coastal topography controls beach formation and size.

To assess the impact and effectiveness of coastal protection schemes, the areal changes between the beach polygons obtained from older imagery (2004-2009) and 2021 were considered which was preferred over more recent ones, as images were taken in spring/summer months (Fig. 3d). The Shapiro-Wilk regularity test for the variable 'beach area change' yielded results $W = 0.889$ and $p < 0.001$ showing that the data do not follow a normal distribution. Thus, the non-parametric Mann-Whitney control was also applied by controlling the following assumptions: H_0, the distribution of the continuous variable "percentage of change of beach area" is similar between beaches with coastal protection works and beaches without protection works; and H_1, the distribution of the continuous variable "percentage of change of beach area" differs between beaches with protection works and beaches without works. The test results show there is a significant areal difference ($U= 260$, $p=0.050$) between beaches with and without coastal works.

Discussion and Conclusions

The analysis of the geo-spatial data using both basic statistical metrics and more complex parametric and non-parametric tests, led to interesting findings regarding the Kos beaches. Comparison of the digitized polygons of the beaches showed erosion trends (Fig. 1) with the average BMW having decreased in 76% of the beaches compared to the period 2004-2009 (average decrease of 3 m). In addition, the area was reduced in 61 beaches out of the 78 beaches of the island, with an average decrease of 15% per beach. As the maximum dry width is considered a relatively conservative indicator of beach erosion (Monioudi and Velegrakis, 2022), the estimation of the areal reduction offers a more comprehensive picture. The analysis also showed that the detection of long-term erosive trends requires availability of time series of data with spatio-temporal resolution better than that currently available in open source imagery. In the near future, when it is expected that the availability of such data will increase significantly (Velegrakis *et al*., 2024), the approach developed/applied in the present study can be used more for the detection (and management) of coastal morphodynamics (erosion). In Kos, the orientation of the beaches does appear to affect the size of the beach, which on the contrary is related to stream presence and sediment texture size. In addition, the presence of backshore cliffs is correlated with small BMWs. Generally, it appears the Kos beach dimensions are primarily controlled by the geology rather the hydrodynamics.

EXTENDED ABSTRACT 217

Innovative educational programs at the Lavreotiki UNESCO Global Geopark: the ERASMUS+ "ARTeMIS" Program Action for Research and Teaching Mineral exploration Inclusive School, Greece

Moraiti E.[1], Voudouris P.[2], Tarantola A. & Barsaki V.

(1) Lavreotiki UNESCO Global Geopark, Lavrion, Greece, eugeniamoraiti@gmail.com (2) National and Kapodistrian University of Athens, Ilissia, Greece

Introduction

UNESCO Global Geoparks (UGGp) are single, unified geographical areas where sites and landscapes of international geological significance are managed with a holistic concept of protection, education and sustainable development. Their bottom-up approach of combining conservation with sustainable development while involving local communities is a fundamental principal and is becoming increasingly popular.

The UNESCO Global Geoparks are ideal destinations that can support local communities and serve the 17 goals of the United Nations' Green Agenda in various ways.

In particular geoparks educate and prepare societies and youths for the new challenges that climate crisis has triggered. Education holds a pivotal role in the operation and management of a geopark. Every member is obliged to implement educational programs based on its geodiversity and biodiversity wealth. Geosites function as experiential laboratories, welcoming students, educators, and visitors to offer them unique experiences and communicate a sustainable way of living.

The ARTeMIS ERASMUS+ program

In the frame of collaboration and the accomplishment of the 17, Lavreotiki UNESCO Global Geopark has joined the ARTeMIS Erasmus + project. This project (funded with 385.000 euros per year and three years duration in total) is led by Alexandre Tarantola, Professor (Associate), head of the first year of the Master's degree in "Earth and Planetary Sciences, Environment", "Earth-Resources System" course of the University of Lorraine, Nancy. Its objective is to develop the methods and tools of geoscience professions through a research-based training approach. It aims to allow students to confront the realities and expectations of the field in geology, to complete their academic career and to broaden their horizons by allowing collaboration with students from other European Universities. This approach brings together various players working on the theme of mineral exploration such as the Friedrich-Alexander-University of Erlangen-Nuremberg, the National and Kapodistrian University of Athens (Scientific Responsible, Professor Panagiotis Voudouris), the Aristotle University of Thessaloniki (Scientific Responsible, Professor Vassilis Melfos) as well as Hellas Gold SA, a subsidiary of the Canadian company Eldorado Gold Corporation, which specializes in the exploration and exploitation of mines worldwide and the Lavreotiki UNESCO Global Geopark with its famous deposits. The Lavrion deposit comprises five different styles of related deposits, a unique geological phenomenon recorded only in Greece and in the Lavreotiki UGG's territory.

Its minerals contain the highest number of different elements (48) of any known mining district and thus more diverse than anywhere else in the world. Lavrion area offers the best opportunity to study the interplay between large-scale tectonic processes which took place during earlier Alpine collision and compression, followed by Miocene extension in the back-arc region of the Hellenic subduction zone; magmatic activity, expressed by emplacement of various igneous rocks in a syn- to post-tectonic regime; hydrothermal activity and fluid circulation within various lithologies, resulting in enormous quantities of ore deposition and related base and precious metal mineralization, later supergene weathering processes, resulting in a unique zone of supergene ore oxidation, which contains, in addition to the primary ores, the most mineral species ever found on a single mining district on earth and the way, geological processes have profoundly influenced ore deposition and the course of human history and technology.

Among many courses and actions, the "ARTeMIS" program includes a 4-days training course in the field (at the geopark's mining galleries) for teachers and students, using spectroscopic analysis tools and the implementation of classroom lessons in mineral resource geochemistry. These actions provide an opportunity to carry out exercises in the use of spectroscopic analysis tools, mapping and reflection on the establishment of metallogenic systems on geological objects that are at the heart of the research carried out by the various partners. The 4-days training course took place in April with great success.

Figure 1. Photography captions during the 4-day training course in the field, at the Lavreotiki UGGp geosites / sites of mining heritage.

Results

The expected results of the "ARTeMIS" ERASMUS+ program are:

- The creation of complementary teaching units for teachers and second-cycle university students engaged in an "exploration and mineral resources" course.
- The use and development of portable field tools suitable for mineral exploration.
- The application of an ergonomic approach to training and research in geology.
- The publication of an educational field guide dedicated to the mineral resources of northeastern Greece.
- The creation of a logistics preparation methodology.

Last but not least, an important aspect of the ARTeMIS project also aims to promote the integration of students with disabilities by making training accessible in order to offer them new opportunities for professional integration. To this end, a collaboration has been initiated with occupational therapists from the Lorraine-Champagne-Ardennes Occupational Therapy Training Institute with a view to identifying avenues for improvement and proposing alternatives. Workshops will be held, bringing together teachers, students, Earth Sciences stakeholders and occupational therapists. In the long term, these solutions will lead to a diversification of jobs and the development of processes that are more in line with the specificities of field geology.

Such substantive partnerships become models of good practices for the adaptation and sustainability of the local communities and the organizations involved in education. These partnerships foster interdisciplinarity and communicate science and universal values, such as collaboration, respect, inclusion, and quality education, to the youth and the next generations. These values are included and promoted by the United Nations Sustainable Development Goals (such as SDG 4, SDG 11, SDG 12, SDG 13, and SDG 17).

Figure 2. SDG 4: Ensure inclusive and equitable quality education and promote lifelong learning opportunities for all, SDG 12: Ensure sustainable consumption and production patterns, SDG 16: Promote peaceful and inclusive societies for sustainable development, provide access to justice for all and build effective, accountable and inclusive institutions at all levels & SDG 17: Strengthen the means of implementation and revitalize the Global Partnership for Sustainable Development.

EXTENDED ABSTRACT 218

Empowering Future Generations: Incorporating Geo - Environmental Education on Climate Change into Greek Compulsory Education

Moshou H., Drinia H.

Department of Geology and Geoenvironment, National and Kapodistrian University of Athens, Panepistimiopolis, 15784 Athens, moshouhara@geol.uoa.gr

Introduction

The urgent need to address climate change has never been more critical, as its impacts are being felt globally, with severe consequences for ecosystems, economy, and human communities. Adapting to a rapidly changing world is equally essential. Climate change poses one of the greatest challenges of our era, making immediate action imperative. Education, including geoeducation, can serve as a key tool in preparing future generations to mitigate and adapt to these challenges. Geoeducation, enriched with geoconservation principles, emphasizes the importance of protecting geological heritage while fostering an understanding of Earth's processes and their relevance to the climate crisis. Therefore, it provides a unique opportunity to equip students with the knowledge and skills to grasp the complexities of climate change and its impact on our planet.

This paper underscores the significance of education, particularly environmental education and geoeducation, in addressing the climate crisis, while also exploring obstacles and challenges regarding the implementation of climate change education in Greece. Additionally, it proposes general strategic approaches for systematically integrating climate change education into the compulsory education system, with the objective of fostering both mitigation and adaptation in response to the climate crisis. The study employs a mixed-method approach to explore integrating climate change education (CCE) into Greek compulsory education. A systematic review of national and international studies identifies best practices, challenges, and gaps in implementing CCE. SWOT analysis evaluates internal factors like teacher preparedness and resources, while PEST examines external political, economic, social, and technological influences.

The Importance of Geo - Environmental Education in Addressing the Climate Crisis

Recognizing the critical role of education in addressing climate change is essential. Environmental education fosters ecological awareness and equips citizens with the skills and attitudes necessary to adopt sustainable practices and social responsibility (Damoah, 2023; Daskolia, 2023; Nantsopoulos & Mogias, 2020). Geoeducation, with its emphasis on understanding Earth's systems, geological processes, and their interaction with the environment, complements this effort by providing a scientific foundation for grasping the complexities of climate change. Together, environmental education and geoeducation not only raise public awareness but also encourage proactive behavior, leading to significant behavioral shifts. Coupled with effective government policies (see Figure 1), they can mitigate climate impacts and enhance societal resilience to environmental challenges.

Georgousis et al. (2021) emphasize that geoeducation, or geoenvironmental education, plays a pivotal role in connecting students with Earth's dynamic processes, promoting a deeper understanding of the natural environment, and fostering sustainable attitudes. They argue that integrating geoenvironmental education into curricula can bridge the gap between theoretical knowledge and practical applications, empowering learners to critically assess and address environmental issues such as climate change. Geoeducation, coupled with geoconservation, not only deepens students' understanding of Earth's dynamic systems but also emphasizes the preservation of geosites, which serve as critical records of past climatic conditions. This dual approach empowers learners to appreciate the interplay between geological heritage and environmental sustainability. By focusing on interdisciplinary learning, geoeducation highlights the interplay between geology, geography, and environmental science, making it an essential component of climate-focused education.

The urgency for climate-focused education is greater than ever, as new generations face complex challenges from the climate crisis. Integrating climate change into school curricula fosters early environmental and geoscientific awareness, shaping responsible citizens (Nantsopoulos & Mogias, 2020). Early education is vital, as misconceptions formed in childhood can persist into adulthood (Boyes & Stanisstreet, 1993). Geoeducation is particularly valuable in helping students understand how climate change affects Earth's physical processes and ecosystems, fostering a holistic perspective. Preparing students with solid knowledge and its geological dimensions about climate change enhances their willingness to act and fosters active participation in addressing future challenges (Lester et al., 2006)..

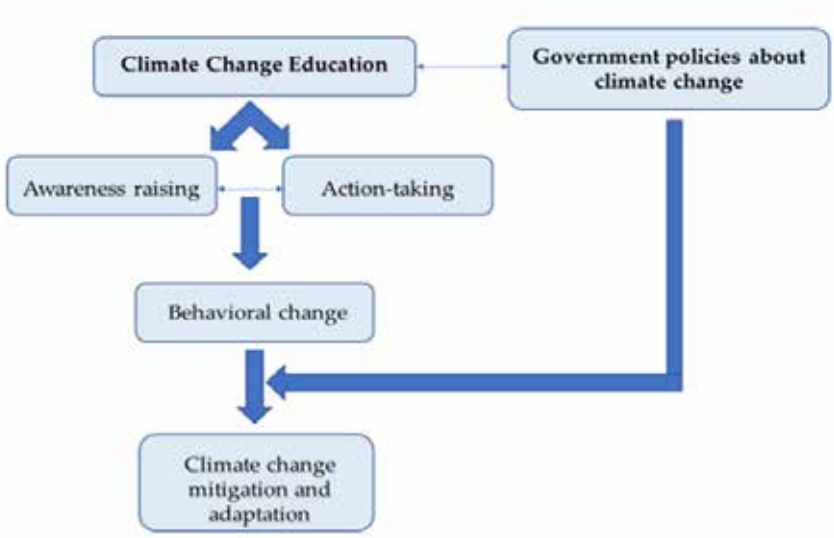

Figure 1. Climate change education as an important part of climate change mitigation and adaptation. (Figure from Moshou & Drinia, 2023)

Challenges and Barriers in Implementing Climate Change Education in Greece

The implementation of climate change education in Greece encounters significant challenges linked to social, political, economic, and educational factors. Although 83% of Greeks recognize climate change as a critical issue of the 21st century (EIB, 2021), integrating environmental education into the national curriculum remains problematic. Since its introduction in 1987, environmental education has been optional and limited to specific programs (Farangitakis & Sbarounis, 2020). Textbooks present environmental topics in a fragmented way, leading to knowledge gaps and misconceptions, such as confusion between the greenhouse effect and ozone layer depletion (Nantsopoulos & Mogias, 2020). Incorporating geoconservation into environmental education could bridge gaps in understanding Earth's history and its relevance to climate change, while fostering a sense of responsibility for preserving unique geological sites as natural laboratories for scientific inquiry. Additionally, inadequate teacher training exacerbates the issue, as many educators lack sufficient preparation in environmental topics (Moshou & Drinia, 2023). These deficiencies are further illustrated in Figure 2, which highlights how early misconceptions formed in childhood persist into adulthood, impacting future educational efforts.

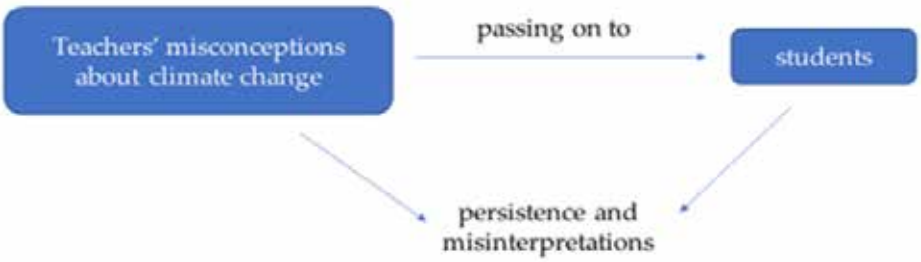

Figure 2. Teachers' misconceptions pass on to students and lead to misconceptions' persistence and misinterpretations (Figure from Moshou & Drinia, 2023)

Further challenges are rooted in Greece's prolonged economic crisis, which limits funding for programs, infrastructure, and teacher training. Environmental Education Centers, critical for raising awareness, face resource shortages, reducing their ability to operate effectively (Farangitakis & Sbarounis, 2020). Psychological distance also plays a role, as many Greeks have yet to experience direct impacts of climate change, diminishing the urgency and public engagement necessary to address the issue. Additionally, unclear legislation and delays in decision-making, coupled with insufficient collaboration among stakeholders, hinder progress. Figure 3 presents a SWOT analysis summarizing these barriers, categorizing them as weaknesses and threats while identifying opportunities for improvement through international best practices and stronger political support.

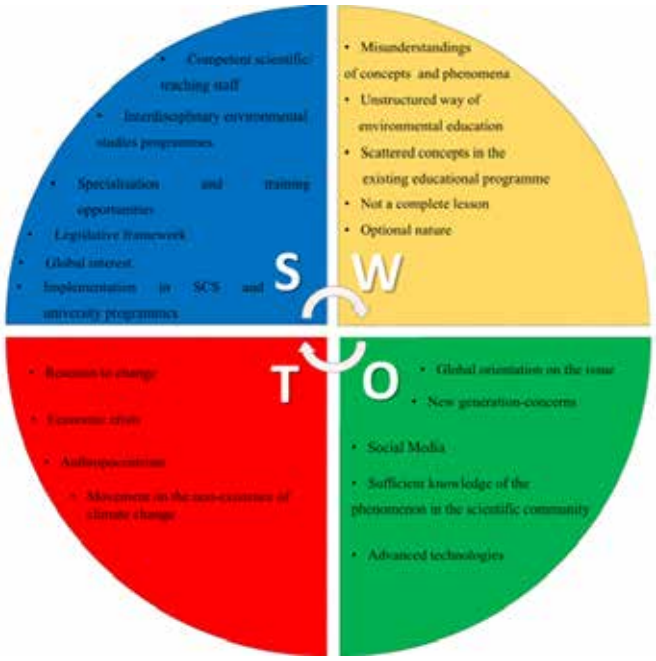

Figure 3. SWOT analysis of environmental education for climate change in Greek Compulsory Education (Figure from Moshou & Drinia, 2025)

Strategic Guidelines for the Effective Integration of Climate Change Education in Greece

The integration of climate change education (CCE) into Greece's educational framework demands a well-structured approach addressing existing challenges. Based on a thorough analysis, including literature reviews, SWOT, and PEST analyses (Moshou & Drinia, 2023; 2025), the following strategic framework is proposed to enhance CCE in Greece:

- Mandatory Environmental Education. CCE must be incorporated as a compulsory subject at all levels of education, ensuring that all students acquire essential knowledge about the environment and climate change. The purpose of this initiative is to provide both theoretical and practical knowledge for reducing environmental risks in the short term and to strengthen students' connection with nature, fostering a lasting environmental consciousness, as well as addressing the main goal of mitigating and adapting to climate crisis.
- Cross-Disciplinary Integration. Given the multidimensional nature of climate change, its integration across various school subjects can promote a holistic understanding of its impact on different aspects of daily life, such as health, the economy, and social equity (Damoah, 2023). While embedding climate change education into existing subjects can be beneficial, it should complement, rather than replace, a distinct compulsory course on environmental education (Moshou & Drinia, 2025). Moreover, it is proposed the inclusion of geoconservation as a key topic within cross-disciplinary education, linking geology, geography, and environmental science to highlight the significance of preserving geosites and their role in understanding climate change.
- Teaching by Specialized Educators. Environmental education, particularly on complex topics like climate change, should be taught by educators with specialized environmental scientists with pedagogical competence. These professionals possess the interdisciplinary knowledge needed to convey accurate information and minimize misconceptions (Moshou & Drinia, 2023).
- Comprehensive Teacher Training. Specialized training programs for teachers are essential to equip them with the necessary knowledge and skills to teach environmental education effectively. Continuous professional development, even for specialized educators, is equally critical to keep pace with the latest scientific developments and pedagogical practices.
- Collaboration with Key Stakeholders. Strengthening collaboration between schools, universities, and local communities is vital for developing innovative educational programs. Partnerships with research institutions can facilitate the design of advanced curricula and educational tools, fostering a culture of environmental responsibility. The collaboration with geologists, conservationists, and UNESCO Global Geoparks to create programs that promote geoconservation and its connection to climate change education aims to foster a deeper

understanding of how geological heritage can play a crucial role in mitigating and adapting to climate change, while also raising awareness about the sustainable management and protection of these invaluable resources for future generations.

- Reducing Psychological Distance. CCE must address the psychological distance that prevents students from relating to climate change. Incorporating local issues and tangible examples into the curriculum can bridge this gap, making the topic relevant and engaging. Emotional and personal connections can motivate students to participate in advocacy and sustainability initiatives actively.
- Utilizing Technology. Technology can play a pivotal role in enhancing environmental education. Digital platforms, interactive applications, and multimedia learning tools can make learning more engaging and effective for students (Nantsopoulos & Mogias, 2020). Moreover, the use of simulations can help reduce psychological distance, allowing learners to better grasp complex environmental issues by visualizing potential outcomes and real-world scenarios.
- Policy Recommendations and Curriculum Policymakers should collaborate with universities and research centers to revise educational frameworks. A clear national framework must outline goals, objectives, and action plans for integrating CCE, alongside timelines and regular program evaluations. The incorporation of geoconservation into national educational policies as a framework to protect geological heritage while enhancing students' understanding of climate and environmental challenges seeks to empower future generations with the knowledge and skills needed to address pressing global issues. By integrating geoconservation into curricula, students can develop a greater appreciation for the role of Earth sciences in tackling climate change and promoting sustainable environmental practices.
- Developing a National Strategy for Climate Change Education. A comprehensive national strategy should be created, taking into account Greece's international obligations and promoting a holistic approach to understanding the climate crisis. This strategy should aim to elevate environmental education as a core component of the educational system, fostering both knowledge acquisition and behavioural change towards sustainability.

Conclusion

Environmental education for climate change is one of the most essential pillars for shaping responsible citizens and fostering a sustainable society. Despite the challenges, integrating environmental education into greek educational system can play a decisive role in developing active and responsible citizens who will be equipped to face and adapt to future environmental challenges.

Developing a cohesive strategy, investing in well-trained educators, and enhancing appropriate teaching methods are key priorities for advancing environmental education. Only through coordinated actions and collaborations can we hope for a sustainable future for the next generations.

Emphasizing sustainable development, cultivating critical thinking, and encouraging active student participation are crucial for achieving this goal. Greece has the potential to become a model country in climate change education if it invests in the appropriate resources and strategies.

Moreover, integrating geoconservation into climate change education not only protects our geological heritage but also provides students with tangible examples of climate change's impact over time, fostering a deeper connection to Earth's history and its future.

Research Highlights

Engineering geological and geotechnical design for slope stability to ensure the long-term protection of the overlying buildings and footpath along a coastal slope in a traditional settlement in the Cyclades, including design implementation, rehabilitation works, and aesthetic interventions.

Introduction - Project area

The failed slope is located in the traditional settlement of Chora on Andros Island, on the northern side of the Chora peninsula, along the southern coast of Nimporio Bay, in the Plakoura area, and approximately 75m southwest of the church of Agia Thalassini. It extends from an elevation of between +2.60m and +3.80m at the slope toe to between +16.80m and +17.40m at the crest, with an average height of 15m. The sickle-shaped slope features a 30m-long arch and a corresponding 25m-long chord, trending NE-SW with a plunge of 85° towards the NW (Fig. 1).

Figure 1. Satellite images of the project area (Google Earth Pro, v. 7.3.4., accessed on 3 October 2021). The yellow outline indicates the location of the failed slope.

Description of the failure

In March 2021, a large volume of rock detached from the central part of the slope, between elevations +9.50m and +14.70m. This event created unsafe conditions for the buildings immediately above the slope's crest and posed a risk of accidents in case of additional rockfalls along the footpath, which runs close to the slope's base. The failed area, measuring approximately 30m^2, is located in the central part of the slope. The failure occurred along a weakness zone in the schist formation, resulting in an 8m-wide, 5m-high and approximately 3m-deep caving (Fig. 2). Moreover, three older, smaller-scale slides, ranging in size from 2m^2 to 4.5m^2, are observed in the central part of the slope at lower elevations, between +4m and +7m (Fig. 2).

Figure 2. General view of the failed slope, the overlying buildings along the slope crest, and the footpath along the slope toe. The location of the failure is indicated by a red outline.

Geology of the landslide area

The slope consists of mica schists (Mehl *et al.*, 2007; Höhn *et al.*, 2022) that are moderately, and in some zones, intensely tectonized. Tectonization of the rock occurred due to four major inverse shear zones (R1, R2, R3, and R4), as well as additional zones parallel to these (R5, R6, and R7), which can be observed on the adjacent property slope (Fig. 3A, 3B). The shear zones extend for several meters, trending NW with plunges ranging from 15° to 25°, and are associated with a compressive tectonic regime, oriented NE-SW. The four major shear zones divide the slope area into five zones, one of which is where the recent slide occurred, while smaller failures have occurred in the other zones in the past.

To investigate the stability conditions, engineering geological characteristics, and properties of the rock mass along the slope, a comprehensive microtectonic analysis was conducted in order to form a complete picture of the tectonism of the rock mass (Fig. 3C). Subsequently, to examine the tectonism of the individual sections of the slope, it was divided into eight sub-sectors: two sectors at the NE end (sectors A and B), one at the SW end (sector H), and five sectors between the faults with a slope direction parallel to that of the slope (sectors C, D, E, F, G, and H). In each sector, a microtectonic analysis was performed (using the software DIPS, v. 5.1, Rocscience) to assess the stability and support of the rock mass (Hoek and Bray, 1981; ISRM Suggested Methods, 1981) (Fig. 3C).

The schistosity is well-developed, showing dips towards the SW in the NE part of the slope, towards the SE to SSW in the central part, and towards the SW to WSW in the SW part, with dips ranging from 15° to 30°. The general dip of the schistosity is oriented towards the SW, with an average dip of 20° (Fig. 3A, 3B). The main joint systems crossing the slope are two: one trending NE-SW with dips towards the NE, and the other trending NNE-SSW with dips towards the ENE. A third, less frequent joint system, with a dip direction parallel to the slope, trends ENE-WSW and dips towards the NNE (Fig. 3A, 3B).

Stability analyses of the slope against wedge and planar failure were conducted (using the software Swedge, v. 5.01 for wedge failures and RocPlane, v. 2.029 for plane failures, Rocscience), based on conservative assumptions (Norrish and Wyllie, 1996; Wyllie and Mah, 2004). Discontinuities were considered planar and of infinite length. The length of the slope was assumed to be L=20m and the rock mass unit weight was taken as γ=26 kN/m^3. Regarding the angle of internal friction, taking into account the characteristics of the schist formation, the condition of discontinuities, and based on literature, a range of values from 25° to 30° was considered (Wyllie and Norrish, 1996). The minimum value of 25° was conservatively selected for the analyses. Regarding cohesion, a value of zero was conservatively assumed, considering the possibility of infilling material being washed out due to groundwater circulation. Analyses were performed for static loading, static loading with hydrostatic pressure on the discontinuities for a 50-year return period (even though a permanent water table was not encountered), assuming partial filling of the discontinuities with water for short periods following intense rainfall, in cases where infiltrating water does not dissipate quickly to lower elevations, and seismic loading.

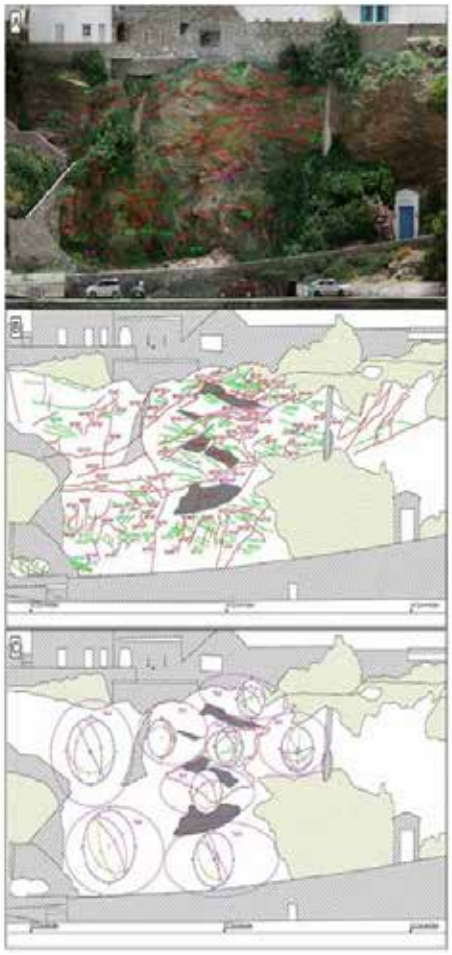

Figure 3. (A, B): View and front view of the failed slope, indicating joints (red lines), schist planes (green lines) and their geometric features. (C): Stereonets of the eight sub-sectors into which the slope was divided. The grey areas in 3B and 3C indicate the locations of recent and older failures.

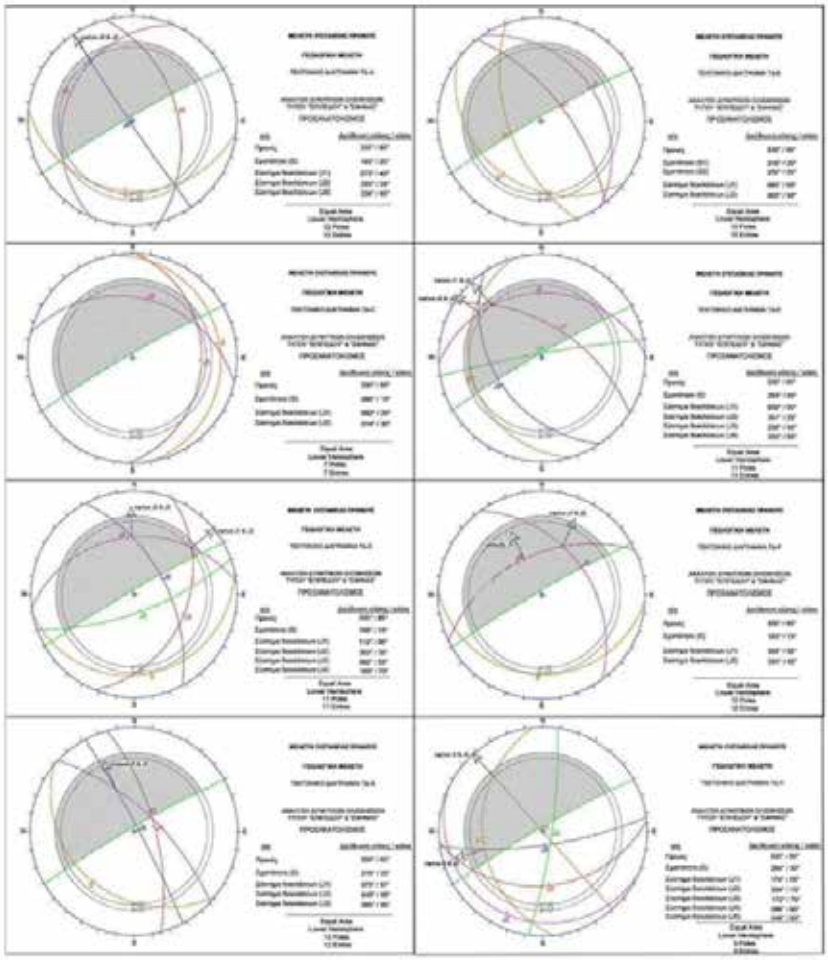

Figure 4. Stereonets of the eight sub-sectors into which the slope was divided. Sliding Kinematic Analysis

Based on the results of the analysis of wedge failure for the overall discontinuity stereonet, as well as for the stereonets of the individual zones of the slope (TΔ-A to TΔ-H, Fig. 3C, Fig. 4), it is inferred that achieving slope stability requires the application of 6m-long rock bolts in a 3m x 3m (v:h) pattern. Furthermore, based on the results of the analysis against planar failure, it is concluded that stabilize the upper six meters of the slope, where planar failures may occur, 6m-long rock bolts in a 2m x 2m (v:h) pattern are needed.

Therefore, from the results of both wedge and planar failures analyses, a rock bolt pattern of 2m x 2m (v:h) was selected for the upper part of the slope, above elevation +9.80m (the higher six meters), and a 2m x 2.50m (v:h) pattern for the lower part of the slope. A rock bolt length of L=6m was chosen for both areas to ensure sufficient anchoring depth (Fig. 5).

Rehabilitation of the slide area

In order to ensure the stability of the slope and provide long-term protection of the rock mass against wedge and planar failure, erosion induced from water runoff, coastal erosion due to the slope's proximity to the sea, and its continuous exposure to wind and waves, as well as to rehabilitate the caving and overall geometry of the slope from both recent and older failures, the most efficient and aesthetically acceptable rehabilitation scheme comprises the combination of rock bolts, shotcrete, and wire mesh across the entire slope surface. The proposed shotcrete coverage aims to provide long-term protection of the rock mass against both surface and in-depth erosion of schist,

while also rehabilitating the slope geometry in areas of failure (recent and older), where cavings and locally negative slope gradients develop. Furthermore, shotcrete in combination with steel wire mesh effectively retain smaller-scale structural failures that may occur between the rock bolts (Fig. 5).

Figure 5. Front view of the slope showing the support and protection measures.

Specifically, the construction of seven rows of rock bolts was proposed for the section of the slope between cross-sections S3 and S12, and six rows for the section beyond cross-section S12 (Fig. 5, 6). In all rows, a horizontal distance of 2m between consecutive bolts is foreseen. The rock bolts are fully grouted steel bars, 24mm or 25mm in diameter, made of S650 steel (for □24mm) or S500 steel (for □ 25mm), with nominal tensile capacity of 200kN, 6m in length, and installed with a downward inclination of 15°. The drillhole diameter for the rock bolts was proposed at least 100mm. Continuous threaded steel bars will be used to ensure good bonding with the grout and also to allow easy screwing of the nut and cutting of any possibly protruding parts of the bars. Additionally, given the proximity of the slope to the sea, all steel bars and relevant materials (e.g. nuts, rock bolt plates) will be hot-dip galvanized to ensure resistance to corrosion.

For the environmental integration of shotcrete, appropriate pigments will be used during mixing, based on relevant in-situ test, to match the natural color of the slope's rock mass. A minimum structural thickness of 10cm of shotcrete was proposed, applied in two layers of 5cm each, with one layer of steel wire mesh placed between them.

In areas of the slope where relatively deep cavings have occurred, consecutive layers of shotcrete will be applied, with additional layers of steel wire mesh installed every 20-30cm of shotcrete thickness. For the first layer of steel wire mesh, to be installed on top of the first five centimeters of shotcrete across the entire slope, T131 wire mesh will be used to provide enough flexibility to conform to the rough slope surface. In areas with extensive and/or deep cavings, the wire mesh layers in between the shotcrete layers will be made of T188 type wire mesh and steel grade B500C. For fixing the additional steel wire mesh layers, bolts consisting of □16mm or □18mm solid steel bars will be used, arranged in an appropriate configuration.

To prevent pore pressure build-up behind the shotcrete facing, drilling of three rows of weep holes (water pressure relief holes), was proposed, each with a diameter of 3'' and ranging from 0.50m to 1.50m in length, depending on the local thickness of the applied shotcrete, and spaced every 2m horizontally. Specifically, the lower row of weep holes was proposed at approximately elevation +7.80m, the second row at +9.80m and the upper row at +13.80m. In addition to the weep holes, two rows of raking drains, transverse to the slope, were proposed, spaced every 2m horizontally. The raking drains will have a diameter of 3'', a length of 6m, and a slight upward inclination of 5° to relieve water pressure in case of a seasonal groundwater table. Inside the raking drains drillholes, □2'' perforated PVC tubes will be installed, coated with separation geotextile to prevent clogging by fines from the surrounding eroding schist rock mass. The lower row of raking drains was proposed at approximately elevation +11.80m (Fig. 6).

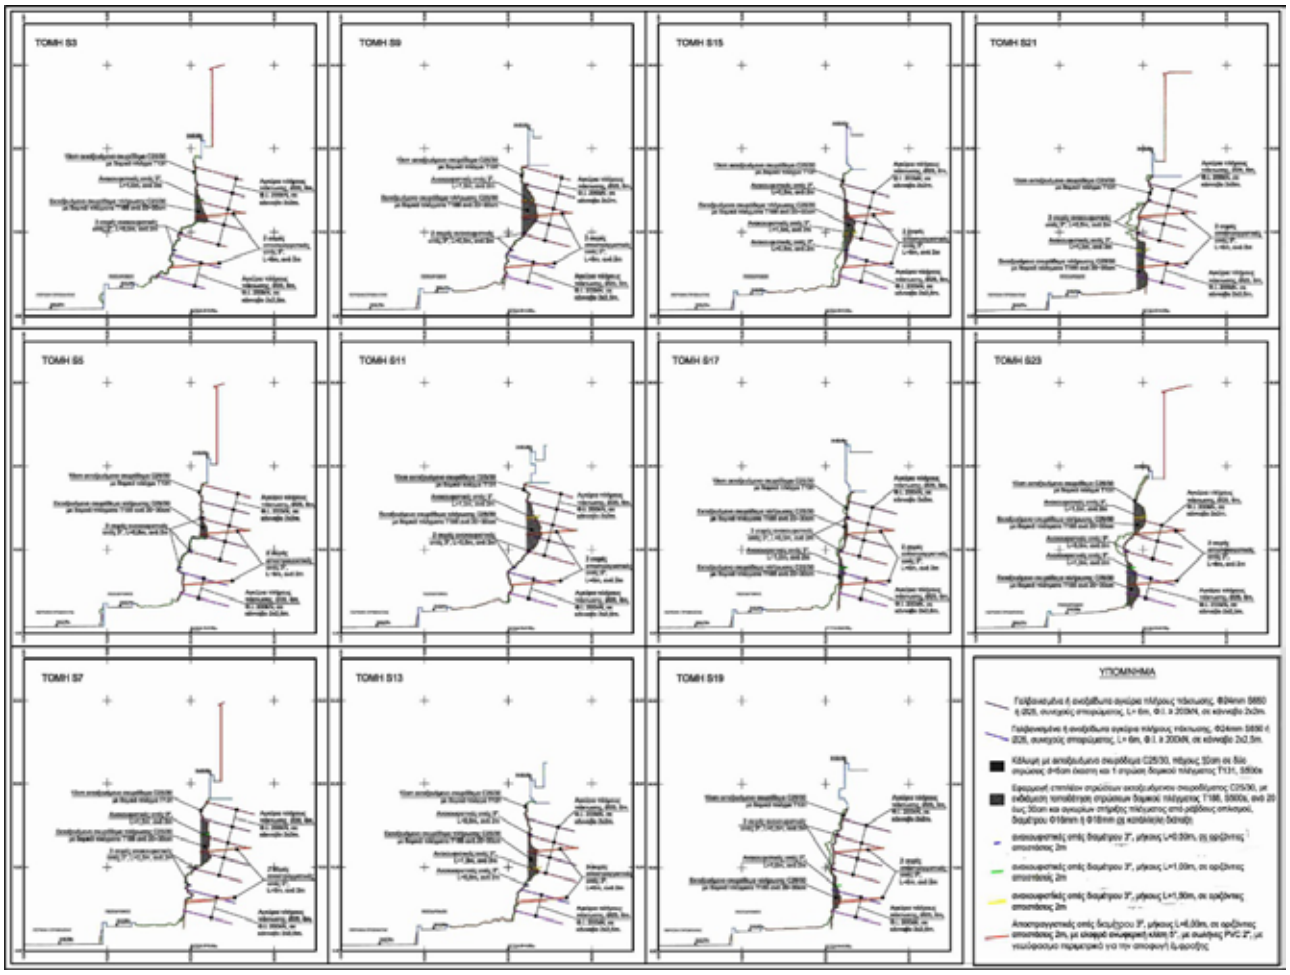

Figure 6. Cross-sections of the failed slope showing the support and protection measures.

Design Implementation

Stabilization and rehabilitation works on the rock slope began in October 2023, following the end of the summer tourist season, to minimize disruption and inconvenience to the visitors of the Agia Thalassini church and those visiting the Andros Chora Castle area, on the northern side of the Chora peninsula (Fig. 7).

Figure 7. Views of the slope after the application of the support and protection measures, before (left) and after (right) the final aesthetic interventions.

Special attention was given to shaping the final slope surface to closely resemble its condition prior to the rehabilitation works, with aesthetic interventions made in consideration of the features of the traditional settlement. Therefore, the shotcrete layers followed the natural slope surface, in accordance with the approved design. Final coloring of the

slope was carried out after the winter of 2024, allowing time for precipitation, sea spray from waves, intense winds, and storms in the area, as well as water seepage (both groundwater and surface water), to naturally balance the color of the shotcrete, which had been already pigmented during shotcreting. An aesthetic intervention followed, involving planting at the slope toe and the reconstruction of the low wall on the footpath side, which was damaged by the slide (Fig. 7).

EXTENDED ABSTRACT 220

The Horizontal-to-Vertical Spectral Ratio Method for Underground Voids Detection: Testing Over Mycenaean Tombs

Moustakas H. I.[1], Roumelioti Z.[1], Sokos E.[1], Evangelidis Ch.[2]

(1) Department of Geology, University of Patras, Patras, Greece, up1060600@upnet.gr (2) Institute of Geodynamics, National Observatory of Athens, Athens, Greece

Abstract

This study investigates the potential of the Horizontal-to-Vertical (H/V) spectral ratio method, a technique typically used for site characterization, as a complementary tool for detecting underground voids. We leverage ambient noise measurements conducted at the Mycenaean cemetery of Voudeni, Peloponnese, Greece, utilizing the site's numerous underground tombs as test targets. We analyzed the H/V spectral amplitudes above the centers of various sized tombs and the spatial variation of horizontal and vertical spectral amplitudes and of their ratio along trial linear arrays. We verify the suggestion of previous research that over voids the H/V curve shows a characteristic drop below unity at high frequencies (in our test cases, typically >20Hz), which remains below unity for a considerable frequency interval. This phenomenon is attributed to a velocity reversal caused by the void within the surrounding rock. We attempt a first-order comparison of the void size and frequency of initiation of the characteristic drop and conclude that larger subsurface voids tend to affect the H/V curve at lower frequencies compared to smaller voids, exhibiting an exponential relationship. We also observe that the H/V drop over our test voids is primarily driven by the amplification of the vertical component rather than de-amplification of the horizontal component and this suggests that using linear arrays of vertical component geophones alone could be effective for void detection, particularly as a complement to other geophysical methods. We demonstrate this possibility through trial linear arrays of vertical sensors. We conclude that the H/V method and linear arrays of vertical sensors hinder promising advancements as void detection techniques, especially considering their readily deployable and cost-effective character, although theoretical modeling and extensive testing in various geological settings and void characteristics are required to better understand the observed phenomena.

Background and Objective

The Horizontal to Vertical Spectral Ratio (H/V or HVSR) method (Nogoshi and Igarashi, 1971; Nakamura, 1989) involves the analysis of earthquakes or microtremor (ambient noise) records to compute the ratio of the spectral amplitudes of the horizontal components to the vertical component. It was originally proposed as a method to calculate the local amplification and resonance frequency resulting from sedimentary layers overlying the bedrock. For the simplified case of a viscoelastic sedimentary soil layer of thickness h and shear wave velocity Vs, over a viscoelastic bedrock, the resonance frequency f_n is calculated by the formula:

$$f_n = (2n+1)\frac{V_s}{4h}, (n = 0,1,2,\dots)$$

Empirical data have shown that the lowest frequency at which the maximum value of the H/V curve is observed at a site, is identical or very close to the resonance frequency, f_0, of the soil by shear waves SH. In addition to f_0, the method can provide information on the thickness of the soil over bedrock, the presence of high density layers, lateral discontinuities of the subsoil layers from variations of the curves at different locations and velocity reversals (e.g. from natural or artificial hard layer over softer soil) (e.g., Field and Jacob 1993; Lermo and Chávez-García 1994a; Bonilla et al. 1997; Bour et al. 1998; Bard 1998; Fäh et al. 2001; Woolery and Street 2002; Molnar and Cassidy 2006; Haghshenas et al. 2008).

As the popularity of the H/V method increases, several aspects of its practical application are being examined in more detail. One such aspect involves the performance of the method at sites where there is a strong velocity reversal very close to the ground surface. This situation often arises when measurements are collected on top of concrete slabs, asphalt, etc, as discussed in detail in Castellaro and Mulargia (2009). A special case falling under this category is the presence of underground voids close to the surface, either natural or man-made (e.g., cellars, underground parking spaces). Castellaro and Mulargia (2009) present H/V curves for several example cases and discuss that under the absence of shallow velocity reversals, the common plot of the spectra of the horizontal and vertical components presents a characteristic oval shape around f_0, what the authors describe as 'eye shape'. According to the same study, the appearance of this feature suggests that the H/V peak is of stratigraphic origin. Also, when there are no velocity reversals the vertical component remains less than or equal to the horizontal component at all frequencies, hence H/V≥ 1, except for a small range near $2\times f_0$ where it can drop below unity due to the elliptic motion of Rayleigh waves (Fäh et al., 2001). In contrast, if the amplitudes of the H/V curve fall below 1 in regions distant from $2\times f_0$ and remain below 1 for a considerable range of frequencies, this may be evidence for a velocity reversal.

In this work, we further investigate the suggestion of Castellaro and Mulargia (2009) that the H/V curve over voids is expected to show characteristic drops below unity. More generally, we examine the working hypothesis that the method could be useful, at least as a complementary method, in the detection of underground voids. For this purpose, we have chosen as test site the Mycenaean cemetery of Voudeni in the Peloponnese, ~4 km east-northeast of the city of Patras. The archaeological site contains

numerous underground tombs that the Mycenaeans constructed more than 3000 years ago by carving into the soft rock (marl) of the area. Many tombs of different sizes and depths have been excavated and their geometry has been studied in detail by Turner (2020), making them ideal targets for our study.

Our study included three phases of ambient noise data collection and processing, which will be presented sequentially in the following. Data collection was conducted during daylight hours and when the archaeological site was not in operation to minimize nearby anthropogenic noise.

Three-Component Single-Point Ambient Noise Measurements Over Voids of Various Dimensions

In the first phase of our study, we performed single-point H/V measurements over several tombs of different dimensions targeting to 1) identify a characteristic imprint of voids on the shape of the H/V curves, as suggested by previous researchers, and 2) identify a possible correlation between the dimensions of the voids on the characteristics of this imprint. Data were collected using a Geometrics Atom-3C seismic acquisition unit with a 2Hz, three-component (3C) geophone and sampling rate of 4 ms (Nyquist frequency of 125 Hz). The sensor was placed over the centers of several ancient burial chambers, i.e. our target underground cavities, it was oriented to the North and was left to record ambient noise for at least 15 minutes. Since all targets are located at shallow depths (<1m to a maximum of 7-8m), longer recordings were not considered necessary.

Figure 1 shows an example measurement setting. The upper part of the Figure contains the plan view of a measured tomb (a; circled in red) and the side view of its detailed reconstruction (b; wireframe from photogrammetry) by Turner (2020). The lower part of Figure 1 (c-d) contains photographs of the tomb. In general, Mycenaean tombs include an entrance passage or “dromos”, a threshold or “stomion”, and the burial chamber/vault or “thalamos”. The facets of excavated tombs extend from the stomion floor to the ground, and we used them as reference planes to measure the distance to the center of the void chamber, first underground and then on the ground surface.

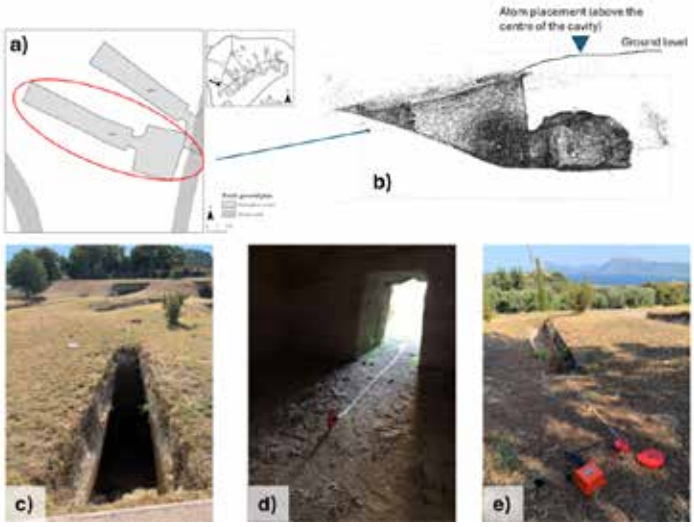

Figure 1. Example measurement setting: a) tomb (circled in red) ground plan and b) side view of its textured photogrammetric model by Turner (2020), c) photograph of the entrance pathway (dromos), d) photograph from the inside of the tomb (thalamos) looking at the stomion and e) photograph of the Atom-3C on the ground surface, over the void chamber.

Although our test site includes 78 excavated burial monuments, we were only able to measure 24, mostly because many chamber tops collapsed over the years or access to their tops was dangerous. Some geometric characteristics of these tombs, as provided by Turner (2020), are summarized in Table 1. The difference between the height of the dromos and the height of the vault is often a good proxy for the depth of the vault top.

The collected data were processed using using SPACPlus module of the SeisImager-sw software from Geometrics Inc. (https://www.geometrics.com/software/seisimager-sw/). Ambient noise time histories were trimmed at the beginning and end of each measurement to remove noise during instrument installation and removal. The common recording for the three components was then divided into segments of 512 samples, i.e. ~ 2 s duration, with an overlap of 50%. Fourier amplitude spectra were computed for each component and each recording segment, and the horizontal component spectra were geometrically averaged. Finally, the H/V ratio was computed for each segment and the results were visually inspected (both in terms of H/V curve shape and directly on the ambient noise records) to remove irregularly noisy segments and spectra. The remaining measurements were used to derive the mean H/V curve for each measured location.

Table 1. Geometric characteristics of the 24 Mycenaean tombs (after Turner, 2020, except those with * vault volume measured in the frame of this study) over which we performed ambient noise measurements.

Figure 2a shows an example output for the measurement over tomb 78 (Table 1). In the upper part of Figure 2a, the horizontal and vertical component spectra are compared, and it is clearly seen that, for a significantly wide range of frequencies (~22-38Hz), the vertical spectral amplitudes are larger than the horizontal, i.e., opposite to what is usually expected. This results in a drop of the H/V curve in the corresponding frequency range, as shown in the lower part of Figure 2a. The H/V returns to amplitude >1 at frequencies ~>35Hz.

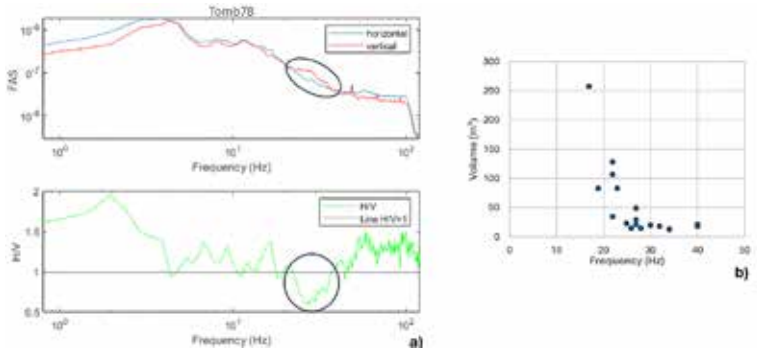

Figure 2. a) Example results of the H/V analysis of data over tomb 78. Upper part: Fourier amplitude spectra (FAS) of the horizontal and vertical components (in blue and red, respectively). The circled area is where the vertical component spectral amplitudes appear larger than the horizontal. Lower part: H/V spectral ratio. The circle marks the characteristic drop of the H/V ratio below unity, at high frequencies and for a significantly wide range. b) Underground void volume (in m^3) with respect to f_{DL} the frequency of initiation of the persistent H/V drop below 1Hz.

We define f_{DL} as the frequency above which we observe a sustained drop in H/V amplitude below 1, and we examined whether this discrete frequency is related to the volume of the underground void. The corresponding plot is shown in Figure 2b and implies an exponential relationship between the compared quantities, i.e. as the void volume increases, the frequency where H/V first drops below 1, in a clear and systematic manner, shifts to lower frequencies. This suggests that larger subsurface voids, at least at the shallow depths investigated here, affect the H/V curve at lower frequencies compared to smaller voids. However, this relationship appears to saturate (flattens) as void volumes become smaller (~<20-30m^3). A similar examination with respect to the depth of the tomb ceilings did not provide evidence for a clear relation, most probably because most ceilings are at very shallow depths of 0.5-1.5m and their geometry varies.

Three-Component Linear Array Ambient Noise Measurements Over a Large Void

One question raised by the previous measurements is how the persistent H/V drop varies spatially, and whether an underground void can be detected even if the ambient noise measurement is not taken directly over its center. Therefore, in the second part of our study, we collected data along a line over one example tomb to investigate, to some extent, the spatial variability of the shape of the H/V curve over a void. The test was conducted on tomb 75, which is the largest of the tombs examined in terms of volume (Table 1). The measurements were made in a linear arrangement across the center of the tomb. The total number of measuring

points was 13, with 2 m between successive measurements. The first was placed 6 m from the north side of the chamber and the last 10 m from the south side (Figure 3a, b).
Examples of results for two of the 13 sites are shown in Figure 3c, d. Specifically, results are shown for location S6, just above the center of the tomb (Figure 3c), and for S12, 5-6 m south of the tomb (Figure 3d). Focusing on the high frequency part of the results, the differences are quite pronounced with a very wide H/V drop below unity at S6 and a flat H/V curve around 1 at S12. Looking at the corresponding results for all 13 sites (not all are shown for reasons of space), the drop of the H/V curve below 1 clearly occurs at sites S4, S5, S6, S7, and S8 (Figure 3b), while at the remaining sites either no drop below 1 or drops within quite short ranges are observed.

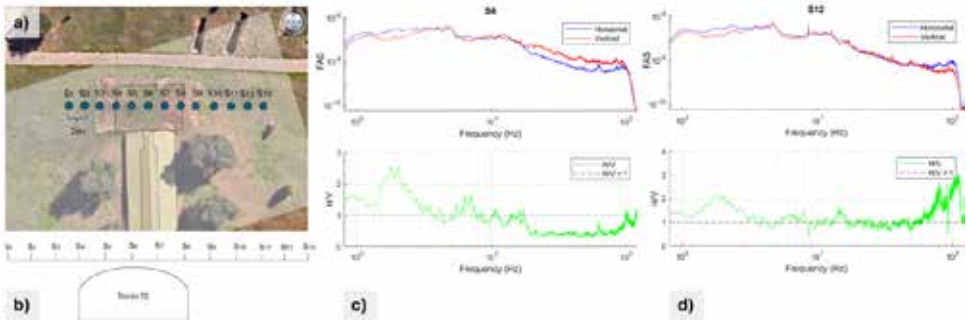

Figure 3. Linear array of 3C measurement points over one of the largest tombs (codenamed 75) in the Mycenaean Park of Voudeni a) in plan view and b) in cross section (depth and volume not to scale); c) Results for the example locations S6 right over the tomb and d) for S12, several meters to the south of the tomb. Top panels in c, d show the Fourier amplitude spectra of the horizontal and the vertical components and bottom panels the H/V curves.

From plots such as those in Figure 3c, d, it is difficult to understand the spatial variability of the results and even more difficult to understand whether the H/V drop is mostly due to de-amplification of the horizontal signal or amplification of the vertical signal. To better demonstrate the spatial variability of our results, we created spectrogram-like plot, but instead of time in the horizontal axis, we plotted the distance of each spectrum or H/V curve from S1. This creates a pseudo-2d spatial variation, which we show in Figure 4 in separate subplots for the amplitudes of the horizontal and vertical Fourier spectra and the H/V curve. The subplots for the horizontal and vertical components (Figure 4a, b) have the same color scale and are directly comparable. Note that since the horizontal axis shows the distance from S1, the measurements directly above the tomb are in the range of 6-14 m. This exact range is clearly colored differently in the H/V subplot (cool colors, mostly <1), starting from frequencies close to 20 Hz and continuing to much higher frequencies. This means that the changes in the wavefield due to the underground void are clearly imprinted on the spatial variability of the H/V amplitudes at high frequencies over the entire structure and not just over its center. In fact, the lateral extent of the structure is well captured in this subplot. By examining the individual component plots, we conclude that the H/V variation is mostly due to a corresponding spatial variation in the vertical component amplitudes (circled areas in Figure 4b). This means that the H/V drop over the studied underground void is mostly due to an increase of the vertical component amplitudes at high frequencies rather than a decrease of the horizontal component spectral amplitudes in the same range.

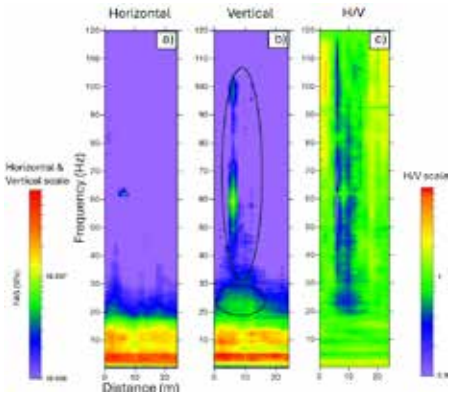

Figure 4. Pseudo-2D plot of results (spectral amplitudes or amplitude ratio vs distance from the starting measurement in the linear array) over tomb 75 for a) the horizontal Fourier amplitude spectra, b) the vertical Fourier amplitude spectra and c) the H/V amplitude. In the central plot for the vertical component, two prominent areas of spectral amplitude amplification are circled.

Vertical Component Linear Array Measurements Over Selected Voids

The preceding results indicated that it is possible to detect the presence of underground voids just by using the vertical component of ambient noise measurements. We further examined this potential by conducting measurements along a second linear array above two adjacent, smaller tombs. In this third phase of our work, we used 6 2Hz, 1-component geophones (Atom-1C, Geometrics), spaced every 1m along a line crossing over the chambers of tombs 28 and 29 (Table 1, Figure 5). The chambers of these two tombs are right next to each other and their separating "wall" was so thin that a small part collapsed, partly joining the two void spaces. It should also be noted that the chamber of tomb 29 is about 6-7 times larger in volume than the chamber of tomb 28 and that their floor depths differ by ~1.5m (Table 1). Fourier amplitude spectra for each recording were computed following the same processing steps as before and plotted against distance. The exact geometry and location of the linear array and the pseudo-2D variation of spectral amplitudes are shown in Figure 5. Distances are measured from geophone A1 (Figure 5a, b). At high frequencies (i.e., >~20Hz) in Figure 5b, we can clearly observe higher spectral amplitudes at distances corresponding to the locations of geophones A1 and A3-A5. A1 was placed exactly over the centre of tomb 28, whereas A3-A5 were over the chamber of tomb 29. A2 and A6 are close to the boundaries of the voids and although they also present elevated amplitudes at high frequencies, these are not as high, either because they are not directly over the voids or because of the lateral deepening of the vaulted tombs ceilings.

Another interesting observation in Figure 5b is that the spatial variation of the elevated spectral amplitudes suggests both the existence of two different voids (lower high frequency amplitudes at the location of A2 compared to those to the left and right of it) and their different dimensions (stronger imprint for tomb 29 and for a larger distance, comparable to the length of its chamber, ~4m). This suggests that denser measurements could provide an even better description of the geometry of the voids as well as their separation.

Figure 5. a) Geophones (A1-A6) placement over the void chambers of tombs codenamed 28 and 29 in the Mycenaean Park of Voudeni. b) Spatial variability of the spectral amplitudes of the vertical component of ambient noise recordings. Black frames mark the interpreted imprints of the two voids in the form of elevated amplitudes at high frequencies.

Conclusions/Discussion

We have tested the H/V method for its ability to contribute to the detection of underground voids as suggested by Castellaro and Mulargia (2009), using as test targets the chambers of Mycenaean tombs of various sizes in the archaeological park of Voudeni in the Peloponnese. We performed single point measurements over the center of the chambers as well as linear arrays over selected chambers using both 3C and 1C geophones. We have shown that the detection and even mapping of the lateral extent of voids by the H/V method is feasible considering the persistent drop of the H/V curve below 1 at high frequencies (in our test cases generally >20Hz). We also showed a correlation between void size and the frequency above which the H/V curve drops below 1. By separately examining the spatial variation of the horizontal and vertical spectral amplitudes over the voids, we concluded that the H/V drop below 1 is mostly due to an amplification of the vertical component rather than a de-amplification of the horizontal. This motivated us to further investigate the potential of detecting subsurface voids based on array measurements with 1C, vertical sensors alone, and we concluded that such an approach is indeed feasible.

Of the 24 single point measurements of ambient noise that we made over voids, 17 of them showed the expected drop in the H/V curve at high frequencies. The reason why the method "failed" in some cases is not yet understood and requires theoretical modelling beyond the scope of this initial feasibility study. It should be noted that although our test site is ideal in terms of the variety of void target sizes, it is also very complicated due to the density and often close proximity of tombs of different sizes, as well as the different shapes of chamber roofs (pyramidal, hipped, vaulted, arched). This was partly demonstrated in the third phase of our measurements, where we measured along a line over two adjacent tombs of different sizes.

Contrary to the preferred interpretation of Castellaro and Mulargia (2009), our results suggest that the drop of the H/V curve below 1 over voids is mainly due to increased spectral amplitudes in the vertical component. This does not mean that the horizontal component is not de-amplified, as would be expected above such an extreme velocity reversal (void within rock), but

that the amplification of the vertical component is more distinct, localized, and easier to detect in terms of its spatial variation. A possible explanation for why the vertical component is amplified above a void was proposed by Kolesnikov and Fedin (2017), who studied an experimental model and proposed the occurrence of standing P waves between the ground surface and the top of the void. This implies a vertical amplification at higher frequencies for shallower voids compared to deeper ones.

In conclusion, our tests support the findings and suggestions of the work of Castellaro and Mulargia (2009) that the H/V curve has special characteristics over voids. This means that the H/V method could be used in the geophysical prospection of underground voids, at least as a complementary method to other more tested and robust methods. Considering that the method is gaining popularity due to its ease of use and cost-effectiveness, it is important for the community to further investigate this possible additional use for void detection, a very common need in geophysical exploration with diverse applications such as archaeological prospection, geological hazard assessment, and infrastructure monitoring.

Our work also suggests that linear array measurements of the vertical component alone may be equally useful. Such measurements are routinely performed by most research groups for site characterization with low-cost equipment, and only require some targeted additional processing to be useful for void detection.

It should be emphasized that, as with all geophysical methods, the interpretation of the results of the proposed methods outside the geological context of a studied site is insecure, and there is always the potential - if not the certainty - that multiple other factors influence the measurements. Several such factors are reviewed and discussed in detail in Castellaro and Mulargia (2009), particularly in relation to the topic discussed here. H/V results can be useful for void detection but should always be corroborated with other geophysical methods for accurate subsurface characterization.

Acknowledgements

The study was carried out in the framework of the research project “UNMASK”, supported by the Hellenic Foundation for Research and Innovation (H.F.R.I.) under the “2nd Call for H.F.R.I. Research Projects to support Faculty Members & Researchers” (Project Number: 2724). We are greatly indebted to the Ephorate of Antiquities of Achaea, and more specifically to its director Dr. A. Koumousi and the archaeologists K. Aktypi and M. Gkazis, for providing the permit and facilitating us in every possible way to perform our measurements in the Mycenaean Park of Voudeni. We also thank them for providing us with supporting archaeological material.

(1) Cartography and Geoinformation laboratory, Department of Geography, University Of the Aegean, Mytilene, Greece.

Introduction / Background

The Petrified Forest of Lesvos, located in the western region of Lesvos Island, Greece, represents a unique petrified ecosystem that encompasses a significant number of fossilized tree trunks and animal remains. This exceptional natural monument was formed approximately 20 million years ago when volcanic activity covered the area in volcanic material, preserving the organisms in ashes. The volcanic deposits revealed an extensive array of fossils, including standing and recumbent fossilized trunks and petrified branches. (Natural History Museum of the Lesvos Petrified Forest, 2020)
To ensure the protection and systematic study of the Petrified Forest, the Natural History Museum of the Lesvos Petrified Forest was established in Sigri in 1994. The museum manages the petrified forest protected area, which spans an area of 15,000 hectares (Geo-Naturpark Bergstrasse-Odenwald., 2022). The Lesvos Petrified Forest was a founding member of the European Geoparks Network in 2000 and was later designated a Global Geopark in 2004, underscoring its geological and cultural significance (Zouros, 2007). Since 2015 the Lesvos island, is recognized as a UNESCO Global Geopark, including the Lesvos Petrified Forest as the geological heritage area of international significance.
Recent infrastructure projects, including the construction of the Kalloni-Sigri road, led to the discovery of numerous fossiliferous sites, including hundreds of fossilized tree trunks, branches, leaves and cones. The research activities for the excavation, conservation and protection of these findings as well as the presentation, interpretation and promotion of this important site facilitated by the integration of innovative geoinformation technologies, using unmanned aerial vehicles (UAVs), for multiscale and multitemporal 2D and 3D mapping.
This study specifically describes the 3D mapping methodology used for the Ioannis Toumpelekis Park (*Map 1*), a fossil site located in Akrocheiras hill, which comprises 212 fossilized tree trunks and branches (Apostolopoulou, 2024). The fossils within the park are categorized into two distinct stratigraphic sections. The lower section predominantly contains lying fossilized trunks, while the upper section is characterized by standing fossilized trunks belonging primarily to the hardwood tree family. The 3D mapping of the fossiliferous area of I. Toumpelekis park provides critical insights into the paleoenvironmental and geological conditions that contributed to the preservation of the forest.

This research emphasizes the use of advanced geoinformation technologies to study and visualize the fossilized ecosystem comprehensively. A multi-scale 3D geovisualization workflow is employed, encompassing data acquisition, processing, modeling, and visualization. UAV technology plays a central role in data acquisition, delivering high-resolution imagery that forms the foundation for detailed 3D models. By integrating UAV-derived images, photogrammetric 3D models, and panoramic imagery, this study creates an immersive and interactive virtual environment, enhancing the understanding and presentation of this unique paleontological and geological heritage.

Map 1. Study Area located at the western part of Lesvos island, North Aegean, Greece

Objectives

The primary objective of this research is to explore and implement multi-scale 3D mapping and geovisualization methods for the study area. To achieve this goal, a comprehensive methodology was developed, encompassing both data acquisition and the presentation of findings. This approach involves the following key steps:

1. Data acquisition: High-resolution data were collected at two different ground sampling distances (GSD) using the DJI Mavic 3E, ensuring the accuracy and detail required for subsequent analysis.
2. 2D thematic orthophoto map construction: The collected data were processed to generate detailed thematic orthophoto maps, providing a georeferenced representation of the study area.
3. Development of a multiscale 3D model: A multi-scale 3D model of the study area was created, enabling a detailed representation of both park and fossil-scale features.
4. Creation of 3D animated maps: Animated visualizations were developed to enhance the communication of spatial and temporal data, offering dynamic perspectives of the study area.
5. Construction of an immersive virtual reality (VR) application: A VR application was designed to provide an interactive and immersive experience, allowing users to explore the fossilized park in a virtual environment.

This methodology integrates state-of-the-art geoinformation technologies to advance the study and presentation of complex fossilized ecosystems. The resulting outputs contribute to a deeper understanding of the site and demonstrate the potential of innovative mapping and visualization tools in geoscientific research.

Materials and Methods

In the following workflow, all the stages of the methodology are presented in detail, structured into three (3) main stages: 1. Data Acquisition, 2. Data Processing, and 3. Geovisualizations. (*Figure 1.*):

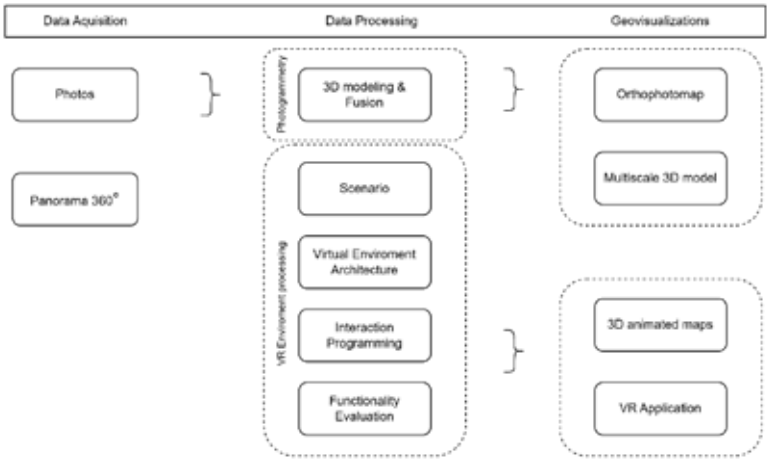

Figure 1. Methodology workflow.

Data Collection

The dataset for the present study was acquired through the deployment of unmanned aerial vehicles (UAVs) for the cartographic documentation of Ioannis Toumpelekis Park and its fossilized tree trunks at two different mapping scales. Specifically, a DJI Mavic 3 Enterprise UAV, featuring a 48 MP camera and a Real-Time Kinematic (RTK) positioning system, was employed to ensure the collection of high-precision spatial data.

Flight operations were carried out in two sessions, on May 1, 2023, and August 31, 2023, at flight altitudes of 70 meters and 2 meters, respectively. These sessions were planned under favorable weather conditions and optimal sunlight to reduce shadow interference and enhance the quality of the captured data. The utilization of the RTK system facilitated positional accuracy, achieving precision of up to 1 cm horizontally and 1.5 cm vertically, thereby obviating the requirement for ground control points. The data acquisition was conducted at two different scales: 1. park-scale (1:150) and 2. petrified tree trunk-scale (1:10). Overlap parameters were set at 80% frontally and horizontally to optimize the creation of image based 3D models and the orthophoto-map. Additionally, 360° panorama was captured at 50m height of flight, providing contextual visuals of the study area for VR geovisualization. (*Table 1.*)

Table 1. Data acquisition information

Image based 3D Modelling

The 3D models for this study were constructed using a systematic workflow designed to ensure high precision and photorealistic outputs. The process began with the generation of a sparse point cloud, followed by the creation of dense point clouds from UAV imagery utilizing the Structure from Motion (SfM) algorithm (Papadopoulou et al., 2022). The sparse point cloud provided an initial geometric framework, while the dense point cloud added detail, accurately capturing surface features essential for realistic modelling.

.

Subsequently, a total of thirteen (13) 3D models were generated by interpolating the dense point cloud data. Twelve (12) of these 3D models were the fossilized trees within the study area and one (1) 3D model depicting the entirety of the park. Textures were then applied to the meshes, ensuring photorealistic visual fidelity. The fusion approach was employed to refine and fuse the models, maintaining high accuracy across both park-scale and tree trunk-scale. This process involved extracting areas containing fossilized tree trunks from the park-scale model and replacing them with high-detail fossil 3D models derived from data captured at a 2-meter flight altitude. (*Figure 2*). The resulting multiscale 3D model of the park enabled seamless transitions between different scales, providing detailed visualizations of the fossilized tree trunks while retaining the broader contextual information of the park.

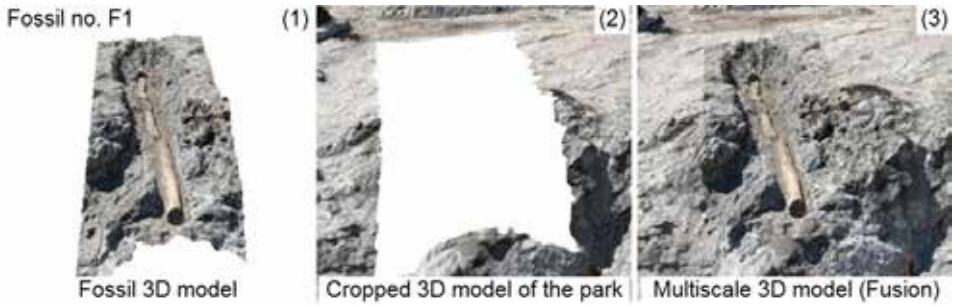

Figure 2. Multi-scale 3D model.

Geovisualization Methods

In the final stage, the 3D models were integrated into a virtual reality (VR) environment utilizing Twinmotion, a real-time 3D visualization software powered by Unreal Engine. This integration facilitated the development of an immersive and interactive experience, enabling users to virtually explore the park. Key features included 3D animated maps, interactive hotspots, and supplementary information highlighting the park's petrified tree trunks.

The development of the VR environment required the establishment of a structured methodology to define the content and features to be presented within the application (Papadopoulou et al., 2022). The process involved the following stages:.

- Scenario Design.
- Virtual Environment Architecture.
- Interaction Programming.
- Functionality Evaluation.

The Virtual Reality (VR) application integrated a 360° panoramic backdrop to enhance spatial awareness and realism within the virtual environment. The incorporation of thematic maps, dynamic animations, and supplementary 3D models—such as fences, staircases, animated human figures, vehicles, and vegetation—further enriched the immersive experience. By adhering to interactive design principles, the application facilitated both free exploration and structured, guided tours, offering users an engaging and intuitive navigation experience.

Results – Discussion

Multiscale 3D Model

The multiscale 3D model was developed through the integration of twelve (12) high level of detail 3D models of fossilized tree trunks with a single (1) overarching model representing the entire Park. This multiscale 3D modeling approach was employed to enhance the overall quality and accuracy of the park's virtual representation by incorporating detailed reconstructions of the petrified tree trunks. The seamless integration of these models enabled a comprehensive visualization of the fossils within their broader natural environment, supporting both interpretative analysis and educational outreach. *(Table 2)*

Fossilized Tree Trunks	Points	Surfaces	Photos	Quality
Fossil no. 105	1,176,473	78,431	53	medium
Fossil no. 109	352,540	47,428	16	medium

Table 2. 3D models information

3D Animated Maps

To further enhance the visualization of the park's multiscale 3D model, a series of 3D animated maps were developed. These maps provided detailed visual representations, accurately depicting both standing and lying petrified tree trunks in their natural positions. The implementation of 3D animated maps offers significant potential as an educational tool for students, researchers, and educators, facilitating a deeper understanding of complex geological processes associated with the evolutionary history of the Petrified Forest of Lesvos.

A total of nine (9) 3D animated maps were generated utilizing two specialized software platforms: Agisoft Metashape and Twinmotion. Of these, seven (7) animations focused on individual petrified tree trunks, while two (2) provided comprehensive visualizations of the entire park. To enhance accessibility, these animations have been made available via the YouTube platform and can also be accessed through QR codes embedded within the park's orthophoto map, offering user-friendly experience. (link : https://www.youtube.com/watch?v=GwVFHR6T2EY&t=150s)

Virtual Reality Application

A virtual reality (VR) application was developed to present the multiscale 3D model of the park and to highlight the high level of detail 3D models of petrified trunks in their natural environment. This application also provides users with information A Virtual Reality (VR) application was developed to showcase the multiscale 3D model of the park, emphasizing the high level of detail in the 3D representations of the petrified tree trunks within their natural environment. In addition to immersive visualization, the application provides users with valuable information regarding: (1) the Petrified Forest of Lesvos, (2) the newly established petrified parks along the Kalloni–Sigri road, and (3) the specific study area. This interactive platform enhances user engagement and serves as an educational tool for exploring the geological and cultural significance of the site.

In the Virtual Reality (VR) application, users commence their experience at the entrance of I. Toumpelekis Park, where an introductory series of maps provides insights into the park's geological significance and spatial context. The application incorporates dynamic interactive features, such as the automatic opening of the park gate and the exploration of a detailed 3D animated map—developed in Twinmotion—that illustrates the walking paths and the distribution of petrified tree trunks. A key feature of the experience is the interactive engagement with tree trunk no. 105, which, when approached, activates a 1:1 scale visualization of the fossil's current state. The immersive journey concludes with a 360° panoramic view, offering users a comprehensive spatial perception of the site. (Figures 3-4)

.

Figure 3-4. VR application contents

Conclusions.

.The development of a multiscale 3D model and its integration into a virtual reality (VR) application for the Park, demonstrated both the potential and challenges associated with employing advanced geospatial technologies for the geovisualization of geosites.

Multiscale 3D model:.

1. The multiscale 3D model successfully combined detailed reconstructions of the petrified tree trunks with a broader, lower-level of detail 3D model of the park, enhancing visual fidelity while preserving environmental context. However, challenges were encountered during the management of the multi scale 3D model within platforms such as Twinmotion and Blender. Issues such as the misalignment of models required manual adjustments, including relocating pivot points and realigning coordinates, to ensure seamless integration.
2. **3D animated maps**:.
3. The 3D animated maps provided an innovative way to visualize the multi-scale 3D model, delivering significant educational value. Nevertheless, certain limitations emerged, including incomplete models and texture distortions caused by insufficient image overlap during UAV data acquisition. Furthermore, user interactivity was constrained to predefined perspectives, limiting the ability to explore specific points of interest freely.
4. **VR application**:.
5. The VR application offered an immersive and educational experience, enabling users to explore the park and visualize the detailed petrified tree trunks in their natural environment at a 1:1 scale. Despite its potential, the implementation revealed technical challenges, including scaling 3D models accurately and managing panoramic displays without distortion. Additionally, the requirement for high-performance computational systems imposed financial constraints, potentially limiting accessibility for institutions with restricted resources.

These findings highlight the potential of multiscale 3D modeling and VR applications to revolutionize geovisualization in geosites while emphasizing the need for further advancements in technology to overcome existing limitations.

Background

This study investigates droughts in Greece based on the meteorological relative humidity index (Tsesmelis *et al.*, 2019, 2021, 2022). Droughts, temporary natural conditions tied to water availability, result from low regional rainfall (Karavitis, 1996; Lujala *et al.*, 2015; Feloni *et al.*, 2017). Their frequency, duration, and severity vary, impacting water resources and ecosystem recovery (Fleming-Muñoz *et al.*, 2023; Pizzorni *et al.*, 2024). Relative humidity (RH) measures air moisture relative to its maximum capacity under the same temperature and pressure (Kiem *et al.*, 2016). Using RH data from 42 Hellenic National Meteorological Service (HNMS) stations (1971–2004), the Standardized Relative Humidity Index (SRHI) was calculated at 1, 3, 6, 9, and 12-month intervals. Diagrams illustrated index changes, while drought maps, created via Inverse Distance Weighting, visualized annual SRHI12 and SRHI6 values. Analysis identified 1989–1990 as the most severe drought, followed by 2000–2001. Additionally, this study explores climate variability in Greece through statistical analysis of RH data from the same stations (1975–2004).

RH measures water vapor in relation to air temperature (US Department of Commerce, n.d.). It is the most used humidity index. It is defined as the ratio of the actual amount of water vapor in the air to the maximum amount it can hold under the same temperature and pressure conditions. In other words, it is defined as the ratio of hydrometric parameters to their corresponding values at saturation, as follows:

$$RH = mv/mvs \text{ } or \text{ } RH = e/es \text{ } or \text{ } RH = r/rs \text{ } or \text{ } RH = q/qs$$

Where: RH: relative humidity, m and mvs: mass of water vapor and the corresponding value at saturation, e and es: vapor pressure and the corresponding value at saturation, r and rs: mixing ratio of air and the corresponding value at saturation, q and qs: specific humidity and the corresponding value at saturation.

Relative humidity is expressed as a percentage (%) and always has a value ≤1. In practical terms, its value indicates how far the current state is from the corresponding saturation state, which occurs when there is fog or rain.

Drought is a complex climatic phenomenon that often occurs over large spatial and temporal scales. It is frequently accompanied by severe social impacts resulting from the reduction in the available quantity of water for human consumption, as well as for agricultural and livestock activities. The attempt to find a precise definition has led to the conclusion that it is a temporary natural phenomenon related to water availability, which usually results from low average rainfall values. It has an uncertain frequency, duration, and severity, causing significant impacts on water availability and the ability of the ecosystem to recover to its original state (Stathopoulos *et al.*, 2018).

Objectives

This study aims to investigate the impact of climate change (CC) in Greece by analyzing climate indices using meteorological data. The primary research question focuses on determining whether and to what extent global CC has influenced the climate of Greece. The literature offers a wide range of indices for assessing both qualitative and quantitative changes in climate. Through the processing and statistical analysis of carefully selected and formatted indices, a more in-depth analysis will be conducted compared to previous reports and records (Tsesmelis, 2017; Tsesmelis *et al.*, 2022, 2023). This study can comprehensively define the key elements related to climate, CC and drought phenomena.

Methods

The lack of studies correlating humidity with the occurrence of potential drought phenomena was the impetus for

further study and analysis in this work. In the first stage, humidity measurement data were collected from 42 HNMS stations across the country. These values were processed to produce daily and then monthly data. For each station, a file was created using a spreadsheet program (Excel) in which the minimum, maximum, mean, median, and standard deviation for each month of each year (from 1971 to 2004) were recorded, in order to make an initial estimate of the general trend of humidity measurements. The same process was followed again after the humidity measurements for each station were grouped to obtain the above statistical values for each study year. Subsequently, the monthly humidity values for each station were entered into a suitable programming language where the SRHI (Standardized Relative Humidity Index) was calculated for each station separately. The index was calculated for all time steps: one month (SRHI1), three months (SRHI3), six months (SRHI6), nine months (SRHI9), and twelve months (SRHI12). Using the values obtained from the program, graphs were created to depict the monthly variations of the indices for all years. In this way, an initial qualitative check of the processed data was performed. In order to study, understand, and interpret the results of the above analysis more extensively and ultimately draw conclusions, the creation of maps was initiated in the next stage. Using the spreadsheet program (Excel) again, a workbook was created in which the codes and names of the stations, the coordinates of each station (x and y in EGSA 87), and the results of SRHI6 and SRHI12 were recorded. Subsequently, 3 maps were created for each year based on the values of SRHI6 for the 6th and 12th month and SRHI12 for the 12th month, respectively. The creation of the maps using the geostatistical method of Inverse Distance Weighting, in which both the extreme values and the colors that represent them with blue (wet period) and red (dry period) were defined. The index used for the analysis is the Standardized Relative Humidity Index (SRHI). The SRHI uses a non-parametric standardization approach. First, the empirical probabilities of the relative humidity data are calculated using the empirical plotting position of Gringorten (Farahmand *et al.*, 2015).

$$p(RHi) = (i-0,44)/(n+0,12)$$

where i: the rank of the relative humidity data from the smallest, n: the sample size
The empirical probabilities of the relative humidity data are standardized as follows:

$$SRHI = \Phi^{-1}(p(RHi))$$

where: Φ-1 is the inverse standard normal distribution function with mean zero and standard deviation one. The standardization is based on the following approximation:

$$SRHI = \begin{cases} \\ \end{cases}$$

where: c_0=2,52, c_1=0,80, c_2=0,01, d_1=1,43, d_2=0,19, d_3=0,00
and:

$$t = \begin{cases} \sqrt{} \end{cases}$$

Negative values of the SRHI index indicate relative humidity below the average and are suggested as a measure of dryness according to climatology. The following table (Table 1) presents the scale of the index values.

Table 1. Categorization of SRHI index values.

SRHI values	Category
> 2.00	Extremely Wet
1.50 to 1.99	Very Wet
1.00 to 1.49	Moderate Wet
0.50 to 0.99	Mild Wet
-0.49 to 0.49	Normal Conditions
-0.50 to -0.99	Mild Drought
-1.00 to -1.49	Moderate Drought
-1.50 to -1.99	Severe Drought
<-2.00	Extreme Drought

The HNMS operates 178 surface stations across Greece and three upper-air stations (Elliniko, Heraklion, Macedonia-Mikra). These stations record primary climate data every three hours, 24/7, for analysis and processing. This study utilized humidity data from 42 stations nationwide.

Results and Discussion

Although the index was analyzed at 1-, 3-, and 9-month intervals, SRHI6 was emphasized in diagrams and maps due to Greece's typically high humidity from October to March. Since humidity varies across regions, SRHI12 was also included. Calculating SRHI at these intervals produced 42 diagrams, with two representative examples shown (Figure 1).

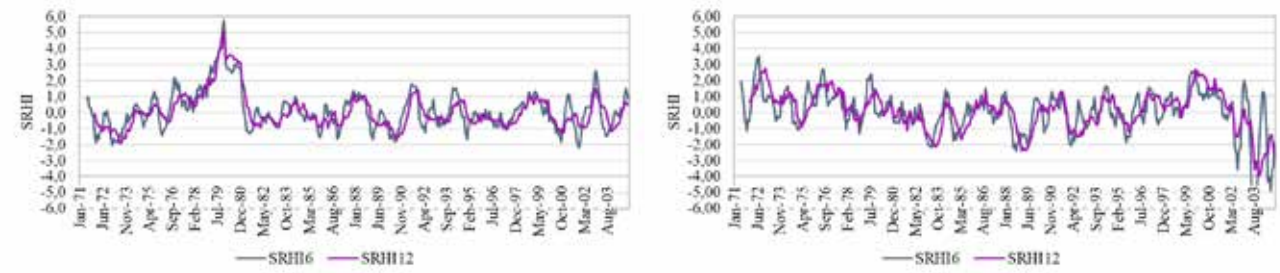

Figure 1. The SRHI index with a time scale of 6 and 12 months for the Lemnos meteorological station where a period of exceptional humidity is observed (left panel) and Methoni where a period of extreme drought is observed (right).

Analysis of the diagrams reveals multiple instances of low index values, indicating past droughts, even before rapid urbanization and increased water consumption. To better visualize drought periods nationwide, 102 maps were generated using Inverse Distance Weighting (IDW) in ArcGIS Pro 3.3—one for SRHI12 and two for SRHI6 annually. Drought patterns varied over the years. Severe droughts affected Arta, southern Peloponnese, Rhodes, and Sitia in 1971–1973, culminating in an extreme nationwide drought in 1974. Another severe drought occurred in 1977, mainly impacting Central Greece and Sitia. From 1979 to 1982, conditions were mostly normal, with localized wet and dry periods. Moderate droughts emerged in southeastern Greece in 1983, followed by a wet phase in 1984, which ended in late 1984 with recurring droughts through 1986, particularly in northern and western Central Greece. A significant shift began in 1988 with moderate drought across western Greece (SRHI12) and nearly the entire country (SRHI6). The most extreme drought occurred in 1989–1990, affecting almost the entire country, with SRHI6 showing more intensity than SRHI12. After milder droughts in 1992–1993, Crete (1995) and Evros (1996) faced localized dry conditions. In 1997, severe drought impacted Epirus, western Macedonia, Thira, and Rhodes. Moderate to severe drought appeared in central Peloponnese (1999), escalating nationwide in 2000–2001, especially in eastern Greece and later across nearly the entire country. In 2002, while Evros faced mild drought, much of Greece experienced unusually wet conditions, particularly Central Greece and Crete. By 2003, extreme drought was again localized in western Peloponnese, Evros, and the Cyclades. This study highlights key drought years: 1974, 1977–1978, 1983–1984, 1985–1986, 1989–1990, 2000–2001, and 2003. In contrast, 2002 was a year of high humidity. Notably, Pyrgella recorded extreme drought values of -6.60 in 1974 and an unprecedented -7.86 in 1975, despite the latter year not being generally dry (Figure 2).

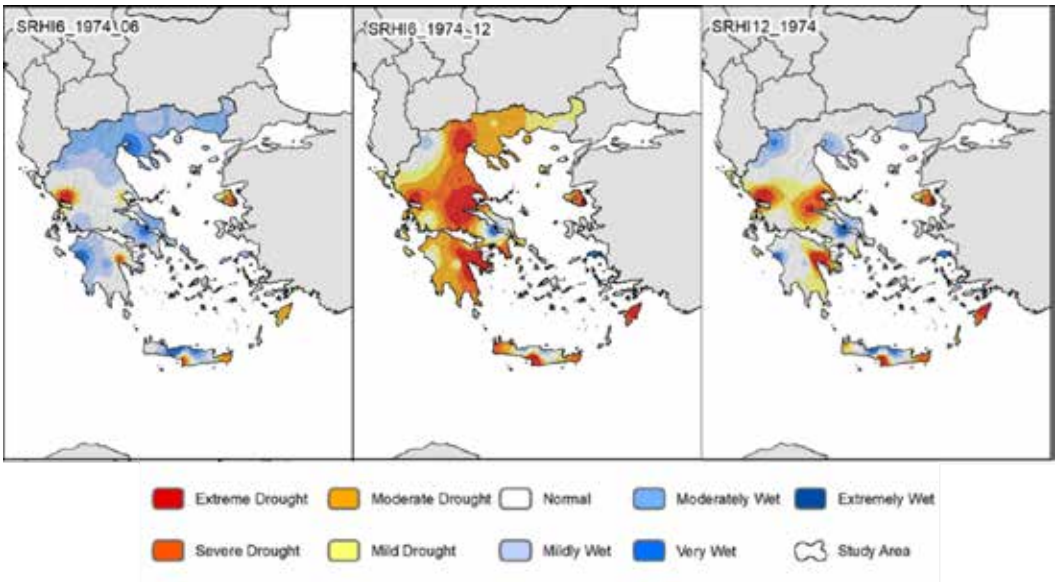

Figure 2. SRHI6 and SRHI12 maps for the year 1974.

The 1977–1978 drought was severe in many regions but not the most extreme recorded. This was followed by 1983–1984, when SRHI6 indicated moderate to high humidity across much of Greece, while SRHI12 showed a milder trend. A similar pattern occurred in 1985–1986, with severe to extreme drought in some areas (SRHI6), but a less intense picture from SRHI12.

In 1988, an extreme drought began, culminating in the devastating 1989–1990 drought—one of Greece's longest and most intense. Nearly the entire country experienced extreme drought, severely impacting agriculture and the economy. June 1990 was the worst month (SRHI6) (Figure 4). To mitigate the crisis, authorities explored solutions, including a proposal by the National Technical University of Athens to transport water by ship, prompting immediate government action (Tsesmelis, 2010).
The next significant drought occurred in 1993, though milder than previous events. It affected much of Northern Greece, Thrace, the Aegean islands, and the Dodecanese. Islands faced heightened drought issues in summer due to increased water consumption from tourism.
In 2000, Greece experienced the most severe drought since 1990, initially impacting Central Greece and northeastern Aegean islands. By year's end, drought spread across the country, with severe crop damage in northern Greece (Figure 5).
In 2001, drought conditions persisted, notably affecting central Peloponnese, Central Greece, and Thrace, but weakened towards the end of the year, returning the country to normal conditions.
Although 2003 had minimal drought issues, localized extremes were observed, such as in Methoni, where SRHI6 recorded the study's most extreme value of -8.11 in August (Figure 6).
Notably, unlike the recorded droughts, 2002 saw exceptionally wet conditions across most of Greece (Figure 7).
Monthly relative humidity analysis revealed two distinct periods: October–March, characterized by high humidity, and April–September, when levels are generally lower. This pattern is evident in station diagrams, though more pronounced in some locations than others.

Conclusions

This study investigates the drought phenomena in Greece from 1971 to 2004 to assess the long-term variability of climate over the years. Using humidity data from 42 HNMS stations across the country, the Standardized Relative Humidity Index (SRHI) was employed for analysis, with results presented through diagrams and maps. The findings highlight the widespread impact of droughts, particularly in island regions, which face unique challenges due to their geographic and socio-economic characteristics. Island areas, especially during the summer months, are particularly vulnerable to droughts. The increased influx of tourists significantly raises water consumption, exacerbating the already limited water resources available. This effect was observed notably in the Aegean islands and the Dodecanese, where droughts became more severe during peak tourist seasons. The study showed that, while mainland regions experience droughts of varying severity, the islands are often at greater risk due to their dependence on limited freshwater supplies, which are further strained by seasonal population increases.

The severe droughts of 1993, 2000, and 2001 particularly impacted the eastern islands, such as those in the northeastern Aegean. These regions experienced significant agricultural losses, which were compounded by the added strain of water scarcity caused by tourism. The 2000–2001 drought was among the most severe since 1990, with widespread consequences for both agriculture and the local economy, disproportionately affecting northern Greece and the islands. This pattern underlines the critical importance of addressing the unique vulnerabilities of island areas in future drought management strategies.

The overall trend shows that Greece's vulnerability to droughts has intensified, driven by both global CC and the substantial increase in water use. The combination of rising temperatures and heightened water consumption calls for immediate and proactive measures to mitigate drought impacts. The study underscores the urgent need for comprehensive drought prevention and management plans, tailored to both mainland and island regions, to minimize the economic and ecological consequences of future droughts. Given the significant challenges posed by droughts, particularly in island areas, further research is essential to develop more robust strategies for water conservation, sustainable tourism, and regional drought preparedness. With proper planning and management, the impact of droughts can be better mitigated, making their management more effective and less disruptive.

EXTENDED ABSTRACT 223

Density modeling based on gravity survey at faulted area around Aigion, Gulf of Corinth, Greece

Mrlina J.[1]
(1) Institute of Geophysics CAS, Prague, Czechia, jan@ig.cas.cz

Introduction and objectives

This paper is based on the gravity survey data and highlights a quite important difference between former geological models and the new density/gravity model along two NNE-SSW oriented profiles crossing three principal normal faults in the Aigion area of the Gulf of Corinth.

The geological models were presented by Ghisetti *et al.* (2001), Ghisetti and Vezzani (2005), and Moretti *et al*. (2003).The current gravity model actually comprises much less conglomerate formations between the Helike and Pirgaki faults.

For this study, a new gravity map of the area was needed, so a gravity survey was carried out in a few steps, and the data were processed into the Bouguer gravity anomaly values. Then a gravity map and a residual gravity maps were constructed as a base for gravity field evaluation. As well, extensive rock sampling of the principal rock types was performed, as no such data were available from former investigations, as stated by Mrlina (2001). Rock densities and porosity were measured in a laboratory in Czechia.

The principal objective of the gravity surveying was to determine tectonic and structural setting of the area which forms the southern side of the Corinth Rift. The principal tectonic features are the WNW-ESE trending normal faults expressed in the topography of the region (Armijo *et al*., 1996, Rigo *et al.,* 1996). The region is prone to strong earthquakes (Bernard *et al.,* 1997). The target was to perform 2D and 2.5D gravity/density modeling to constrain existing tentative geological profiles. No such gravity models had been published in literature to that date.

The location of the study area is presented in Fig. 1

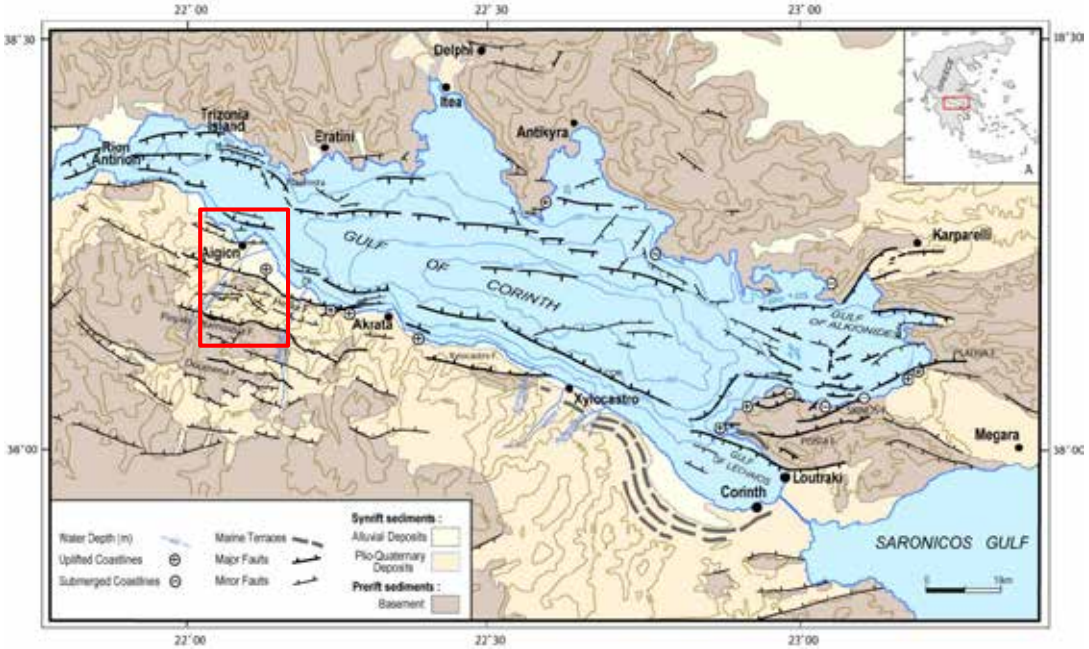

Figure 1. Tectonic map of Gulf of Corinth (after Moretti *et al.,* 2003). The study area around Aigion is marked by a red rectangle. Principal normal WNW-ESE faults are presented in the map.

Methods

The gravity survey was performed using the LaCoste&Romberg D-188 and LCR Graviton-EG gravimeters supported by the Trimble GNSS instrumentation. GNSS survey was connected to a few local Greek geodetic network stations (Lagios *et al.,* 1994), while the gravity measurements were referenced to relative gravity bases. One such base was established in the drill site of the AG10 well (see Fig. 2 for location) that was bored within the EC project Corinth Rift Laboratory.

Daily gravity loops included a few repeated points in order to define an accurate secular drift of a gravimeter. Also, independent control points were observed in order to define the repeatability of the gravity measurements that was evaluated to 0.010 mGal (1 mGal = 10^{-5} m/s^2). The rms of the Complete Bouguer anomaly values was 0.017 mGal. The final range of the gravity field within the gravity map in Fig. 2 was 17 mGal.
The Complete Bouguer anomaly (CBA) was calculated with a traditional formula with normal gravity field correction, elevation correction and Bouguer plate reduction for density of 2.50 g/cm3. Terrain corrections were computed to the distance of 167 km from each point. Terrain model included both onshore and offshore topography. The gravity map is shown in Fig. 2.

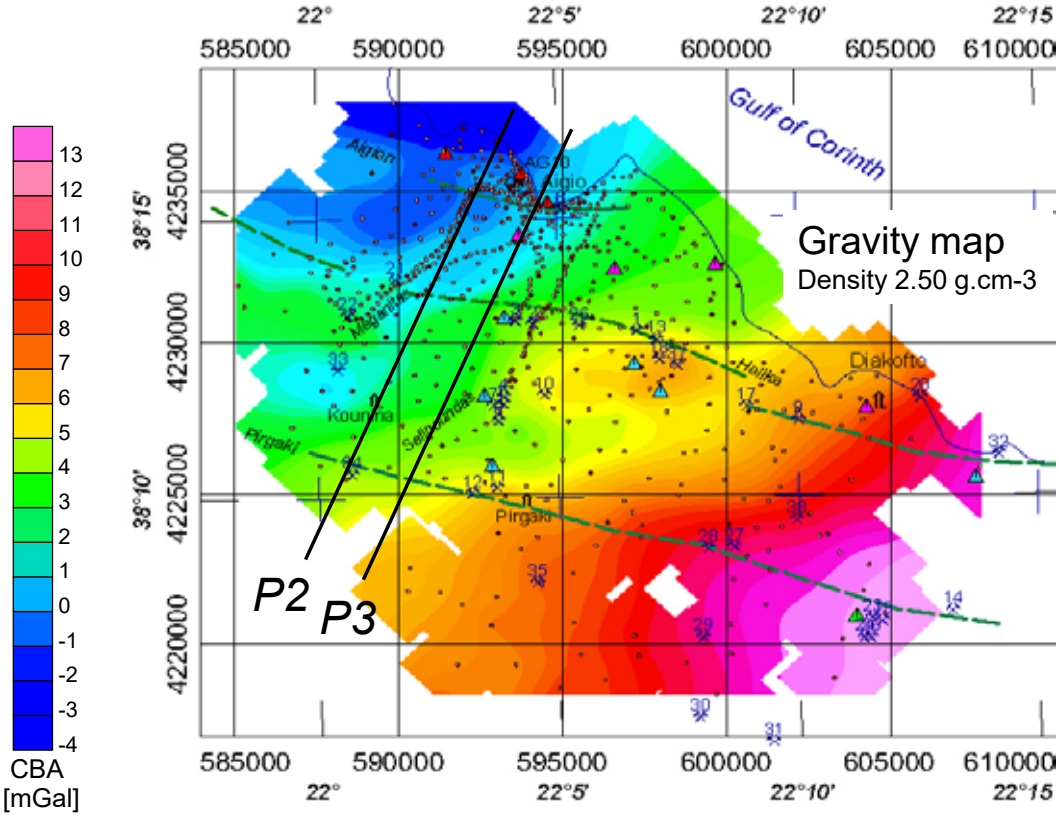

Figure 2. Gravity map of the Aigion area for reduction density 2.50 g/cm3. The total range of the map is 17 mGal. Principal faults are presented as green dashed lines. Two geological profiles P2 and P3 are located in western side of the map. Rock sampling locations are marked by crossed-hammers (mining) symbols. Blue triangles show gravity monitoring stations. Coordinates are WGS84 (degrees) and UTM34N (meters).

Density analysis was performed based on 135 rock samples collected during the field work. Sampling locations are shown in Fig. 2 as 'mining' symbols with numbers; each number represents a few samples from the given location (a,b,c, etc.). Relatively fresh samples were attempted in order to represent respective rock type as well as possible. Still, it is necessary to keep in mind that the samples cannot provide a complete idea on real rock fracturing inside a rock massif. Therefore, they provide approximate values of densities of the given rock types and keep certain freedom for the gravity/density modeling.
In the laboratory, five parameters were determined: bulk (volume), wet (saturated) and grain densities, porosity, and magnetic susceptibility.
The first collection of samples focused on the two principal rock types – limestone and conglomerate. The respective values are presented in Fig. 3, where wet (saturated) density is used, as it represents the most probable status of rocks in the natural conditions inside rock formations. There are 31 samples in the graph showing also average values for limestones and conglomerates, respectively.
As the sampling was further extended, the final collection contained 135 samples. They were separated into 8 groups, while limestone and conglomerate were still the most frequent rock types, see Fig. 4

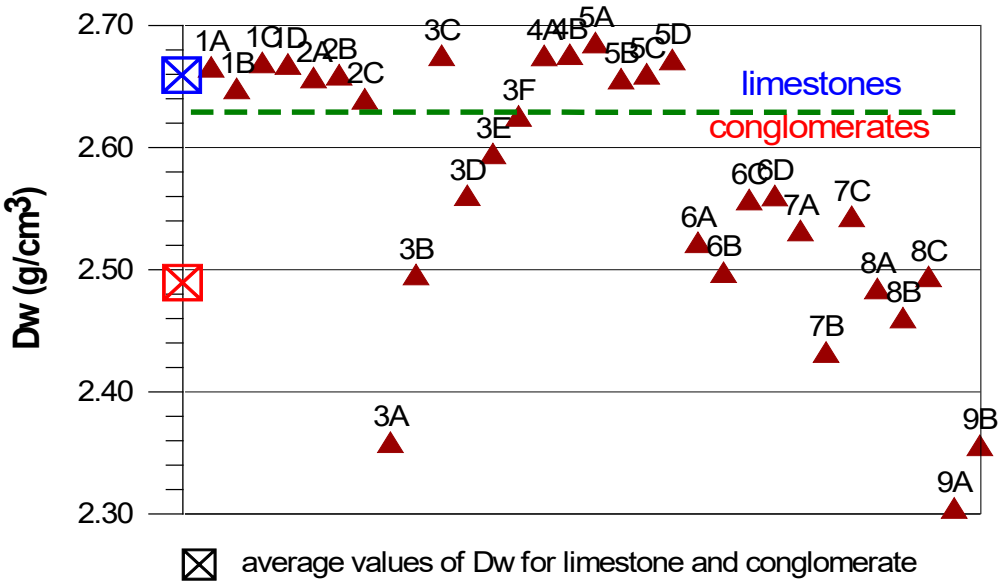

Figure 3. Collection of 31 rock samples (14 samples of limestone, and 17 of conglomerates). Average values of both groups are shown on wet density axis, blue for limestone, red for conglomerate.

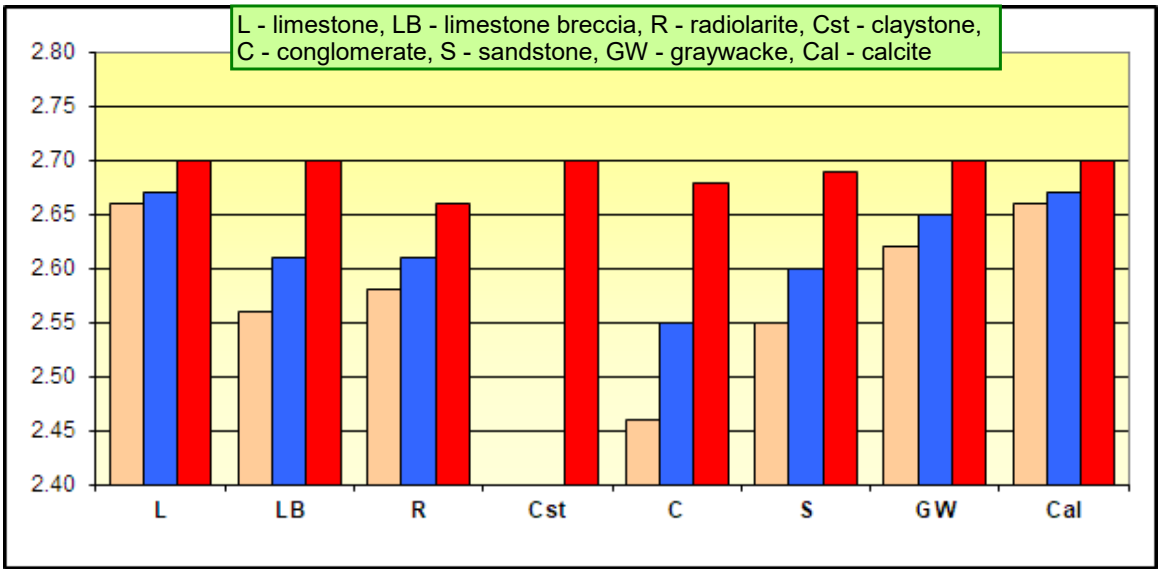

Figure 4. Up: Database of 135 rock samples and respective average values of particular density parameters, as well as porosity and magnetic susceptibility. Each parameter has also respective range of values. Down: Column graph of 3 density parameters for all 8 rock types. It is evident, that grain density Dg has a quite small range (red column), while bulk/volume (Db, orange) and wet/saturated (Dw, blue) densities show much larger differences. Rock type abbreviations are explained in the green window between the two parts of the figure.

Results and discussion

The analysis preceding the gravity modeling focused on the existing geological models. Average density values were attributed to particular formations present in the geological model. The density model was simplified into just two formations – limestone basement, and young rift-related sediments formed mainly by conglomerates (marls, claystones, radiolarites were neglected). Two differential densities were used to calculate these geological models – 0.11 and 0.18 g/cm^3, respectively. The calculated gravity response curves were printed on top of the models.

An example of this procedure is given in Fig. 5. Profile P2 is shown in color where green is limestone formation (basement) and yellow to brown formations are the young sediments. The two calculated gravity curves for both differential densities are presented above the geological model. The general trend is the gravity decrease from south to north due to increase of the thickness of the young sediments. The important features on the calculated curves are the local positive spikes related to fault zones, where the basement is elevated towards the surface – the best example is related to the Helike fault.

However, on top of the figure there are two other lines which show the real observed gravity data on P2 and P3. It is evident that theoretically calculated curves of the model do not fit with the observed data. Therefore, a new density model was developed with certain significant changes with respect to the original geological model, see Fig. 6.

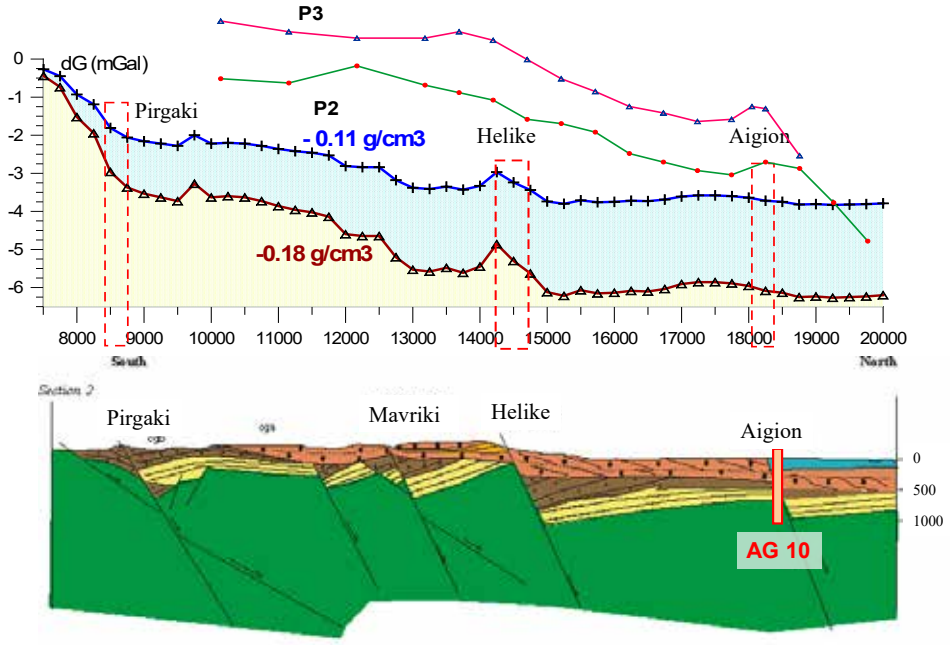

Figure 5. Geological tentative Profile 2 by Ghisetti *et al.* (2001). 2D gravity modeling performed for two differential densities between conglomerates and limestones (0.11 and 0.18 g/cm^3). Residual anomalies based on real observed Bouguer gravity values are different, as shown by two colored lines on top (for both P2 and P3). This justified significant changes in the models, as demonstrated on P3 in Fig. 6.

In the complex Fig. 6 there are actually 4 partial figures. At the bottom (D) the original geological model of Profile P3 (location in Fig 2) is presented. It is evident that all the section between the Pirgaki fault and the Gulf of Corinth is covered by the young sediments of variable thickness which is reaching even more than 1000 m in a few places. The smallest thickness is near the Helike fault where the blocks of the young sediment are strongly tilted to the south.

However, the gravity modelling could not fit the data until in the central part of the profile was completely changed and almost all young sediment removed. Like this the basement has only shallow cover of those young sediments. In part C a simple sketch of the density model is presented so that the descriptions are better visible, contrary to B where the geological formations are presented with raster and colors.

During the modeling process it was necessary to introduce two densities for the limestone formation – 2.70 g/cm^3 at deeper section, and 2.67 g/cm^3 in the upper parts. As well, within young sediments also claystone was incorporated (beside conglomerates) with low density of about 2.35 – 2.40 g/cm^3.

The A part shows observed and calculated gravity curves. In the substantial part of the profile the fit of the two curves is perfect, just in the southern end the data deviated from each other. This may be due to limited extend of the profile,

but also due to too high thickness of conglomerates on the hanging wall side of the Pirgaki fault.
It should be mentioned that the geological and gravity profiles are not completely identical in the field and they differ as for morphology, especially near the Helike fault, where the gravity survey avoided the steep slope of this fault. However, this does not affect the existence of the evaluated difference of the geological and gravity models.

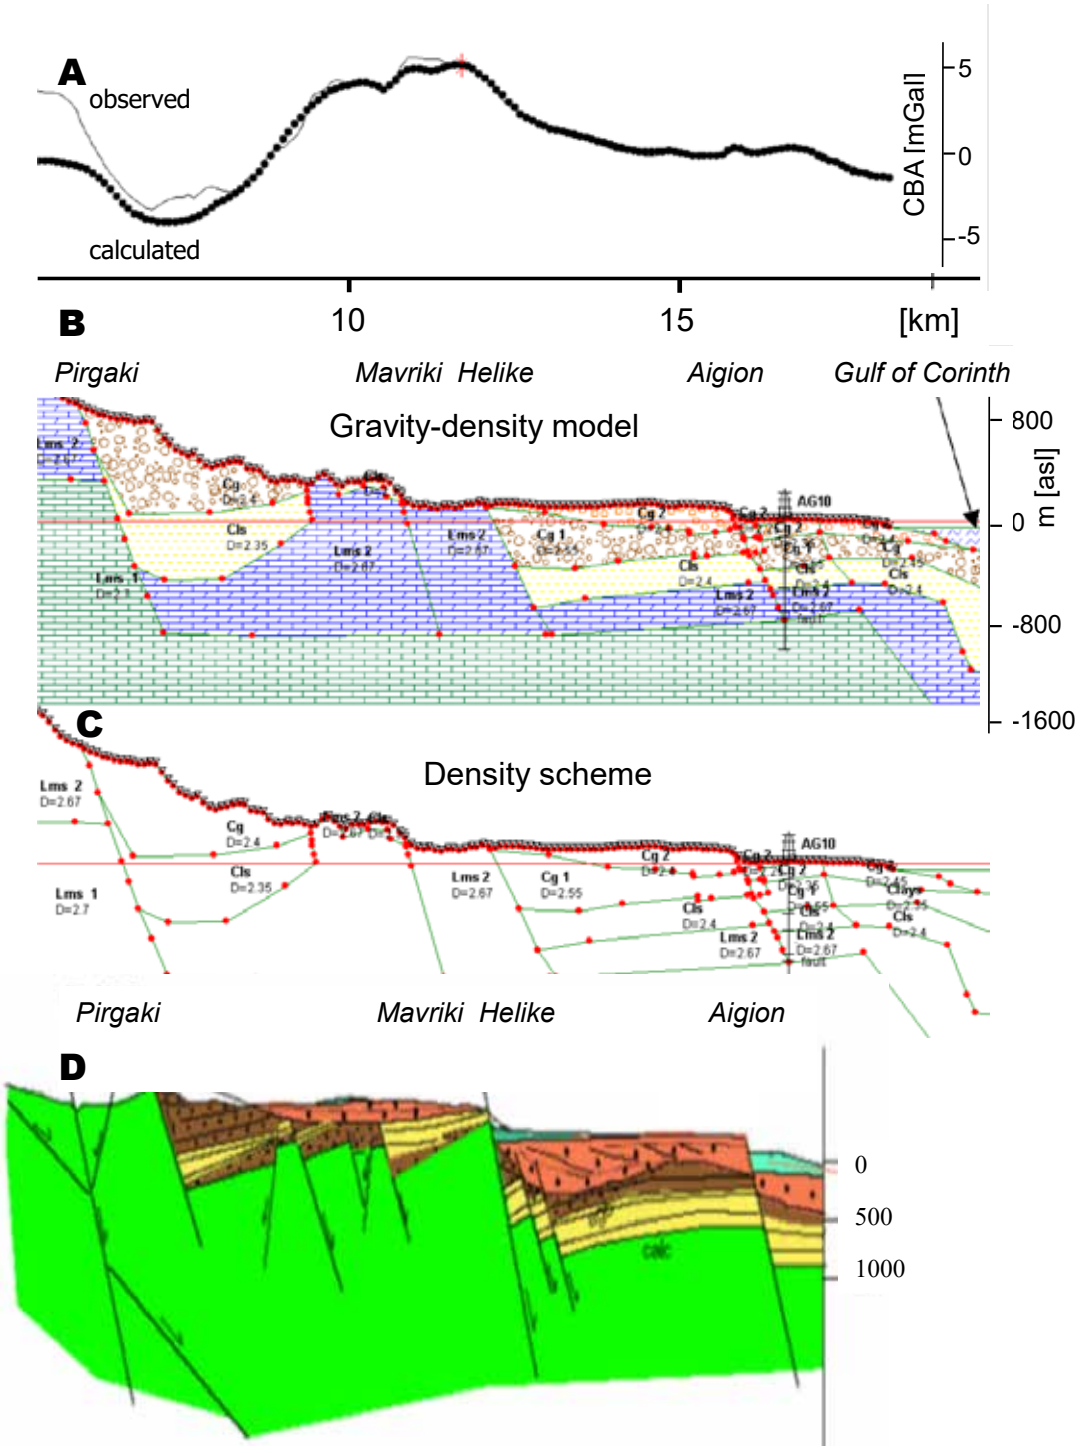

Figure 6. Residual (observed) and calculated gravity (A) for the new model of P3 shown in (B). In (C) simplified density model with rock types (Lms = limestone, Cg = conglomerate) is presented. Gravity/density model (B) is confronted with structural geological model (D) of Ghisetti et al. (2001). The principal difference of the models is exhibited between Helike and Pirgaki faults.

Conclusion

The presented work showed that the geological tentative profiles in complex tectonic and structural setting may suffer from inaccuracies. Therefore, some constraining techniques are recommended to be applied. For geological structures study the gravity method is a suitable geophysical tool.

It is also important to evaluate the rock densities for correct interpretation of the data. In this study we determined the difference between the two principal rock types, limestone and conglomerates, to range from 0.11 to 0.18 g/cm^3. In the Gulf of Corinth rift region it was found (by the gravity surveying and modeling) that the volumes (blocks) of particular formations significantly differ from the geological idea. Along the given NNE-SSW profiles P2 and P3, passing around Aigion city, especially in their central part between the Helike and Pirgaki faults, the volume of young rift-related sediments is much smaller than previously expected. Even if the density difference between basement (limestone) and young sediments cannot be perfectly determined, despite extensive sampling and laboratory work, the density models fit the observed data. In Fig. 6 such a result is presented.

Acknowledgements

The author wishes to appreciate I. Moretti for supporting the idea of a field gravity investigation, F. Ghisetti for sharing geological knowledge of the area, the assistance of M. Seidl with GNSS measurements during the gravity survey, and E. Lagios for providing information on geodetic/gravity networks in Greece. Field operation was supported by the EC project Corinth Rift Laboratory ENK6-CT2000-00056 NAS-3F-CORINTH.

EXTENDED ABSTRACT 224

Gravity monitoring at Santorini volcanic island, Greece

Mrlina J.[1]
(1) Institute of Geophysics CAS, Prague, Czechia, jan@ig.cas.cz

Introduction and objectives

Santorini island in the Aegean Sea is a famous volcanic structure, not only because of its beauty, but mainly for its catastrophic eruption about 3500 years ago. This eruption eliminated the Minoan civilization in Crete, and caused the volcano collapse forming the current day caldera. The volcano is one of the principal volcanoes of the Greek volcanic arc related to the collision of the African and Eurasian plates. The arc comprises also Kos-Nisyros volcanic system, the Milos island, and the Methana peninsula, see Fig. 1.
This volcano is still active, with the last lava flow in the central island of Nea Kameni in 1950. The island hosts numerous population and therefore is a subject of multiparameter control, starting with seismological permanent observations, GNSS (Global Navigation Satellite System) with permanent and campaign-style stations, gas monitoring, etc.
This situation was a motivation of introducing repeated gravity monitoring campaigns in 2013, after the volcano increased activity in 2011-2012. There was no lava eruption, however, the signals from GNSS were showing the inflation of the caldera with the central point in Nea Kamenni. Previously, there was an attempt of such research, but actually only two campaigns could be compared – the one in the 1970s, and the other in 2012-2014 (Paraskevas et al., 2021). Such gravity monitoring was applied e.g. in the Merapi volcano area (Indriana et al., 2023).
IGCAS (Institute of Geophysics, Czech Academy of Sciences) could support and perform this 4D gravity investigation thanks to the EPOS/CzechGeo project, see Acknowledgement. The objective was to indicate possible changes in the gravity field that may be related to mass changes and/or fluids movements inside the caldera.

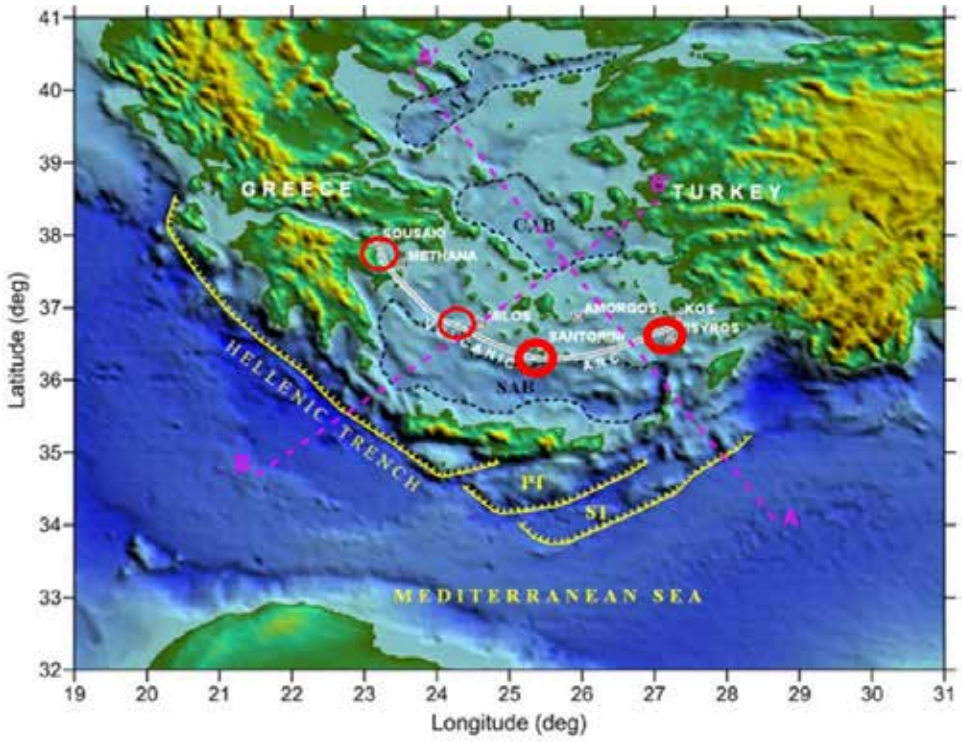

Figure 1. Position of Greek volcanic arc with four principal volcanic edifices – from left to right – Methana, Milos, Santorini, Nisyros.

The island is formed by lava extrusions of dacite, ryodacite, andesit and basalt, but the surface is covered mainly by pyroclastic formations of various composition, see Fig. 2. There are also outcrops of basement formed by carbonates (E, SE), but also metamorphics (slope to the new port) on the western side of Thira (Thera in Fig. 2). Tectonic zones are marked by white lines, as the principal ones of Columbo and Kammeni ones.

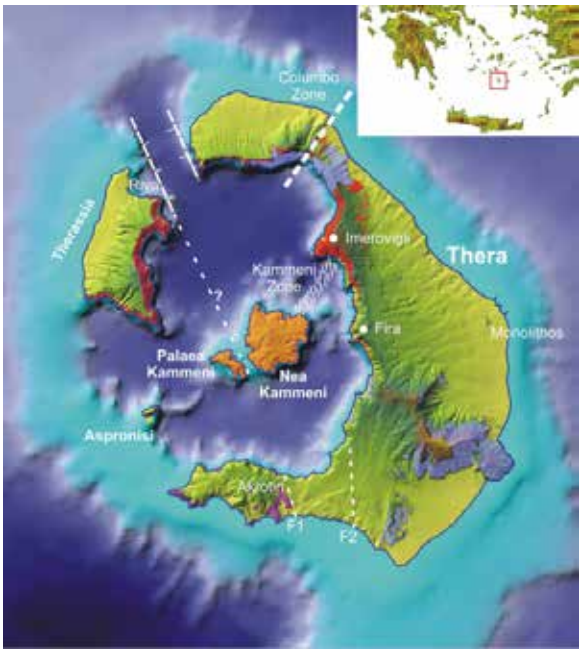

Figure 2. Position of principal tectonic features (Kammeni zone, Columbo zone) in Santorini, and principal lava flows (brown – dacite, ryodacite, andesite; light violet – basalts; medium violet – carbonate basement; green – various pyroclastic formations); after Lagios et al. (2013) and Druitte et al. (1999). Bathymetry after Nomikou et al. (2012).

The primary geophysical method for monitoring volcanoes and active faults is seismology, showing the active regions within the Earth crust. In Santorini two areas of different type of seismicity are located in the center of the caldera, and to the NE of Thira part of Santorini, see Fig. 3. Around Nea Kameni the epicenters are concentrated to a small area of about 5 x 3 km, actually along the Kammeni fault zone (see Figs. 2, 3), while in the NE they are spread on a large area with a diameter of more than 10 km.

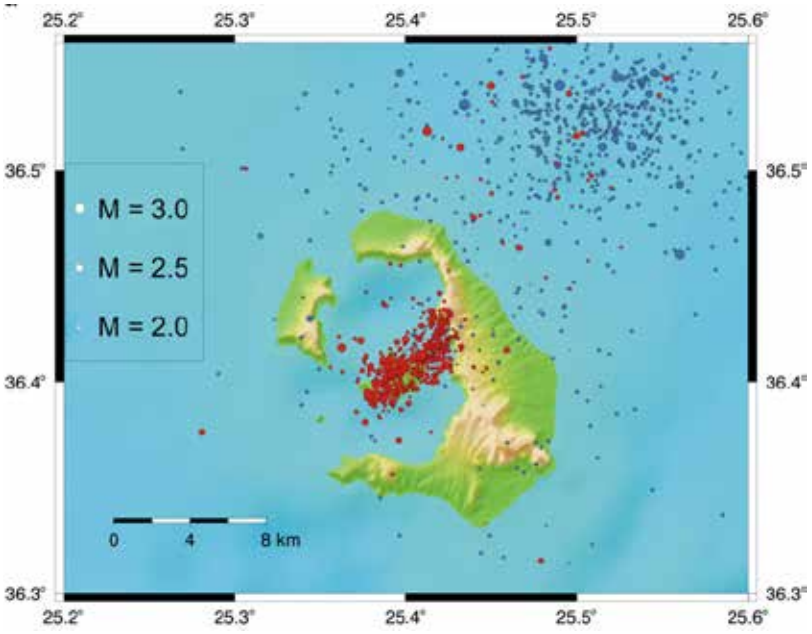

Figure 3. Seismicity around Santorini volcano in 1990-2010 (Lagios et al., 2013). It is evident that many events were recorded inside the caldera where Nea Kameni island is located. Earthquakes epicenters are accumulated within quite small elliptical area with longer axis less than 5 km. On the other side, in the area NE of Santorini seismicity shows much larger spread of epicenters around submarine volcano Kolumbos.

Gravity monitoring

The gravity monitoring is based on repeated measurements of gravity at a fixed network of stations. The observations at each station consist of a set of gravimeter readings, when a homogenous set has to be achieved (outlying readings are cancelled), as presented e.g. by Mrlina (2009, 2024).

Most, or all stations of the daily observation loop are measured three to five times in order to evaluate daily drift of the gravimeter. In this project one LaCoste&Romberg D-188 was used (2013-2021), later the Scintrex CG-6 gravimeter (2019-2024) was used, while in 2019 and 2021 both gravimeters were used simultaneously to provide enough overlap, see Fig. 4.

The network was based on the stations of NKUA (National Kapodistrian University of Athens) with the reference base stations No. 20, see the photos in Fig. 4. This base seems to be a reference point also for other gravity surveys in the Santorini island.

The old stations were continuously supplemented by new stations, as the author wished to cover some areas more densely, or to focus on some areas of higher interest, see Fig. 5. These new stations were selected in stable locations near churches, or similar, to ensure stable gravity observations. However, due to the general noise from the sea and from the volcano itself, exceptionally also of vehicles/people movement, some disturbed readings had to be eliminated. Some stations are increasingly difficult to operate due to difficult access in towns with enormous traffic (Fira, Oia).

The gravity campaigns usually lasted 9-13 days and also included one or two days to connect to Nea Kameni island stations by boat.

Each tie between any two stations was measured normally four times, which required a lot of driving by car (about 4 – 5 thousand km), or, in some cases, walking.

All these measurements, even simultaneous with two gravimeters, were performed as a single-man-job by the same operator (author), with the same gravimeters, and in the same period of a year.

Figure 4. Position of the principal reference base station in Monolithos to NE of the airport. It is a solid pillar with concrete filling at the parking near Monolithos church, built on the limestone basement block (see the hill behind the base). Gravity readings were always stable at this base. Gravimeter Scintrex CG-6 is presented at the bottom photo, LaCoste&Romberg D-188 gravimeter is inside to black box to stay protected from sunshine.

Some ties were repeated in other days in order to evaluate the repeatability. Standard deviation of the measurements was usually better than 4 uGal.
Each campaign was processed and the differences (ties) between stations were calculated. Then these differences were compared between any couple of campaigns. In this way the temporal changes of gravity field were evaluated. Then, the changes for each point were obtained and could be interpolated into a map. Such differential map is presented in Fig. 6 for the years 2013 versus 2021.

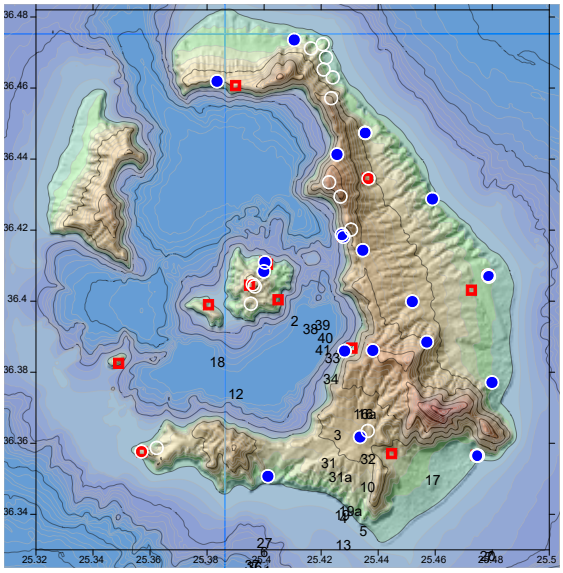

Figure 5. Position of the gravity monitoring network. Red rectangles are the old stations of the 1970s, full blue circles are the stations established by NKUA (Lagios et al., 1988), and white circles are stations used and established by author (IGCAS). Reference base station is No. 20 located in Monolithos to NE of the airport.

Results and discussion

The analysis of the data was focused on the temporal gravity difference between 2013 and 2021 (as in 2021 the campaign was performed with the LaCoste&Romberg D-188 gravimeter for the last time).
As mentioned above, the gravity differences at each station were used to interpolate all the differential values and the differential map was obtained, see Fig. 6.
There are two principal features in the map. The negative gravity changes in the northeastern side of Thira at the stations 3 and 16, and the positive change at the station 26 in the new port.
Most important is the negative change. It can be caused by continuous extension along the Kolumbo fault zone, which may decrease the volume density of the rocks within this zone. At the same time it may be responsible for the development of the Kolumbo submarine volcano with huge amount of fluids emissions through the opening fractures.
In order to exclude the impact of elevation change (that affect gravity values), the vertical component of the permanent GNSS station SANT was checked (courtesy of V.Sakkas). It is clear that within the period under study there was just a slight uplift 2013-2015 of less than 10 mm. Such value cause a gravity change of 2 uGal, which is almost negligible in respect to the amplitude of the negative zone (-50 uGal). Therefore the vertical displacement cannot be responsible of that significant decrease of gravity.
Another potential cause of the gravity decrease could be the emissions of fluids, but this is less probable as the released fluids would be substituted by water or other fluids coming from the deeper subsurface.
On the other hand, the old data 1976-2012 were showing the principal gravity increase in Nea Kameni (evaluated from data of Paraskevas et al., 2021), which was probably related to the magma and fluids rising to surface before the 2011-2012 crisis. During this crisis no lava erupted to surface, but the GNSS data showed inflation of the caldera and active fluid emissions were also encountered. In the NE there was also relative gravity decrease recorded.
This may justify the hypothesis that in the NE side of Santorini there may be an ongoing extension process.
For this reason the Author established another four new gravity monitoring stations 38-41 in the northeastern side of the island, see the white circles 38-41 in Fig. 5 and dark red triangles in Fig. 6. These stations were observed in 2023 and 2024, which is too short period for making any conclusions. The stations will be repeated in each potential future gravity monitoring campaign in the Santorini caldera.

The sharp gravity change between two nearby stations 10 and 26 (Fig. 6) can be affected by very sharp vertical difference, as 10 is located on the top of the cliff, while 26 is down in the new port. Here more investigation is needed to evaluate the impact of enormous change of air pressure during the measuring of this tie.

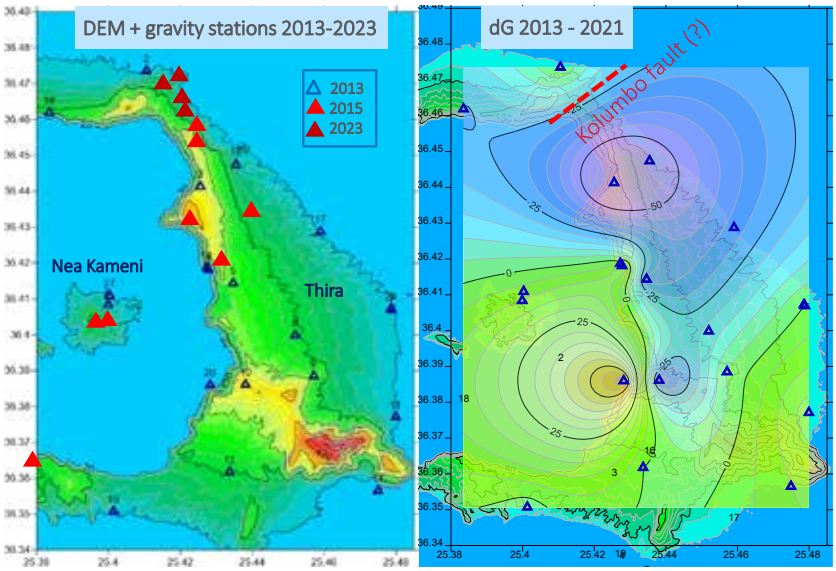

Figure 6. Left: Gravity monitoring stations used by IGCAS in 2013 (blue triangles established by Lagios et al., 1988), and established by IGCAS in later years 2015 and 2023 (red and brown triangles) for 4D gravity measurement campaigns. Right: Gravity difference between 2013 to 2021 in uGal (10^{-8} ms^{-2}) - principal feature is the gravity decrease in NE part of Thira (over -50 uGal) at stations 3 and 16.

Conclusion

This paper documents that the gravity monitoring of the Santorini volcanic island shows temporal gravity changes. As the vertical surface displacements play negligible role in affecting the gravity changes in the study period 2013 – 2021, the changes must be explained by geological/geodynamic processes.

Most significant is the temporal gravity decrease in the northeastern side of Santorini (Thira) where a long-term extension process in the underground may be causing the decrease of the volume density of the rock massif. Such extension within the Kolumbo fault zone also enables the opening for the currently active volcanic process around the Kolumbo underwater volcano with active fluids emissions.

In order to investigate this feature of the gravity field change, dense network of the monitoring stations was established in 2023 around the assumed Kolumbo fault zone.

Additional Comments

- In 2024 the author performed a small gravity survey in the NE part of Thira in order to investigate the Kolumbo fault zone which is related to the Kolumbo underwater volcano. This volcano has been recently very active with a lot of gas emissions. Seventy gravity stations were measured and data processed into the Complete Bouguer anomaly (CBA) with a traditional formula with normal gravity field correction, elevation correction and Bouguer plate reduction for density of 2.50 g/cm3. Terrain corrections were computed to the distance of 167 km from each point. Terrain model included both onshore and offshore topography. The gravity map has to be enlarged during next campaigns so that the tectonic pattern of this part of Thira can be updated.
- Similar gravity monitoring is performed by Author in Kos- Nisyros caldera, to be presented next time.

Acknowledgements

The author appreciates the financial support of the EPOS/CzechGeo project No. LM2015089. As well, Author thanks E.Lagios for introducing the existing stations in 2013 and V.Sakkas for performing random GNSS campaigns in Santorini and providing info on vertical movement trend from the permanent GNSS station SANT.

Ostracod-based environmental reconstruction of Lake Koronia, (Central Greece) during the Holocene

Navrozidou, V.[1,5], Koukousioura, O.[1,2], Doani, S.[1], Frenzel, P.[3], Triantaphyllou, M.[4], Albanakis, K.[1], Syrides, G.[1]

(1) Aristotle University of Thessaloniki, Thessaloniki, Greece, vnavrozi@geo.auth.gr (2) University of Cologne, Cologne, Germany (3) Institute of Earth Sciences, Friedrich-Schiller-Universität Jena, Jena, Germany (4) National and Kapodistrian University of Athens, Athens, Greece (5) The Goulandris Natural History Museum – Greek Biotope/Wetland Centre Thermi, Greece

Introduction

Lake Koronia is located in the western lowland area of the Mygdonia Basin, northeast of the city of Thessaloniki in northern Greece (40° 41′ N, 23° 09′ E, 75 m a.s.l.). It is the remnant of a once larger lake in the region (Psilovikos, 1977), but is now a shallow, hypertrophic and heavily polluted water body (Moustaka-Gouni *et al.*, 2012). It has experienced substantial degradation over time due to human activities, but has also dried up several times in the past two decades (2002, 2007, 2009 and 2014), resulting in its current state, formerly the fourth largest lake in Greece (Demertzioglou *et al.*, 2022). Despite its current ecological challenges, Lake Koronia is recognized as a protected wetland under international and national legislation, highlighting its importance (Malamataris *et al.*, 2017).

The aim of the present study was to investigate the paleoenvironmental evolution of Lake Koronia and the distribution of ostracod assemblages through time using a combination of core and recent surface sediment samples.

Methods

The KOR core (40°41'45.4" N, 23°11'08.8"E; Fig. 1) was drilled at 71 m b.s.l. and reached a depth of 368 cm. A total of 36 sediment samples were studied in order to reconstruct the paleoenvironmental evolution of the lake. In addition, two sediment samples were collected by boat, using an Ekman grabber from the upper 1 cm of the lake bottom for the analysis of the recent ostracod fauna. For ostracod analysis, 50 ml of each surface bottom sediment sample was wet sieved with tap water through a 125 μm pore size standard sieve. For core samples, 10 g of dried sediment was treated with hydrogen peroxide (H_2O_2) and wet sieved as described above. The residue was oven dried at 60°C and all ostracod valves over the >125 μm fraction were hand-picked under a Zeiss Stemi 305 binocular stereoscope. Species were identified, counted, and stored in microslides. Taxonomic identification of the species was based on the morphological features of the carapace using several published works, ostracod atlases and ostracod databases. In addition, radiocarbon dating was performed using accelerator mass spectrometry (AMS ^{14}C; Beta Analytic USA laboratory). Finally, a Q-mode cluster analysis was performed for the sediment samples of the core.

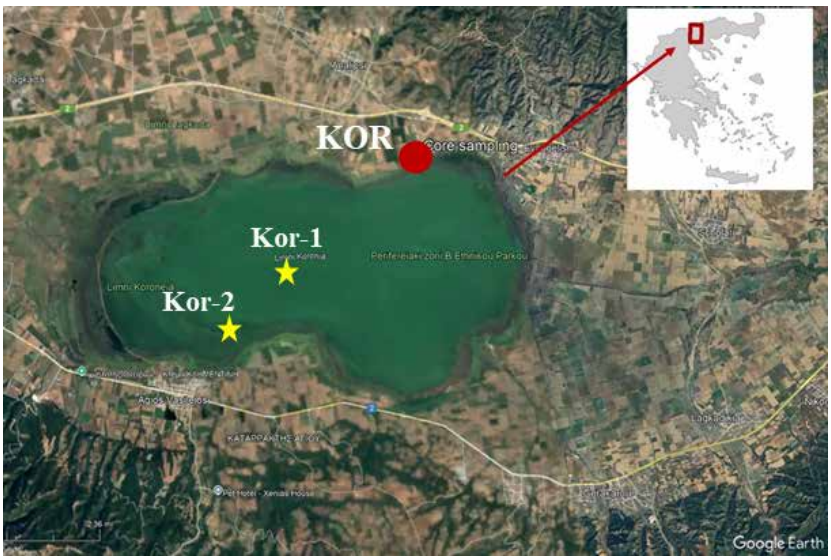

Figure 1. Sampling stations of surface sediments and the location of KOR core in Lake Koronia (modified from Google Earth).

Results and conclusions

The ostracod assemblage of Lake Koronia, both in the surface sediments and in the KOR sedimentary sequence, consisted of five taxa: ex gr. *Candona* juveniles, *Cyprideis torosa*, *Darwinula stevensoni*, *Heterocypris salina* and *Limnocythere inopinata*. In the recent surface sediments, station Kor-1 had a significantly higher abundance compared to station Kor-2. The *Candona* species dominated the assemblage, while *L. inopinata* was the second most abundant species of the total ostracod fauna recorded in the lake, with all other taxa showing relatively low abundances.

The ostracod valves obtained from the core (KOR) were well preserved and relatively abundant, with the number of valves/g reaching high values in some intervals, while the diversity indices showed relatively low values. The species *L. inopinata* dominated the assemblages, reaching even 100% in several intervals, followed by ex gr. *Candona* juveniles and *H. salina*. The species *D. stevensoni* and *C. torosa* accompanied the assemblage with lower but significant values.

The resulting dendrogram of the Q-mode cluster analysis performed on the KOR core sedimentary sequence, pointed out three distinct groups of samples associated with different assemblages and thus different paleoenvironmental conditions. The paleoenvironmental record of Lake Koronia revealed conditions of slightly elevated salinity between 2752-1437 cal. yr BP, occurring in a shallow environment with clear water and the absence of benthic macrophytes. The presence of *Cyprideis torosa*, a true brackish species (Meisch, 2000), further confirmed the elevated salinity during this period. After 1437 cal. yr BP, the fauna diverged significantly, and the environment transitioned to a purely lacustrine system, extremely shallow and with extensive macrophyte vegetation. At the top of the sedimentary sequence, the environment undergoes a further change, characterized by a significant increase in diversity, a deepening of the environment, and the establishment of well-oxygenated water conditions. This interval is comparable with the recent surface sediments in terms of faunal composition and diversity, but not in terms of abundance which was significantly higher at the recent stations.

Lake Koronia is a severely impacted lake that has faced significant degradation over the past few decades. Over the last 20 years, the lake has experienced a dramatic decrease in volume, surface area, and maximum depth (currently almost 2 meters) due to unsustainable water resource management. Further investigation of the benthic conditions and biota, coupled with the paleoenvironmental record of the lake, will be invaluable in this important biotope ecological assessment.

Acknowledgements

Sampling support for the recent sediment samples was provided by the Greek Biotope Wetland Centre.

EXTENDED ABSTRACT 226

Rapid Detection of Landslides Triggered by Mediterranean Cyclones Using Google Earth Engine and Open-Access Data

Nefros C.[1], Kitsara G.[2], Loupasakis C.[1], Giannakopoulos C.

(1) Laboratory of Engineering Geology and Hydrogeology, School of Mining and Metallurgical Engineering, National Technical University of Athens, Athens, Greece, email: kostasnefros@central.ntua.gr

(2) Institute for Environmental Research and Sustainable Development, National Observatory of Athens, Athens, Greece

This research introduces a methodological framework integrating Google Earth Engine and open-access data, to rapidly detect landslides triggered by Mediterranean Cyclones, which nowadays pose an increasing threat for the eastern Mediterranean region. This framework aims to enhance the timely identification and management of these hazards.

Introduction / Background

Medicanes or Mediterranean Cyclones are extreme meteorological phenomena, characterized by intense rainfall and winds speeds approaching hurricane strength (Lagouvardos et al., 1999). Their intensity and duration are expected to increase, along with a spatial shift toward the Ionian Sea and the eastern coasts of southern Italy (González□Alemán et al., 2019). Beyond causing floods and coastal waves, medicanes can trigger a series of landslide events within a short timeframe. These landslides often affect extensive areas and have impacts on various sectors (social, economic, transportation), making their management challenging for local authorities. This study introduces a methodological framework that integrates open access data, including Sentinel-2 and Google Earth imagery, combined with the computational power of Google Earth Engine (GEE), for the rapid identification and mapping of landslides activated by medicanes. The frequent revisit times of Sentinel-2 satellites over Europe and the high processing capabilities of GEE make this framework a valuable tool for the timely mapping of landslides. By enabling authorities to quickly assess the extent of landslide activity, following a medicane, the framework facilitates more effective management. The Ianos medicane, which struck the Cephalonia Island, Greece, in September 2020, was selected as a case study. Using the proposed approach, the activated landslides were identified and mapped. Moreover, the framework proved particularly effective in detecting landslides in remote, mountainous regions, underscoring its potential in difficult to reach areas.

Methods

The proposed framework is illustrated in Figure 1 and it leads to the creation of a comprehensive landslide inventory after a medicane, by using remote sensing techniques and open access data. The data used in the proposed methodology is derived exclusively from open-access or publicly available databases.

Case Study – Ianos Medicane

A medicane named Ianos by the National Observatory of Athens (NOA), struck Greece between 17 to 19 September 2020, severely impacting areas such as Cephalonia Island, Karditsa, and Fthiotida (Lekkas et al., 2020; Zekkos et al., 2020). According to Lagouvardos et al. (2022), the daily accumulated rainfall at the “Antipata” meteorological station in northern Cephalonia reached 644.7mm, which is the highest ever recorded value during a medicane and among the highest ever recorded in Greece. This extreme precipitation significantly exceeded the local precipitation thresholds for landslide activation across the Cephalonia Island, triggering widespread landslides. These landslides caused numerous damages to buildings, bridges, the local road network and other critical infrastructure. The large number of the activated landslides, combined with their extensive distribution, including remote and mountainous areas, posed significant challenges for local authorities in promptly documenting and mapping these events for their effective management. Cephalonia Island, situated in the Ionian Sea, in the west Greece, is characterized by steep terrain, limestone-dominated geology prone to karstification, and a dynamic hydrological network. These features, along with its history of frequent landslide activity, render Cephalonia particularly susceptible to landslides during heavy rainfall events. For these reasons, the island of Cephalonia was selected as a case study to examine the landslides activated by Ianos, highlighting the potential of the proposed framework.

Figure 1. Proposed Framework

Results and Discussion

As illustrated in Figure 2, by using the GEE, the Cephalonia Island was established as the Area of Interest (AoI) along with the time period before and after Ianos medicane. Sentinel-2 images were downloaded for the AoI.

Figure 2. GEE Environment

Cloud cover was mitigated in the Sentinel-2 images using the QA60 band. Specifically, bit 10 (value 1), was used to detect opaque clouds, while bit 11 (value 1) identified cirrus clouds, ensuring clearer imagery for analysis. The Normalized Difference Vegetation Index (NDVI) was then calculated for pre and post Ianos conditions, using the following equation:

$$NDVI = \frac{NIR-R}{NIR+R} \quad (1)$$

where the R factor corresponds to the red band, and NIR the near infrared band of the electromagnetic spectrum. NDVI values range between -1 and 1, reflecting vegetation health and coverage. Slope information was assessed using the Shuttle Radar Topography Mission (SRTM) Digital Elevation Model (DEM) provided by the of the United States Geological Survey (USGS). The SRTM DEM is version GL1, obtained from OpenTopography (portal.opentopography.org). This version provides a 30-meter resolution, ensuring reliable topographic representation. Potential landslide areas were identified based on two criteria: NDVI differences greater than 0.2 between pre and post Ianos, and slope angles exceeding 15°.

Subsequently, CHIRPS (Climate Hazards Group InfraRed Precipitation with Station data) precipitation data provided by the University of California, Santa Barbara (UCSB), were integrated into GEE to estimate the local/regional precipitation values that activated the landslides. CHIRPS were used to generate a raster file representing rainfall distribution over the AOI on the date medicane Ianos impacted Cephalonia. This dataset enables the spatial correlation of each detected landslide with the precipitation values, responsible for its activation. Thus, it facilitates the creation of a comprehensive landslide inventory, which

can be further used during the assessment of the local precipitation Intensity Duration (ID) thresholds.
Figure 3, illustrates the areas identified as potential landslides using the proposed framework, focusing on the Myrtos Beach area in north-western Cephalonia.

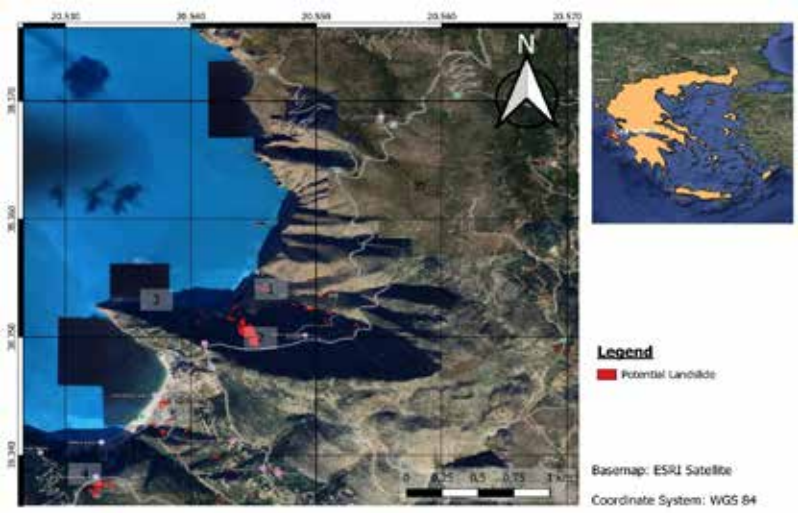

Figure 3. Potential Landslides according to GEE

Verification of these areas was conducted using high-resolution Google Earth imagery, as shown in Figure 4.

(a) (b)

Figure 4. Validation of the landslides using Google Earth Images before Ianos (a) (14-5-20) (Google Earth a) and after Ianos (b) (26-6-2021) (Google Earth b).
Results verification was also achieved using open-access landslide inventories derived from in situ investigations carried out after Medicane Ianos (Lekkas et al., 2020; Zekkos et al., 2020). These independent datasets provide ground-truth validation, supporting the accuracy and reliability of the detected landslides.
As it was revealed, the framework did not provide sufficient results in areas with sparse or absent vegetation, due to its reliance on NDVI changes. To address this issue, the landslide inventory was enriched with additional open access data and advanced remote sensing techniques, such as Persistent Scatterers Interferometry (PSI) processed using SNAP software provided by ESA. Specifically, PSI derived ground displacement velocities were analyzed, and a threshold of -2 mm/year was applied to identify areas exhibiting significant motion, improving landslide detection in non- vegetation regions.
The proposed framework introduces an efficient and rapid methodology for landslide detection by integrating GEE. Nevertheless, it has limitations, particularly in areas with sparse or absent vegetation, as it relies primarily on two criteria: slope angle and NDVI change. In the current study, this limitation was mitigated by incorporating supplementary open -access data and additional remote sensing techniques. However, future studies could address this issue further by enriching the GEE code with additional criteria, improving the framework's performance in diverse landscapes and enhancing its applicability. The final landslide inventory containing more than 600 landslides, is presented in Figure 5

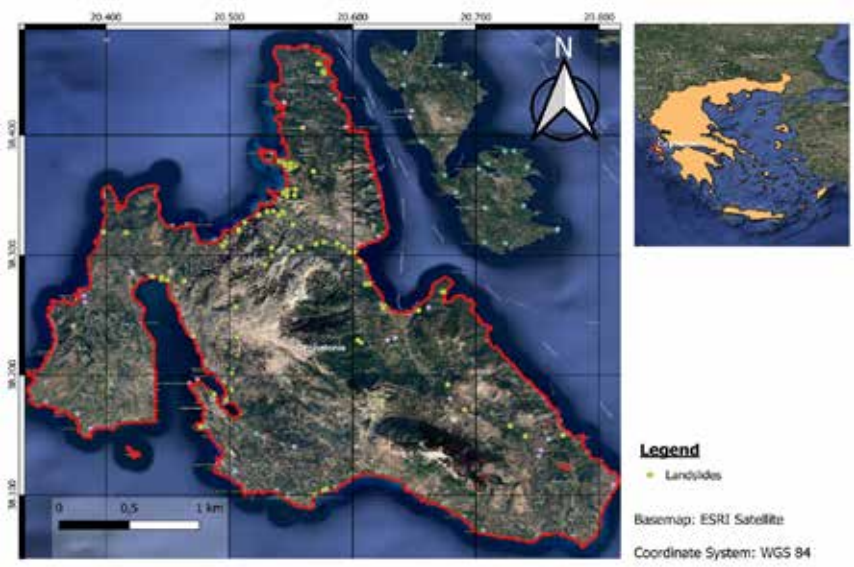

Figure 5. Landslide Inventory Map

These findings confirm the high intensity of the Ianos medicane and provide insight into the exceptionally large number of landslides it triggered. As illustrated in Figure 5, the activated landslides are distributed widely across the island. This widespread impact underscores the challenge of relying solely on in situ investigations for their identification and mapping, which require significant resources, time, and effort, particularly in remote and difficult to access areas.

The proposed framework, integrating open-access data and the computational power of Google Earth Engine (GEE), emerged as an effective, low-cost solution to tackle these challenges. By automating and accelerating the identification and mapping process, this framework minimizes the reliance on extensive field surveys while maintaining accuracy and spatial coverage.

Furthermore, this study highlights the potential of GEE, as a fundamental component of the proposed framework, demonstrating its ability to rapidly process and analyze large volumes of geospatial data. This capability is critical for the prompt identification and mapping of landslides, enabling authorities to respond more effectively. By facilitating timely decision-making and resource allocation, the framework contributes to the broader goal of efficient disaster management and mitigation, even to such extreme events, as the medicanes.

Conclusions

Medicanes are extreme phenomena that, due to climate change, pose nowadays a significant threat to regional or/and local communities in the Mediterranean region. Their destructive impact, including landslides activation, underscores the urgent need for effective disaster management strategies. This study not only highlights the severity of this threat but also introduces a practical solution through the proposed framework.

By leveraging the computational capabilities of GEE and open-access data, the framework offers a cost-effective solution that can assist authorities in promptly identifying regions most vulnerable to landslides. This enables them to implement promptly the necessary mitigation and civil protection measures and apply the necessary recovery measures.

Nisyros Geopark, located in the Southeastern Aegean, is a candidate for inclusion in the UNESCO Global Geoparks Network, recognized for its exceptional volcanic heritage and its integration of geological, natural, and cultural elements. Covering 481 km², the geopark is centered on the active Nisyros volcano and nearby islands, forming a dynamic landscape shaped by the South Aegean Volcanic Arc. Among its 24 geosites are active hydrothermal craters, a collapse caldera, volcanic domes, and numerous coastal hot springs, all of which serve as key focal points for educational activities.

Education is a cornerstone of the Geopark's mission, with a range of ongoing programs designed to share its unique geological story with diverse audiences. Workshops, guided tours, summer schools and educational programs are regularly organized to connect participants—ranging from local students to international visitors—with the island's volcanic and cultural history (Fig. 1,2). These activities have yielded significant outcomes, including increased local awareness of geohazards, active participation from hundreds of students annually, and strengthened collaboration with academic institutions. Evaluations indicate that participants develop a deeper understanding of volcanic processes and their environmental implications, contributing to a broader appreciation of geoconservation. These activities aim to foster an understanding of the dynamic processes that shaped the island and their relevance to contemporary environmental issues.

Figure 1. CIVIS Summer School "NATRISKS", May 2024
"Vulnerability of the Eastern Mediterranean: Natural Processes and Climate Risks "

Modern communication tools further enhance the educational experience. The Geopark's official website (www.nisyrosgeopark.gr), along with dedicated mobile applications, provides accessible and engaging resources, enabling visitors to explore the region's geoheritage independently or as part of structured activities. Partnerships with schools, universities, and cultural institutions ensure that educational outreach is deeply integrated into the community, encouraging active participation and fostering a long-term appreciation of the island's natural and cultural heritage.

By combining hands-on experiences, innovative communication techniques, and collaborations with educational organizations, Nisyros Geopark is establishing itself as a hub for learning and discovery. These efforts position the Geopark as a model for integrating education with the preservation and celebration of volcanic heritage, ensuring its significance is understood and valued by future generations.

Acknowledgements
We sincerely thank the management body of Nisyros Geopark (DIKEN) and the Mayor of Nisyros, Mr. Koroneos Christofis, for their invaluable contributions and steadfast support. Their dedication has been pivotal in fostering sustainable development, preserving the region's unique geological and cultural heritage, and enriching its educational activities. These efforts have greatly enhanced the geopark's role as a center for learning and exploration, while also advancing its candidacy as a UNESCO Global Geopark.

Introduction

On March 29, 2024, a M_L 5.9 earthquake occurred offshore western Peloponesse, near the Strofades Islands in Western Greece. The region lies within the complex tectonic setting of the western segment of the Hellenic Subduction System (HSS), where the African plate is being subducted beneath the Aegean microplate with rates of 30-35 mm/yr (e.g., Chousianitis et al., 2015). The seismotectonic setting is controlled by the active subduction and the Kefalonia Transform Fault, which hosts the lateral transition from subduction to collision between Eurasian and Apulian plates. The mainshock was preceded by a M_L 4.1 foreshock and followed by an aftershock sequence consisting of hundreds of events that continued until June. The sequence occurred at depths ranging from 25 to 35 km, with the mainshock located at 33 km depth within the subducting slab.

The seismic sequence occurred in a region with limited station coverage, particularly offshore, where the azimuthal gap exceeds 180°. Onshore station coverage in western Peloponnese is adequate, but offshore seismic monitoring is significantly constrained. However, the mainshock and its aftershock sequence were well-recorded by the newly installed Pelops network (Harrington et al., 2023), consisting of eight broadband stations deployed by Ruhr University of Bochum in collaboration with the University of Patras and the Institute of Geodynamics of the National Observatory of Athens (NOA).

Using high-resolution seismic data from the Pelops, HUSN and Adria Array networks, we apply machine learning techniques to develop an enhanced catalog. We analyze the sequence through earthquake relocation, focal mechanism solutions, and stress tensor analysis, aiming to provide new insights into the seismic activity and fault dynamics in the western segment of the Hellenic Subduction System.

Data & Methods

To investigate the M_L 5.9 seismic sequence, we analyze the seismicity recorded across the broader region following the deployment of the Pelops network in December 2023. Seismic data include waveforms recorded from December 2023 to September 2024 by the Hellenic Unified Seismological Network (HUSN), Pelops, and Adria Array networks. Using machine learning techniques, we construct a joint catalog, by applying the PhaseNet picker (Zhu and Beroza, 2019) for automatic phase-arrival picking and the PyOcto associator (Münchmeyer, 2024) for correlating phase picks with corresponding events.

We obtain earthquake locations using NLLoc (Lomax et al., 2000) and achieve high-quality hypocentral solutions by applying Source-Specific Station Terms (SSST) travel-time corrections and a coherency analysis of earthquake waveforms (Lomax & Savvaidis, 2022). We use the 1D Vp velocity model of Sachpazi et al. (2020) that we edit by replacing the first two layers with those from the velocity model of Kassaras et al. (2014). We assume a Vp/Vs ratio of 1.81, derived from events in our catalog that have at least 10 reliable Vp/Vs pairs.

We further investigate the sequence by obtaining moment tensors for five events, consisting of the foreshock, mainshock and three larger aftershocks, through full-waveform inversion using the ISOLA code (Sokos & Zahradnik, 2008). We analyze 20 additional aftershocks of lower magnitudes and determine their focal mechanism solutions from first-motion polarity data using the FPFIT program (Reasenberg & Oppenheimer, 1985). Finally, we conduct stress tensor analysis with the StressInverse code (Vavryčuk, 2014) using moment tensor-solutions and well-constrained focal mechanisms.

Results & Discussion

The M 5.9 March 2024 Strofades earthquake ruptured a NE-SW left-lateral strike-slip fault. The distribution of relocated aftershocks aligns with the NE-SW strike inferred from the focal mechanism solution of the mainshock and delineates a structure approximately 10-12 km in length and 6-8 km in width (Figure 1). The foreshock and the mainshock occurred at 30 and 33km depth, respectively, while aftershocks were distributed between 25 to 35 km (Figures 1,3).

The top of the subducting slab in the region is estimated to lie at approximately 20 km depth (Makris & Papoulia 2014, Sachpazi et al. 2016, Bocchini et al. 2018), suggesting that the rupture occurred within the subducting slab.
Focal mechanism solutions derived from moment tensor inversion and first-motion polarities, predominantly indicate strike-slip and normal faulting (Figure 2). The moment tensor solutions of the foreshock, mainshock and largest aftershocks suggest NE-SW strike-slip faulting, with the exception of one event, which exhibits normal faulting with a significant strike-slip component (Figure 2). Focal mechanisms derived from first-motion polarities are compatible with the kinematics of the mainshock (Figure 2, inset).
The geometry of the ruptured area is well-constrained in the two cross-sections, which were constructed parallel and perpendicular to the strike of the aftershock sequence, in SW-NE and NW-SE directions, respectively (Figure 3). The spatial distribution of the sequence is evident in the A-A´ profile, showing the width and length of the ruptured area. The B-B´ cross-section reveals a well-constrained vertical structure, with hypocenters aligned with the dip inferred from the focal mechanisms (Figure 3). Stress tensor analysis indicates a σ_3 axis oriented in an E-W direction, σ_1 oriented horizontally in a N-S direction and a vertically oriented σ_2 (Figure 2). P- and T-axes azimuths are consistent with the inferred stress axes within the subducting plate (Shaw & Jackson, 2010).
The mainshock and its aftershock sequence are not related to any mapped faults at the surface, as their location, geometry and kinematics do not align with the observed spatial distribution of the sequnce (Figure 1). The rupture occurred within the subducting slab, with no evidence of slip along any mapped offshore structures, as further indicated by the cross-sections (Figure 3).
After the mainshock, a sequence consisting of numerous events was recorded onshore in the eastern part of the study area (Figure 1). Future work will assess any potential connection to the Strofades seismic sequence.

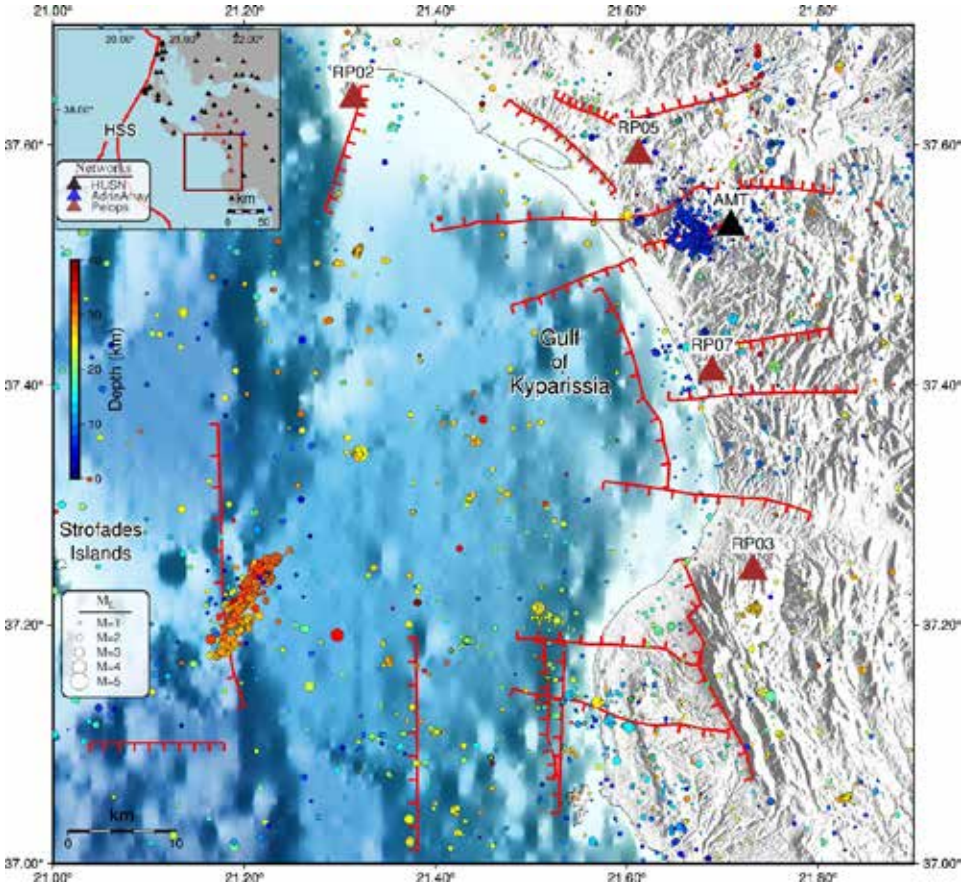

Figure 1. Seismicity map of the broader Gulf of Kyparissia region, showing relocated earthquakes of the M 5.9 earthquake sequence and regional seismicity recorded between December 2023 and September 2024. Earthquakes are depicted as circles, scaled by magnitude and color-coded by depth. Triangles denote the seismic stations operating within the study area. The inset map shows the location of the study area, station coverage across western Greece, and the Hellenic Subduction System (HSS), the main seismotectonic feature of the region. Mapped active faults (in red colour) from Ganas (2024).

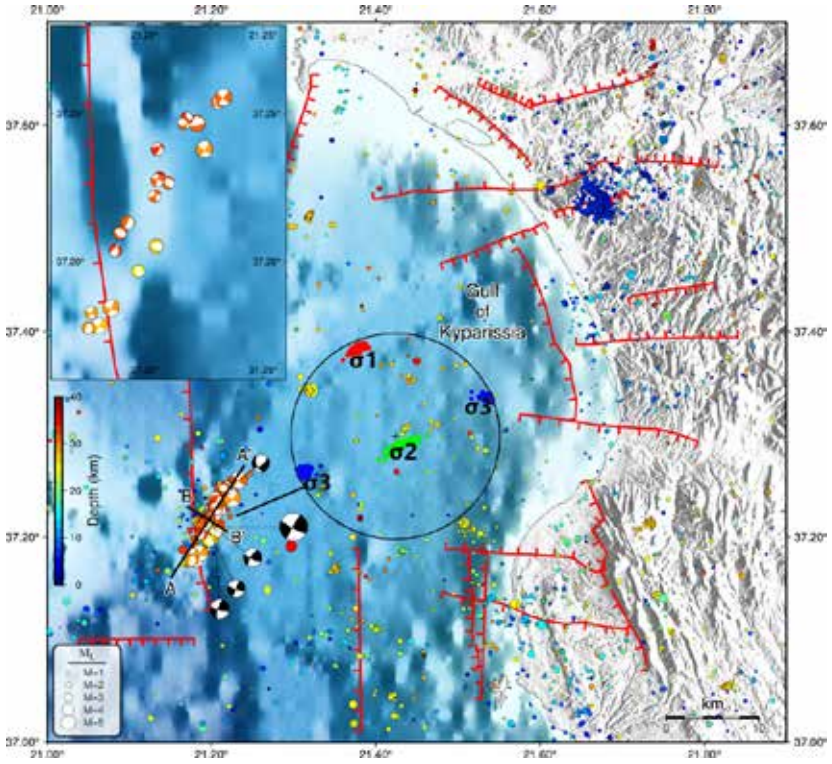

Figure 2. Focal mechanisms of the foreshock, mainshock and 23 major aftershocks of the Strofades sequence, polarity-based solutions are color-coded by depth, centroid moment tensors are the black beachballs, black lines connect the beachball with the centroid location. The location of the A-A´ cross-section and its perpendicular B-B´ cross-section is also shown. A zoomed-in view of the focal mechanisms of the aftershocks in the inset. Principal stress axes (σ1, σ2 and σ3) orientation is shown in the stereographic plot. Mapped active faults (in red colour) from Ganas (2024).

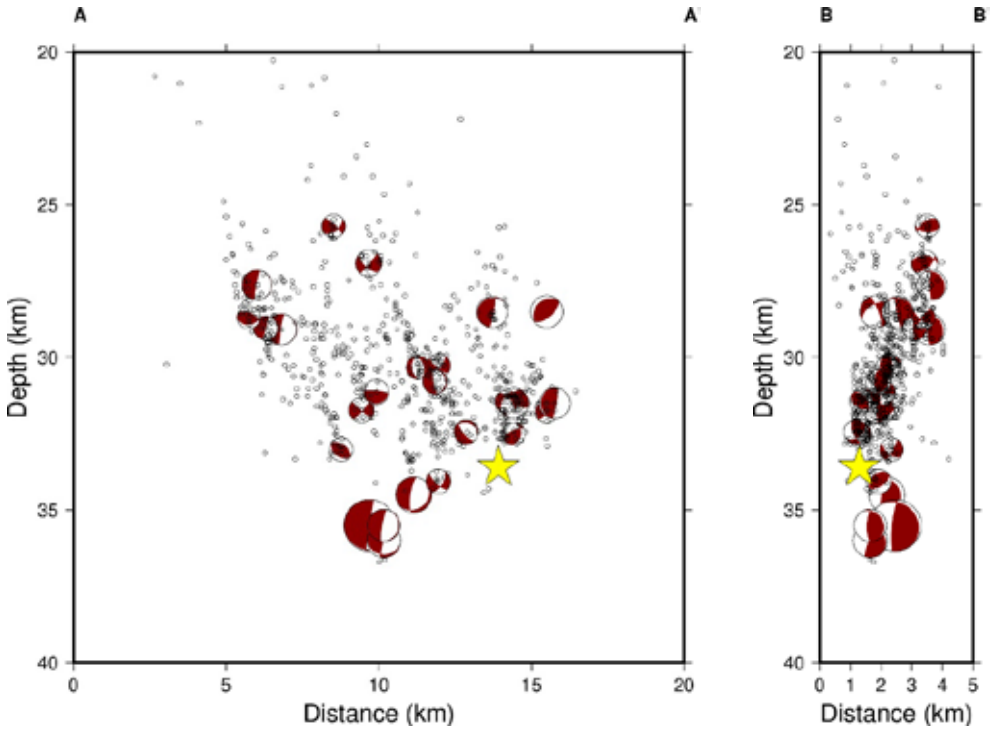

Figure 3. Distribution of the relocated hypocenters in A-A´ (along strike) and B-B´ (along dip) profiles. Beachballs are projected at the centroid location, yellow star denotes mainshock's hypocenter.

Sinkholes, roads and exceptional transports, a risk to be assessed

Stefania Nisio[1], Sergio Madonna[2], Giancarlo Ciotoli[3], Francesco Gentili[2], Livio Ruggiero[3]

Introduction / Background

The Italian territory, characterised by its complex geological and geomorphological features, faces a unique combination of natural hazards, including volcanic activity, landslides, floods, sinkholes and seismic events.
These hazards, which affect nearly the entire country, pose significant challenges to the safety and resilience of transportation networks. Among these geohazards, natural and anthropogenic sinkholes represent a particularly insidious threat due to their sudden and unpredictable nature, often resulting in severe disruptions to road infrastructure.
This danger is further exacerbated by exceptional transports (ETs)—vehicles carrying oversized or heavy loads—which require stable and robust roadways to ensure operational safety.
Italy's urban centres' historical and archaeological richness introduces an additional layer of complexity. Many Italian cities, with their millennia-old history, rest on a network of underground cavities, often remnants of ancient quarries, tunnels, and cisterns. These subterranean voids, many of which remain undocumented, frequently intersect the modern road network, creating hidden vulnerabilities. In historical centres where traffic is already constrained, the passage
A critical dimension of this issue lies in Italy's current nuclear waste management challenges. The absence of a national repository for radioactive waste has necessitated the storage of such materials in numerous temporary facilities scattered across the country, many of which are considered suboptimal in terms of security and stability. Once a national repository is identified, extraordinary transport will play a central role in transferring these hazardous materials to a single site.
The combination of geohazards, infrastructure vulnerabilities, and the logistical demands of nuclear waste transport underscores the critical need for comprehensive risk assessment and mitigation strategies
Comprehending the relationship between sinkhole formation and the transportation of heavy loads is essential, as incidents can increase the risk of human life loss, environmental pollution problems, and significant economic and infrastructure damage.

Objectives

This study aims to raise awareness among public administrations, as well as public and private entities about the significant hazards posed by natural or anthropogenic sinkholes, particularly in the context of exceptional transport planning. The goal is to ensure that this geohazard is systematically accounted for in decision-making processes to mitigate potential safety threats and infrastructure damage.
The issue is especially critical in the historical centers of Italy's art cities, where intricate networks of underground cavities create hidden vulnerabilities that can be exacerbated by exceptional transports or by the placement of heavy temporary structures. The concentrated stress from such activities can trigger or accelerate sinkhole formation, posing a serious threat not only to the stability of the ground but also to the preservation of invaluable cultural and architectural heritage.
Beyond urban areas, this problem is equally relevant in sparsely populated rural and extra-urban regions. Here, the planning of exceptional transports—particularly those involving extremely heavy or high-risk cargo, such as nuclear waste. By highlighting these risks, this study seeks to provide a comprehensive framework for integrating sinkhole hazard assessments into the planning and execution of exceptional transports. This includes developing guidelines for evaluating subsurface stability, strengthening coordination between public and private stakeholders, and implementing preventive measures to enhance the resilience of both urban and rural infrastructures.
By emphasising the importance of continuously updating datasets and integrating diverse geospatial layers, this study seeks to establish a best-practice model for sinkhole risk assessment and mitigation, facilitating safer and more informed decision-making for exceptional transport and infrastructure planning.

Methods

The foundation of this study is the recently updated database of sinkholes and underground cavities developed as part of the PNRR Geosciences IR Project (figure 1A, B). This comprehensive dataset provides a crucial resource for understanding the spatial distribution of sinkholes across Italy and their potential impact on infrastructure. By leveraging Geographic Information System (GIS) technologies, it is now possible to overlay the mapped distribution of currently catalogued sinkholes (point vector layer) with the layout of primary and secondary road networks (line vector layer). The distance from each sinkhole to the nearest road segment can be calculated using GIS tools, such as QGIS's "Distance to Nearest Hub," ArcGIS's "Near" tool,

or GRASS GIS's v. distance. Specific sections of roads can be classified into hazard categories according to their distance from sinkholes. To refine this assessment, additional geospatial layers, including structural elements (e.g., tectonic features), gas emission distributions, geological (e.g., karst terrains, soluble rock types, etc.) or hydrogeological data (e.g., groundwater flow, water table fluctuations, etc.), historical variations of hydrography, land use, etc. can be integrated to identify areas where environmental, geological or anthropogenic conditions may exacerbate sinkhole hazard along specific road segments. Finally, thematic maps are created to visualise risk zones; statistical analyses can identify high-risk clusters, and the results with field data or expert knowledge to ensure accuracy and local relevance. This approach provides a comprehensive framework for evaluating sinkhole hazards near road networks while allowing for site-specific adjustments based on additional data.
Thematic maps, like susceptibility maps, could be created to visualise the likelihood of sinkhole occurrence across large hazard zones. Still, the results must be validated with field data, analysis, and expert knowledge to ensure accuracy and local relevance. Particularly, the development of susceptibility maps for major urban areas offers invaluable tools for planning exceptional transport and positioning temporary heavy loads, such as those used for events or maintenance activities on buildings and infrastructure.

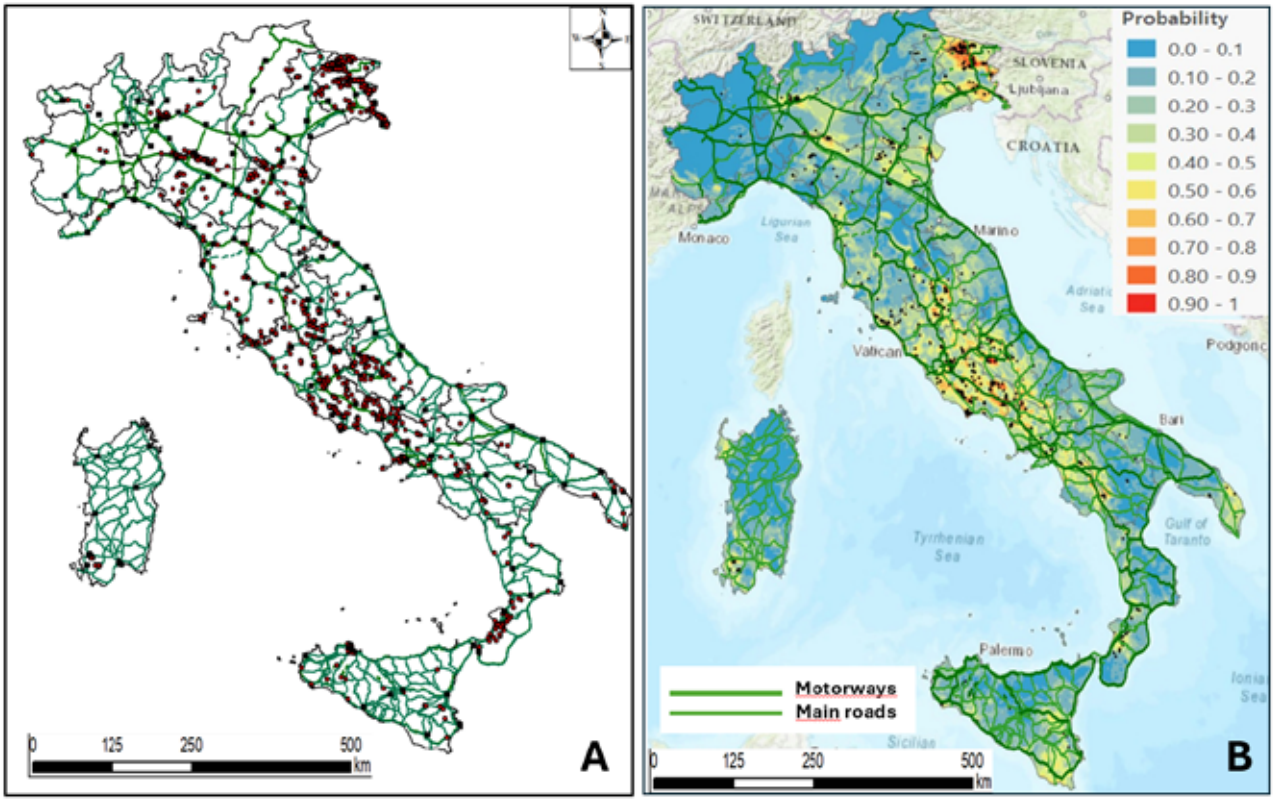

Fig. 1 - Main roads in Italy and: A) Natural sinkhole distribution B) susceptibility maps. From the GIS database PNNR-Geosciences-IR

The first phase of constructing an anthropogenic sinkhole susceptibility map involved constructing a conceptual model identifying potential predisposing factors for anthropogenic sinkholes in urban areas. All selected factors (independent variables), along with the sinkhole database (response variable), were entered into a geodatabase managed in a GIS environment in shapefile format (point, linear, and polygonal geometries) and/or raster format (grid). All grid layers (original and/or produced) were constructed with a resolution appropriate for the purpose of the study. The density analysis of event distribution is a fundamental and straightforward technique to determine the area most prone to a specific geographical phenomenon. The density model is based on the hypothesis that areas with a higher presence of events are more likely to experience additional occurrences. The density analysis was carried out using the "Kernel Density Estimation" (KDE) (Silverman, 1986). The KDE produces a density map representing the number of elements per unit area based on the neighbourhood distance around those elements. The neighbourhood distance is determined by the observed mean distance using the NNI. Density analysis can be calculated for both point and linear elements. Density maps provide preliminary zoning of the territory; a sinkhole density map constitutes an initial evaluation element of an area's susceptibility to this phenomenon.

Random forest regression, a supervised machine learning model that combines decision trees to make accurate predictions, was used to develop a sinkhole susceptibility map (figure.1B). Sinkhole presence, transformed into a binary variable (presence/absence), was used as target variable. Predisposing factors of various types were considered as predictors, organised into a national 10x10 km grid. These included geological variables (GEO, KA), geomorphological factors (DTM, TPI, HAND, Slope), hydrogeochemical indicators (DensGas, DistGasCat, DensSpring, DistSpringCat), seismic features (EQD) and structural parameters (FD). Both continuous and categorical variables were processed to capture detailed local environmental conditions. The supervised method split the data into training and test sets to ensure robust model evaluation and validation. With its ability to handle non-linear relationships and complex variable interactions, the Random Forest model was trained on these data to identify areas with higher susceptibility to sinkhole formation. In addition, the model provided insight into the key drivers of sinkhole susceptibility by providing a Receiver Operating Characteristic (ROC) curve to assess its predictive performance and quantify the importance of each variable.

Results and discussion

Sinkholes are large depressions that suddenly open in the ground catastrophically, with diameters and depths varying from a few to hundred of meters. They are divided into two main categories: natural sinkholes that mostly occur in plain areas and anthropogenic sinkholes affecting basically urban centres, particularly in large metropolitan areas. Natural sinkholes are related to the area's geological, structural, and hydrogeological context, while anthropogenic sinkholes are directly or indirectly related to human activities, particularly the presence of underground cavities.

In recent decades, many sinkholes have opened up in or near important road arteries in extra-urban (figure 2A, B) or urban (figure 2C, D) areas.

Fig. 2 - Examples of sinkholes affecting extra-urban and urban roads: A) provincial road near Ravenna; B) provincial road that crosses the Vepe-Latera caldera (Volsini Volcanic Complex - Latium); C) Viterbo - collapse of the vaults of underground environments under an urban road; D) Rome urban road Via Sestio Mensas.

The recent event that occurred inside the Latera-Vepe caldera (figure.2B) near (about 5m) from Provincial Road 118 leading to Lake Mezzano points out that even volcanic areas are not exempt from these phenomena, which are too often underestimated (Puzzilli et al., 2024). This case also shows that sinkholes are very easily filled with water almost simultaneously with their formation. It is common, after their formation, for groundwater or water rising from deep aquifers to flow into the cavity, turning it into a small lake, and this could lead to further complications in the sinkholes open in communication infrastructure.

The National Database of ISPRA is a fundamental tool for mitigating sinkhole hazards (Caramanna et al. 2008; Nisio et al.

2007; Nisio 2008). Among its various applications, we want to emphasise its usefulness in managing and planning exceptional transport and positioning temporary large loads. ISPRA's National Sinkhole Database was developed using ESRI's ArcGIS software with the WGS84/UTM Zone 33N reference system and has been updated to include further natural sinkhole inventory in the flat areas of Italy, plateau regions, and the transition zones between plains and slopes. The current census is up to date, with more than 6,000 sinkhole phenomena catalogued and classified according to the Italian case typology proposed by Nisio (2008) (Fig. 1A), creating a unique database in Italy.

More than 6000 cases of natural subsidence in plain or slope areas, attributed to natural sinkhole phenomena, have been catalogued and studied by ISPRA through field investigations and archival studies. Many of the catalogued phenomena are hypothesized to relate to the upward migration of aggressive fluids. The areas most susceptible to sinkholes are concentrated in the central Tyrrhenian slope, particularly in the regions of Friuli Venezia Giulia, Lazio, Puglia, Abruzzo, Campania, and Tuscany. Due to its geological-structural setting, the Adriatic side is not affected by these types of sinkholes, nor are the Alpine arc and the Dolomites.

The conditions are different in Northern Italy (where the census is still ongoing). Small diameter depressions with modest depth (known as "occhi pollini") are also widespread in the Po Valley and Lombard plains. The genetic mechanisms of these depressions, probably caused by surface suffusion phenomena, are currently being studied. In the plains and internal basins of Veneto, Friuli-Venezia Giulia (Calligaris 2019 a, b; 2020), Puglia, and Sicily, as well as the Autonomous Province of Bolzano, subsidence phenomena are closely controlled by the dissolution of evaporitic and carbonate lithotypes found beneath relatively thin covers, which are therefore attributable to cover-collapse sinkhole types.

On the other hand, the phenomena reported in Calabria are linked to small cavities, now filled in, whose location is difficult to pinpoint. These originated entirely during seismic events and are associated with liquefaction phenomena in the soils. The geological context appears substantially different in Sicily and Puglia, where subsidence cases are influenced by the presence of evaporitic (gypsum and salt) or calcareous soils and by thinner clayey or sandy covers.

Anthropogenic sinkholes typically occur in large metropolitan cities and are primarily associated with the presence of a complex network of underground cavities (figure 2C), many of which are still unknown. The cities most affected by this phenomenon are Rome, Naples, Cagliari, and Palermo (figure 3A), for which more detailed time series data is available (Ciotoli et al. 2013, 2015 a, b, c; Nisio et al. 2017; Tufano et al. 2022). Similarly, the regions with extensive outcrops of volcanic rocks, such as Lazio and Campania (figure 3B), are the most affected by anthropogenic sinkholes, given the millenary history of occupation and exploitation of its subsoil.

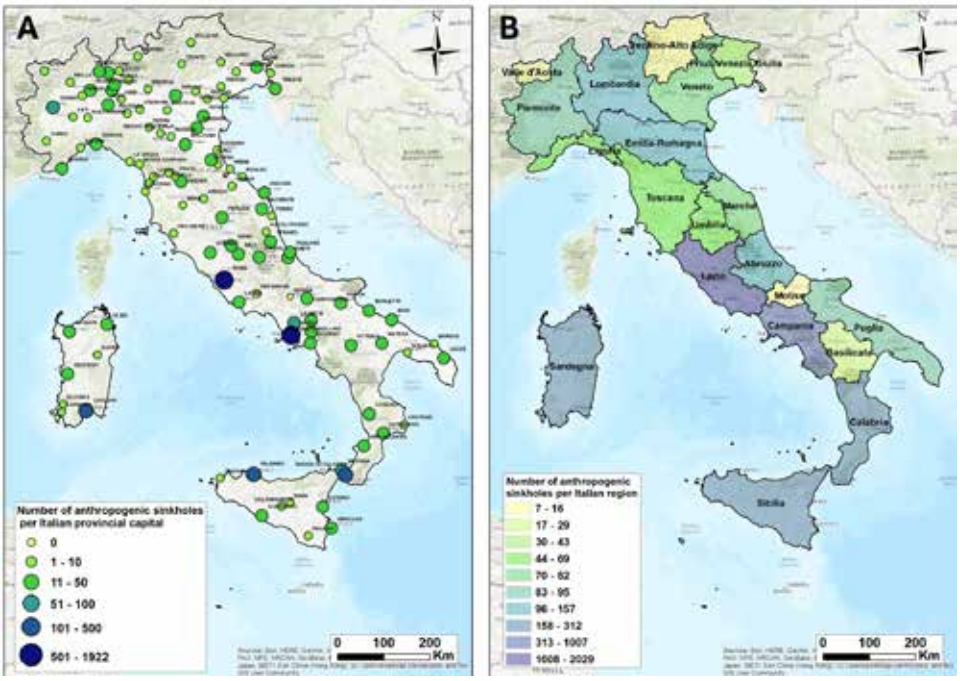

Figure 3-- - Number of anthropogenic sinkholes per Italian provincial capital A) and region B). From the database PNNR-Geosciences-IR.

These cavities have been created by human activity at various times over more than two thousand years. The presence of underground cavities can, under certain conditions, cause the more superficial soil layers to collapse, resulting

in sinkholes (anthropogenic sinkholes). An additional factor that contributes to the formation of such anthropogenic sinkholes is the malfunction, leakage and general dysfunction of the hydraulic network of the underground services. In the last forty years, the frequency of these phenomena has increased due to the denser and more indiscriminate urbanization of the area, and possibly also due to changes in rainfall patterns, which in recent years have led to very intense rainfall events and permanent flooding in certain areas of the city.

The application of the Random Forest Regression model provides a sinkhole susceptibility map, integrating predisposing factors such as geological, geomorphological, hydrogeochemical, and structural variables. The model achieved high predictive performance, as evidenced by the ROC curve with an AUC of 0.96 for the test data, indicating excellent discrimination between sinkhole-prone and non-prone areas. The variable importance analysis revealed that earthquake density (11.5%), gas emission density (11.4%), and karst areas (10%) were the most significant predictors, followed by fault density, mineral spring density, and slope.

The sinkhole susceptibility map (Fig. 1B) highlights areas of high probability, concentrated in karstic and faulted regions, as well as areas with high seismic activity or significant hydrogeochemical anomalies (Di Salvo et al.2024) The map provides valuable insights for land-use planning and risk mitigation, helping prioritise monitoring and intervention efforts in vulnerable areas. The updated sinkhole inventory, combined with this susceptibility analysis, represents a critical resource for understanding and managing sinkhole risks at a national scale.

The processes that create sinkholes are very complex and sometimes difficult to define, not solely attributed to gravity or karst dissolution but to a series of predisposing and triggering causes: liquefaction phenomena, the presence of cavities deep underground, easily erodible cover soils, tectonic features such as faults or fractures, CO_2 and H_2S upwelling, seismic events, heavy rainfall, and human activities like water extraction, mining, excavation, etc.

In urbanised areas, the most significant predisposing factor is generally related to the presence of pre-existing underground cavities, such as catacombs, hypogea, quarries, etc. The collapse or instability of these cavities can propagate to the surface, causing sudden collapses. Another critical element is associated with underground erosion processes caused by infiltration or exfiltration due to the deterioration of the sewer drainage system or underground water supply network. This progressive deterioration of underground cavities can lead to sudden collapses on the surface. Additionally, extreme meteorological events (prolonged or intense rainfall) can act as a triggering factor, especially in urban areas prone to flooding (Di Salvo et al., 2018).

In all these cases, however, the presence of heavy loads and vibrations caused by exceptional transports (ETs) can act as a significant triggering factor for sinkhole formation. These vibrations, combined with the concentrated weight of vehicles, can exacerbate the instability of subsurface voids or weakened geological structures, particularly in karst terrains or areas with soluble rock formations. Repeated mechanical stress from traffic can accelerate the collapse of cavities by dislodging loose sediment, compacting unconsolidated materials, or increasing subsurface pressure, leading to sudden subsidence. This effect is particularly pronounced in areas where groundwater flow or fluctuating water tables have weakened the subsurface, making it more susceptible to external forces. Such dynamics highlight the importance of monitoring high-traffic zones for sinkhole risks, especially in regions with vulnerable geological conditions.

Conclusion

In Italy, natural sinkholes predominantly affect extra-urban areas, while anthropogenic sinkholes are more prevalent in towns and cities. These phenomena pose significant dangers to road infrastructure, threatening public safety and causing substantial economic losses. Among the triggering factors for sinkholes, both natural and anthropogenic, are vibrations and overloads generated by human activities. Specifically, vibrations induced by heavy mechanical equipment used in construction or agriculture, as well as traffic from heavy vehicles, contribute to subsurface instability. Similarly, overloads from exceptional transports (ETs) or the temporary placement of very heavy loads create additional stress concentrations in the soil, further exacerbating pre-existing geological vulnerabilities.

These activities are particularly hazardous in areas prone to sinkhole formation, as they can destabilize subsurface structures and trigger collapses. In urban centres, most sinkholes occur on roadways due to the concentrated impact of traffic and infrastructure stress. In extra-urban areas, sinkholes are frequently found near major road infrastructures and railways, where the cumulative effects of vibrations and heavy loads are most pronounced. The hazard is heightened in regions with karst or pseudokarst formations, where underground cavities or soluble rock layers create a predisposition to collapse. Similarly, areas with unconsolidated soils or shallow water tables are at increased risk, as the additional stress from ETs can lead to soil liquefaction, suffusion, or piping phenomena. The impact of these overloads is not confined to natural sinkholes but extends to urban environments, where anthropogenic sinkholes are linked to underground cavities, failing hydraulic infrastructure or malfunctions of sub-service networks. Most Italian cities are built on a complex network of underground cavities, many of which are still unknown. In the last forty years,

the frequency of these phenomena has increased due to the denser and more indiscriminate urbanisation of the area and possibly also due to changes in rainfall patterns, which in recent years have led to very intense rainfall events and permanent flooding in certain areas of the city. Addressing these risks is essential to safeguard infrastructure, minimise hazards, and mitigate the socio-economic impacts associated with sinkhole formation.

The ISPRA dataset provides a crucial resource for understanding the spatial distribution of sinkholes across Italy and their potential impact on infrastructure. This has practical implications for improving the planning and management of exceptional transport and temporary heavy loads. The sinkhole susceptibility maps can guide decision-makers in prioritising monitoring efforts, implementing preventive measures, and mitigating risks associated with ETs and road infrastructure.

Integrating advanced modelling techniques, such as random forest regression, has proven essential for understanding and predicting natural sinkhole susceptibility. Through the combination of geological, geomorphological, hydrogeochemical and structural factors, the model provides a robust framework for assessing the likelihood of sinkhole formation across Italy. The model's high prediction performance (AUC of 0.96) demonstrates its reliability, while variable importance analysis identifies key drivers, including seismicity, gas emission densities and karst regions. These findings provide a better understanding of the sinkhole phenomenon and demonstrate the potential of machine learning to deal with complex geohazard scenarios.

Future work should focus on refining predictive models by incorporating time-series data, climate change projections, and emerging urbanisation trends. Enhancing these models will improve their reliability and applicability to complex geohazard scenarios. Ultimately, integrating advanced modelling techniques with historical and geospatial data provides a scalable and reproducible methodology for addressing sinkhole hazards.

Nisyros Geopark, a candidate for nomination as a UNESCO Global Geopark, is distinguished by its remarkable geological, natural, and cultural features. Situated in the Southeastern Aegean, it spans 481 km² and includes the active Nisyros volcano along with nearby islands (Fig. 1). Positioned at the southeastern edge of the South Aegean Volcanic Arc—one of the world's most significant active volcanic systems—the geopark offers a unique terrestrial and submarine landscape shaped by its volcanic origins. The geopark encompasses 24 geosites (Fig. 2), showcasing its rich geological history. Visitors can explore the impressive collapse caldera, hydrothermal craters and lava domes on the western side, stratified layers of lava, ash, and pyroclastics, which chronicle its extensive geological evolution (Parcharidis et al., 2018). Active hydrothermal craters and numerous coastal hot springs highlight ongoing hydrothermal activity, while the submarine aspects of the geopark are key to its formation and development. These features attract international scientific research, positioning Nisyros Geopark as a prominent natural geological laboratory in the Eastern Mediterranean. As part of the South Aegean Volcanic Arc, the geopark features a striking landscape shaped by five eruptive cycles over the past 160,000 years (Dietrich & Lagios, 2018). These cycles have left their mark on both the land and the seabed (Nomikou & Papanikolaou, 2011). The offshore region continues this volcanic landscape beneath the sea, hosting basins, underwater volcanic structures like craters and lava domes, fractures, and even a prehistoric caldera, Avyssos, located northeast of Strongyli islet (Tibaldi et al., 2008; Nomikou et al., 2021).

Figure 1. Nisyros Geopark location map

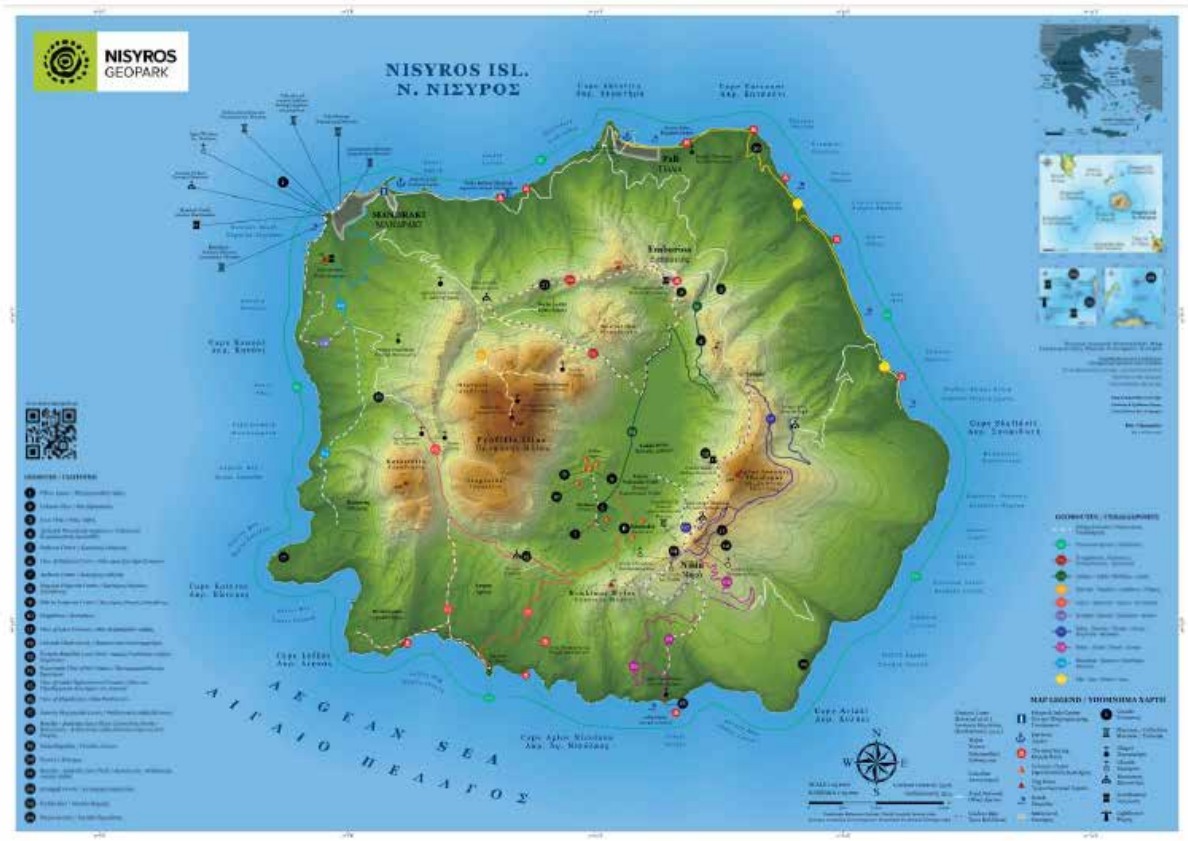

Figure 2. Nisyros Geopark geotouristic map

Beyond its geological wonders, the geopark is steeped in cultural heritage. Despite its modest size, the region has been continuously inhabited for millennia and is linked to the myth of Gigantomachy. The region's cultural heritage has stood steadfast through the ages, showcasing the brilliance of art and civilization through its prehistoric and historic sites and monuments. It is home to remarkable archaeological and cultural landmarks, including fortresses such as Paleokastro and the Mandraki castle, remnants of ancient settlements, numerous Byzantine-era churches and monasteries like the famous Panagia Spliani Monastery (Fig. 3), as well as thermal springs tied to its long-standing tradition of thermal baths. Together, these elements have shaped the region's history, fostering the traditions and preserving the tangible and intangible heritage cherished by its local communities today. Moreover, the Geopark features rich biodiversity protected by the two internationally designated Natura 2000 areas including its entire surface, as well as three wildlife refuge areas recognized at a national level. A great number of species of flora, avifauna and reptiles thrive within the geopark's area (Antoniou et al., 2019).

Figure 3. Panagia Spiliani Monastery (left) and ancient wall of Paleokastro (right)

To enhance visitor engagement and educational opportunities, Nisyros Geopark is upgrading its services. Current initiatives include the development of two free mobile applications, Nisyros Geopark App and Nisyros Volcano App, an informative website (www.nisyrosgeopark.gr) and a variety of educational materials. The geopark actively promotes awareness through talks, workshops, summer schools, and media campaigns, fostering an appreciation of its unique geological and cultural significance among residents and visitors alike.

Acknowledgements
We extend our heartfelt gratitude to the management body of Nisyros Geopark (DIKEN) and the Mayor of Nisyros, Mr. Koroneos Christofis, for their invaluable contribution, unwavering support, and dedication to the vision of the geopark. Their efforts have been instrumental in promoting the sustainable development of the region, preserving its unique geological and cultural heritage, and advancing its candidacy as a UNESCO Global Geopark.

EXTENDED ABSTRACT 231

Assessment of groundwater quality and seasonal dynamics in Chortiatis, northern Greece: Insights for sustainable resource management

Ntona Maria Margarita [1], Stavropoulou Vasiliki [2], Lampropoulou Dimitra [3], Zagana Eleni [2], Pouliaris Christos[2], Kazakis Nerantzis [2]

(1) Laboratory of Engineering Geology & Hydrogeology, Department of Geology, Aristotle University of Thessaloniki, 54124 Thessaloniki, Greece, margaritantona@yahoo.com (2) Laboratory of Hydrogeology, Department of Geology, University of Patras, Faculty of Natural Sciences, 26504 Rion, Patras, Greece, nkazakis@upatras.gr (3) Department of Chemistry, Aristotle University of Thessaloniki, 54124 Thessaloniki, Greece

Research Highlights:

- Groundwater samples are characterized by Ca-HCO□ water type.
- Seasonal groundwater level variations reveal various recharge patterns based on precipitation events.

Introduction / Background

Various geological formations and significant seasonal variability in precipitation influence complex hydrogeological environments (Luo *et al.*, 2023). In these cases, effective groundwater management requires a comprehensive understanding of both groundwater levels and quality parameters, especially under the pressures of the climate crisis (Davamani *et al.*, 2024). This study presents the results of field measurements as well as hydrochemical and statistical analysis to assess groundwater quality in the Chrotiatis region, Greece. By combining these methodologies, a comprehensive hydrogeological profile of the region is provided with valuable insights for future resource management. In this aspect, hydrochemical analyses of groundwater samples reveal potential sources of pollution, while groundwater level data provide insights into seasonal fluctuations and recharge patterns of the study area. Additionally, groundwater level measurements reveal temporal trends, including seasonal declines offering key insights into the dynamics of the region's water resources. The findings are expected to benefit water authorities and local stakeholders by offering reliable insights for sustainable groundwater management, protection strategies, and the mitigation of pollution risks.

Study area

The study area is located in northern Greece in the Central Macedonia region (Figure 1). The upper geological units in the area comprise alluvial deposits and red clays, while the Alpine formations, including clay schists, limestones, and igneous rocks, reflect significant tectonic and magmatic activity in the study area. The presence of quartzites and various igneous rocks, such as gabbros and peridotites indicates volcanic processes. These formations contribute to the area's aquifer systems and play a key role in water storage and water movement through the complex lithology. The presence of these diverse geological formations contributes to several types of aquifers in the area, namely alluvial, fractured, and karst aquifers. Based on the Copernicus database, the study area is occupied by transitional forested and shrubland (27.9%), agricultural activities with significant parts of natural vegetation (18.7%), and non-irrigated-arable land (15.7%). Mineral mining sites of limestones and mixed forests are also noted.

Methodology

The combination of qualitative and quantitative data can provide significant information about groundwater dynamics, the influence of local geological formations, and the potential sources of pollution in the aquifers (Kazakis *et al.*, 2015). In this study, monthly groundwater level measurements were obtained across the study area during the period of 2023-2024 to establish a hydrogeological framework using a judgmental sampling approach (Ntona *et al.*, 2023). Additionally, chemical analyses of sixteen (16) groundwater samples from deep boreholes were performed in June 2024 to assess the concentrations of major ions and trace elements, revealing mixing processes and ion exchange reactions in the study area. Piper and Durov diagrams are constructed in AquaChem software, while the maps were designed in ArcMap software. Precipitation data was obtained from the meteorological station Eptapurgio (meteo.gr), located near the study area. Raster file of digital elevation model (DEM) downloaded by NASA open data.

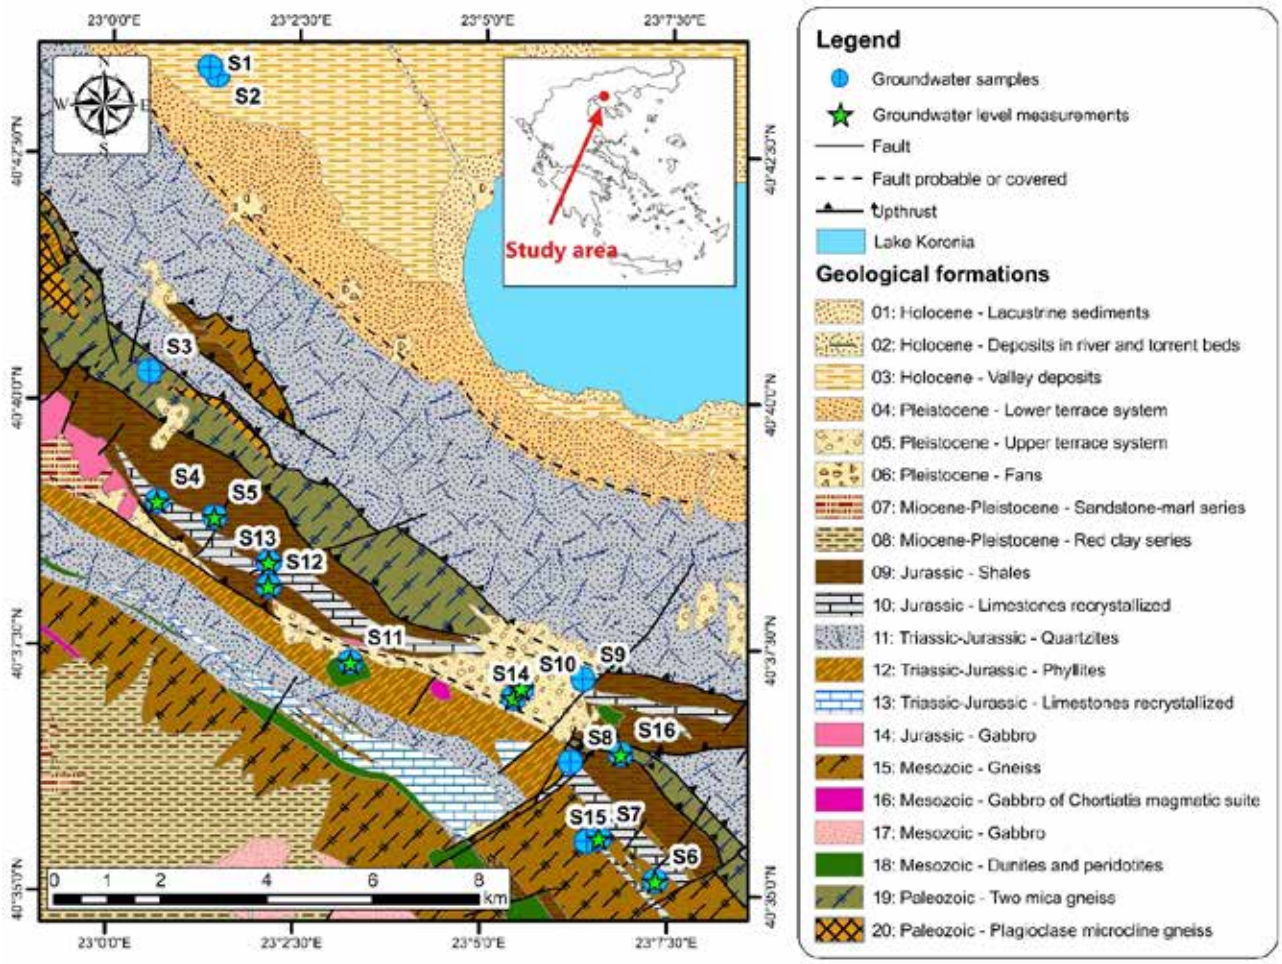

Figure 1. Geological map of the study area (HSGME with modifications, scale 1:50,000, sheets: Thessaloniki and Thermi).

Results and discussion

The chemical composition of all samples is shown in Table 1 and on Piper (Piper, 1944) and Durov (Durov, 1948) diagrams (Figure 2), which demonstrate the proportions between the major water components of the study area. The results of groundwater chemical analyses reflect both natural processes and some potential pollution sources. The pH levels range from 7.4 to 8.5, pointing to slightly alkaline conditions likely influenced by the local carbonate rocks. Electrical conductivity (EC) values vary from 525 to 1640 μS/cm with a mean value of 833 μS/cm (Figure 3a). High concentrations of calcium (Ca) and magnesium (Mg) indicate the presence of calcite and dolomite rocks. Sodium (Na) and chloride (Cl) concentrations vary from 3.7 to 63 mg/L and from 7.5 to 59 mg/L, respectively. These values indicate a mix of natural mineral dissolution and possible pollution from human activities in the area. Nitrate (NO_3) concentrations vary between 2.7 and 78.5 mg/L with a mean value of 18.6 mg/L, indicating agricultural or/and urban pollution. According to Piper and Durov diagrams, the most dominant water types are Ca-Mg-HCO_3, while samples S1 and S2 indicate Ca-Na-K-HCO_3 and sample S11 indicate Na-HCO_3 and Mg-Ca-HCO_3 water types, respectively. Samples S1 and S2 are projected at the center of the cations' triangle, indicating the groundwater origin from different sources of ion exchange processes.

The ratios of the major ions are provided in Table 2. The obtained proportions indicate insightful information about the geochemical characteristics of groundwater and potential sources of pollution in the study area. The results noted elevated Na/Cl and Mg/Cl ratios in several samples, suggesting varying degrees of cation exchange and mineral dissolution, possibly linked to carbonate geological formations (Figure 3b). High values of the ration (Ca+Mg)/(K+Na) in groundwater samples indicate a dominant presence of calcium and magnesium, which could be linked to natural mineralization processes from limestone and dolomite rocks. Within the study area the value of (Ca+Mg)/(K+Na) is higher than 1 highlighting the continuous recharge of the aquifer. On the other hand, values <1 of the Cl/SO_4 ratio observed in ten (10) samples highlight sulphate concentration, possibly from gypsum dissolution or agricultural activities.

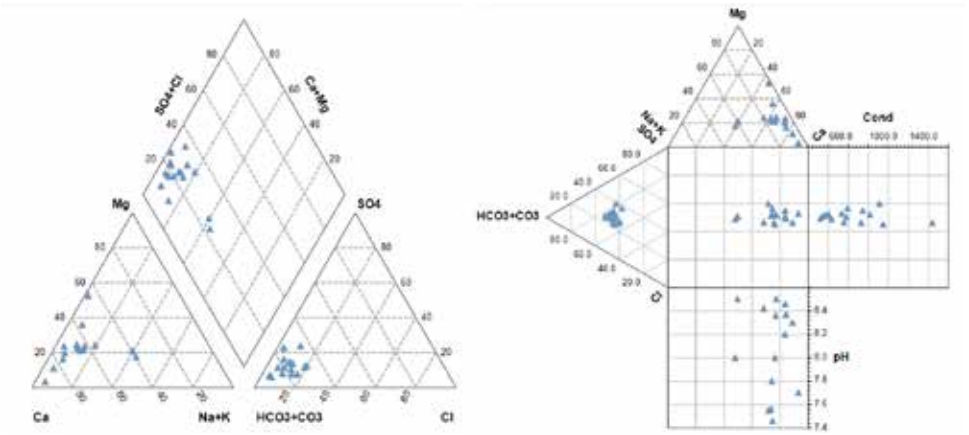

Figure 2. Classification of groundwater samples in Piper and Durov diagrams for the period of June 2024.

Table 1. Descriptive statistics of water quality parameters in the study area for the period of June 2024.

Parameter	Unit	Min value	Max value	Mean value	St.dev.
pH	-	7.4	8.5	8.0	0.4
T	°C	12.0	22.3	17.4	2.8
ORP	mV	-87.0	-20.0	-38.6	16.0
O_2	mg/l	0.0	9.9	4.6	3.3
EC	μS/cm	525.0	1640.0	833.5	295.0
Ca^{2+}	mg/l	50.0	124.0	95.8	25.0
Mg^{2+}	mg/l	2.7	56.8	21.3	13.1
Na^{+}	mg/l	3.7	63.0	21.9	17.2
K^{+}	mg/l	0.3	2.1	1.1	0.5
HCO_3^{-}	mg/l	272.1	451.4	335.7	51.8
SO_4^{2-}	mg/l	16.0	109.0	44.4	26.4
Cl^{-}	mg/l	7.5	59.0	27.8	14.5
NO_3^{-}	mg/l	2.7	78.5	18.6	20.6
NO_2^{-}	mg/l	0.0	0.0	0.0	0.0
NH_4^{+}	mg/l	0.0	0.1	0.1	0.0
PO_4^{2-}	mg/l	0.0	0.2	0.1	0.1

Table 2. Descriptive statistics of components ratios of groundwater samples in the study area.

Ion ratio	Min value	Average value	Max value	St.dev.
Mg^{2+}/Cl^{-}	0.5	3.0	14.4	3.2
Na^{+}/Cl^{-}	0.4	1.3	3.3	1.0
Cl^{-}/SO_4^{2-}	0.1	1.0	2.3	0.6
Mg^{2+}/Ca^{2+}	0.0	0.4	1.2	0.2
Na^{+}/K^{+}	12.7	39.1	148.8	33.5
$(Ca^{2+}+Mg^{2+})/(K^{+}+Na^{+})$	1.3	12.2	51.8	11.7

The trace element analysis of groundwater samples reveals a diverse chemical composition influenced by both the geological regime and possible pollution sources. The concentrations of iron (Fe) in the samples vary from 30.5 to 875.0 μg/L with a mean value of 141.9 μg/l, while the potable limit for Fe is 200 μg/L (EU Council directive 2020/2184). Strontium (Sr) concentrations vary from 52.1 to 581.3 μg/L with a mean value of 374.4 μg/L. High concentrations are also noted by the elements of boron (B) and zinc (Zn). It is worth noting that B element is only presented in the samples at the northern part of the sampling area, with a mean value of 216.7 μg/L and a maximum of 284.0 μg/L, potentially indicating anthropogenic activities such as agricultural fertilizers. Uranium (U) concentrations are below the potable limit of 30 μg/L and range from 0.1 μg/L to 12.7 μg/L.

Table 3. Descriptive statistics of trace element concentrations in groundwater samples of the study area (μg/L).

Trace elements	Min	Max	Mean	St.dev.

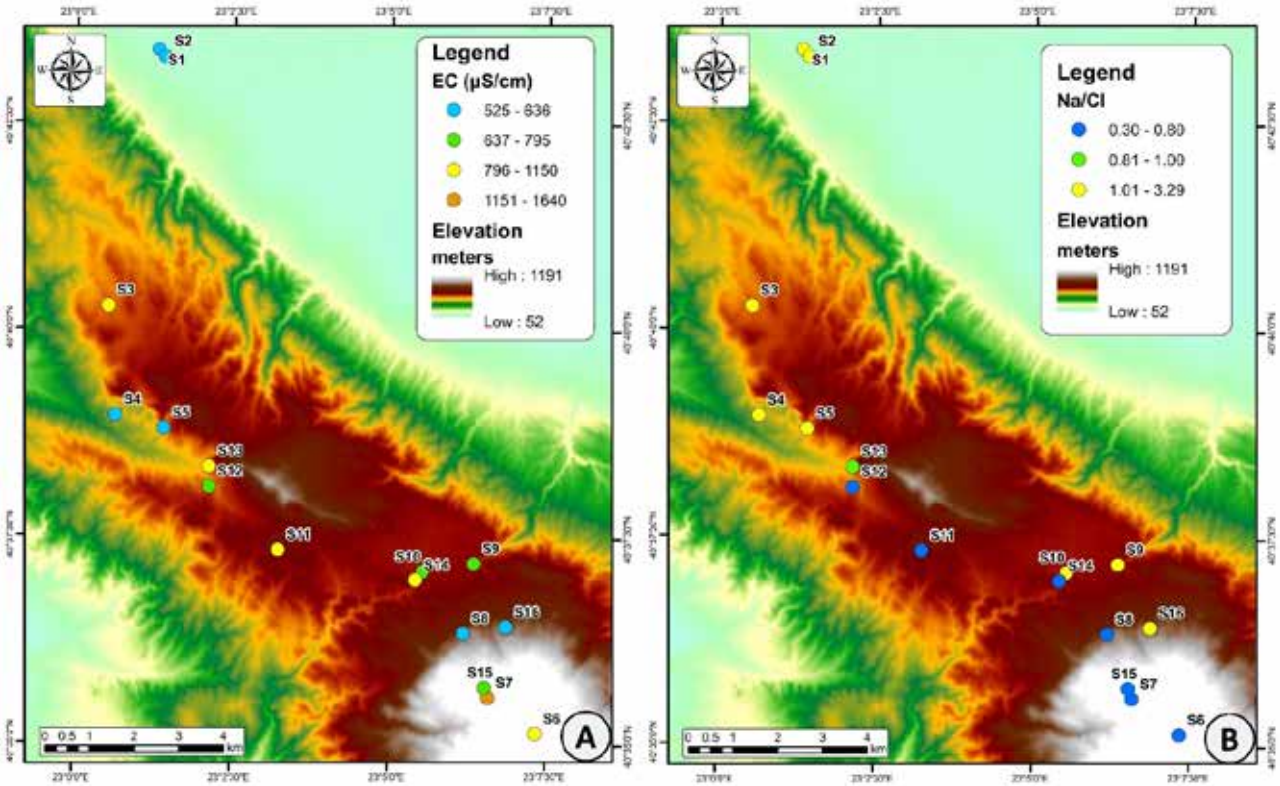

Figure 3. Spatial distribution of the (a) EC (μS/cm) and (b) Na/Cl ion ratio in the study area.

The monthly variation of precipitation and groundwater level for the monitoring wells are also provided in Figure 4, highlighting the groundwater dynamics and spatial heterogeneity of the aquifers. In the diagram of Figure 4a, the groundwater level exhibits a gradual decline over the year, despite a rainfall peak in March 2024. In Figure 4b, a marked rise in groundwater levels is noted following significant rainfall in March and April 2024. No significant variations are mentioned in the diagram of Figure 4c for a long period, on the contrary, low recharge and/or high groundwater exploitation values are noted during the period of June to September 2024. Higher groundwater levels, compared to the other wells, are noted in Figure 4d with a clear seasonal recharge pattern. It should be noted that this particular well has been out of operation for more than a year.

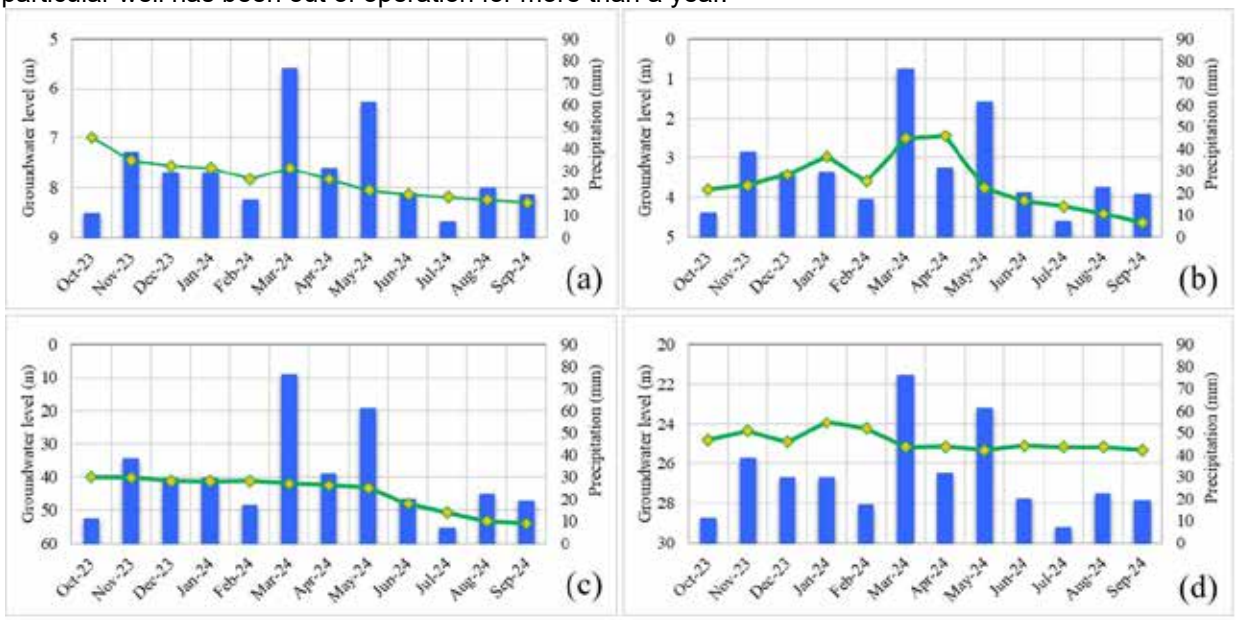

Figure 4. Groundwater level measurements in the hydrological year 2023-2024.

Conclusions

In this study, the hydrochemistry of major ions and trace elements is used to define the hydrochemical characteristics of groundwater in the Chortiatis region. Based on the results, the quality of groundwater is affected by geological regime and human activities. This research indicates that Ca-HCO_3 is the predominant groundwater type, with notable concentrations of sodium-chloride ions. Additionally, elevated concentrations of trace elements such as iron (Fe) and manganese (Mn) highlight the interactions with mineralized rock layers and potential contamination risks that require further monitoring. The results also reveal groundwater level variations across the hydrological year, characterized by seasonal recharge patterns following significant precipitation events and notable declines during dry months. Spatial heterogeneity among the monitoring wells highlights differences in recharge capacity and aquifer exploitation intensity, providing valuable insights for sustainable groundwater management.

Acknowledgment

This research was carried out within the framework of the project entitled “Development of a methodology for investigating the phenomenon of groundwater flooding and defining protection measures and zones for water abstraction projects and infrastructure in the Municipal Unit of Chortiatis.” with Scientific Coordinator Prof. Kazakis Nerantzis and was funded by the Water and Sewage Management Company of Pylaias-Chortiati (DEYA) and the Municipality of Pylaias-Chortiati.

EXTENDED ABSTRACT 232

Evaluation of National Groundwater Monitoring Network at the Peloponnese, Greece

Ntontos P.
Freelance Geologist, Naflpio, Greece, ntontosp@gmail.com

Abstract
The Water Framework Directive requires the establishment of monitoring programmes covering groundwater quantitative status, chemical status and the assessment of significant, long-term pollutant trends resulting from human activity. Greece has a significant disadvantage in developing such a monitoring programme because of its geological complexity. This disadvantage is further magnified by the obligatory choice of Greece, due to lack of data, to delineate «Groundwater Systems» and not «Groundwater Bodies» as Guidance Documents describes.
The basic principles that Guidance Documents suggest are not followed by the developed monitoring network in the region of the Peloponnese. There are fewer than the necessary number of monitoring sites, which are badly distributed over the area and, in many cases, not representative of the monitored aquifers. In contrast to the particularly costly and time-consuming solution of developing an adequate and representative ground water monitoring network, the alteration of all existing wells/boreholes to monitoring sites by establishing of institution of "Well Inspector" seems to be the only direct and sustainable solution to the problem.

Background
The WFD 2000/60/ec for groundwater aims to prevent further qualitative degradation, prevent or contain pollutants, restore groundwater quantity, restore groundwater quality by progressively reduce pollutants, and ensure a balance between abstraction and recharge of groundwater.
To achieve these objectives, the member-countries were obliged to describe "Groundwater Bodies" which are defined as "distinct volumes of groundwater within one or more aquifers". According to the specifications the GroundWater Bodies (GWBs) should be defined in all three dimensions. The GWBs are not necessarily homogenous in their natural characteristics or the concentration of pollutants in them. However, the GWBs should be defined in such a way that the definition of their qualitative and quantitative state is possible (Guidance Document No. 2).
For the accurate definition of the quantitative and chemical status of the GWBs, the appropriate selection of the measures necessary for the achievement of the environmental objectives of the directive, the evaluation of the effectiveness of these measures and the detection and reversal of the pollutants of human intervention in the groundwater, the member-countries should develop a monitoring programme. For this programme to be representative, it should be designed according to the theoretical model and the understanding of the general schema of "recharge-pathway-discharge" for each GWB. The determination of the monitoring sites in the design of the monitoring network should be made by taking into consideration the three-dimensional nature of the GWBs, as well as their spatial and temporal variability. The number of the monitoring sites and the frequency of the sampling procedure should be proportionate to the difficulty in evaluating the UWB status, the presence of pollutants, and the probability of wrongful estimations which the restoration measures may be based on. For GWBs which are at risk, a minimum number of 3 monitoring sites is recommended (Guidance Document No. 15).
The monitoring programmes comprise 3 network categories which are of quantitative monitoring, surveillance monitoring, and operational monitoring, The operational monitoring takes place in the GWBs that are at risk of not fulfilling or are already not fulfilling the objectives of the 2000/60 directive (Guidance Document No. 15). To implement this monitoring programme, Greece enforced the National Monitoring Water Network for the first time in 2011, which was amended in 2021. Groundwater is monitored by part of this network.

Delineation of the GWBs and the Groundwater Monitoring Network
In Greece, the implementation of the 2000/60 directive did not lead to the delineation of "GroundWater Bodies", but of "GroundWater Systems" (GWSs). This was according to the hydrolithological classification of the geological formations that accommodate the underground aquifers. The boundaries were determined according to the outcrop at the surface of these formations, without attempting to evaluate their three-dimensional development or the possible differentiation in the hydraulic behaviour of the formations.
The first River Basin Management Plans (RBMPs) of the 14 Water Districts of the country were conducted either through studies assigned to 5 different joint-venture study groups, or by studies of the Special Secretariat for Water itself. The weaknesses and errors that emerged during the process are the disagreement of the philosophy in the

determination of the GWSs according to the study group, the merging of different aquifers in a single GWS and the determination of the GWSs with geological and not hydrogeological criteria (Ntontos, 2022(a)).
In the first RBMPs, 539 GWSs were determined. Later, in their first revision in 2017, the GWSs were redefined, and the number reached 553, while in their second revision in 2024, the total number reached 598.
The complex and complicated structure of the GWSs which have been determined requires the development of a similarly complex and complicated monitoring network, so that it can be representative and adequate. It should be noted that for a GWS to be characterized as in poor quantitative status, the monitoring sites should present an established water level decline for more than a year, at a rate of at least 20% of the monitoring sites. For a GWS to be characterized as in poor chemical status, at least 20% of the monitoring sites should present exceedance (due to human activities) of the highest acceptable value regardless of the parameters measured. Both characterizations are valid on condition that monitoring sites are uniformly distributed in the whole area of the GWS and not locally placed.
The first governmental attempt to develop such a network was in 2011 with JMD 140384/2011, which included 1,392 groundwater monitoring sites. This network, which is in operation today, was enriched and slightly amended in 2021 with JMD 107168/1444/2021 and now includes 1,895 monitoring sites. The development and monitoring of this network was conducted by an informal assignment to H.S.G.M.E.

Adequacy Inspection Methodology of the Groundwater Monitoring Network

A statistical index, the Representative Index, Ru, has been developed (Grath et al., 2001) for the evaluation of the monitoring network with the following form:

$$R_U = \frac{37.7}{dist_{ave}\sqrt{k / Area}} \ [\%]$$

where

- $dist_{ave}$ is the minimum average distance of any site of the GWS from the closest monitoring site
- k the number of monitoring sites
- Area the area of the GWS

However, this index can be used only in hydrogeologically uniform GWSs. When they are heterogenous, the representation should be estimated solely on hydrogeological criteria. For this reason, the methodology for examining the network quantitative adequacy should abide by the following rules:

- The GWSs that are in a good quantitative and qualitative status, the minimum number is established at 3 monitoring sites (Guidance Document No 15).
- The GWSs that are in poor quantitative and/or chemical status and are hydrogeologically uniform, the minimum number is established at 5 monitoring sites so that 20% of these sites is at least 1 site.
- When the GWSs consist of different aquifer systems (karstic, granular, fissured), the minimum number is established at 3 monitoring sites for every type of significant aquifer. For an aquifer system to be considered as significant, we arbitrarily establish as the minimum area the 10% of the total area of the GWS, or it should accommodate at least 10% of the current productive wells/boreholes in the GWS.

For a monitoring network to be qualitatively adequate, the monitoring sites should be well distributed in the area, and, at the same time, they should be representative of the aquifer formations that form the GWSs. Furthermore, they should not be productive wells/boreholes, except if the measurement frequency is at least every hour (Guidance Document No. 15, ANNEX 2).

Groundwater Monitoring Network of the Peloponnese

According to the 2nd revision of the RBMPs, in the Peloponnese there are 90 Groundwater Systems or Subsystems. These systems have been separated into hydrolithological units, the surface area of which has been calculated. According to the quantitative and chemical status of the GWSs, 71 are in good quantitative and chemical status, 8 in poor quantitative and chemical status, 8 only in poor quantitative status, and 3 in only poor chemical status.
The Groundwater Monitoring Network as defined by the J.M.D. 140384/2011 (O.G.G. 2017/B΄/9-9-2011) included 294 monitoring sites in the Peloponnese. Of these sites, 198 were productive boreholes, 36 productive wells and 60 springs. After revising the network according to J.M.D. 107168/1444/2021 (O.G.G. 5384/B΄/19-11-2021) monitoring sites increased approximately 26%, to 371 sites. Of these sites, 270 are productive boreholes, 35 productive wells and 66 springs. In only 3 of the boreholes the measurement frequency is every hour.

Network Evaluation in the Peloponnese

According to the methodology developed, the first rule for the 71 GWSs that were of good quantitative and chemical status, and the second one for the 19 GWBs that were of bad quantitative and/or chemical status were examined. Table 1 presents the number of GWSs per number of monitoring sites. This table shows that 31 GWSs that are of good quantitative and chemical status, and 5 GWSs that are of poor quantitative and/or chemical status, do not have quantitative adequacy of monitoring sites.

Table 1. Number of GWSs with specific number of monitoring sites in them.

	Number of monitoring sites												
	0	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**13**	**14**
GWSs of good quantitative and chemical status	10	7	14	14	10	3	2	5	1		2	2	1
GWSs of poor quantitative and/or chemical status	2	1		1	1	2	2	3	1	3	1	2	

The third rule was examined for the 14 GWSs that are in poor quantitative and/or chemical status (Table 2) and have more than 5 monitoring sites. It was found that GWSs comprised more than one significant hydrolithological systems, 4 of which have less than the minimum required monitoring sites.

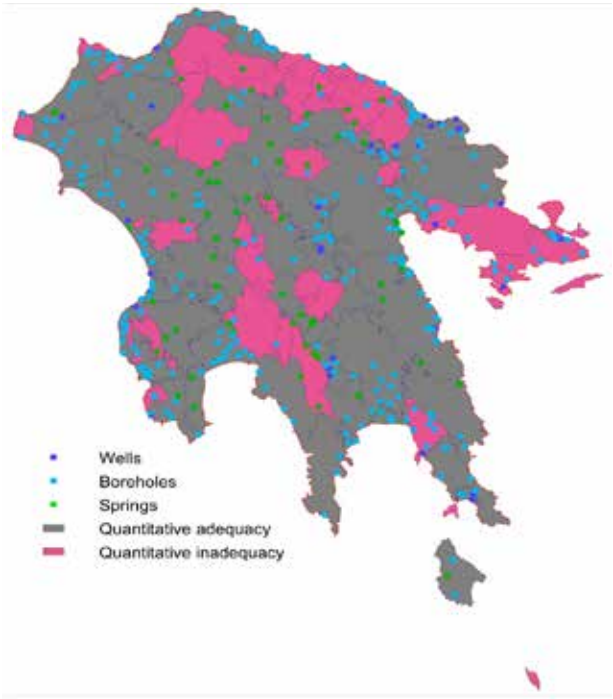

Figure 1. Illustration of the quantitative status of GWSs in the Peloponnese.

Table 2. Area of each significant hydrolithological system (%) of the total GWS area, and number of existing and required monitoring sites.

GWS's code	K1	P1	P2	P3	P4	A1	A2	Number of existing sites	Minimum number required
EL0100100		52,2		45,4				13	6
EL0100170		10,0		87,1				9	6
EL0200091		95,9						7	5
EL0200171		22,3	19,6	48,6				9	9
EL0200173		14,2	11	72,1				6	9
EL0200190		96,3						9	5
EL0300030		98,6						10	5
EL0300040		99,0						13	5

EL0300090		71,5			26,2			7	6
EL0300130				95,0				5	5
EL0300150		15,9		43,8			30,2	7	9

K1: Calcareous formations of high to medium permeability. P1: Granular, mainly fluvial deposits of variable permeability. P2: Neogene/Pleistocene deposits of medium to low permeability. P3: Granular, non fluvial deposits of low to very low permeability. P4: Scree of variable permeability. A1:

Fissured formations of low to very low permeability (flysch). A2: Fissured formations of low to very low permeability (phyllites, quartzites, schists).
* Hydrolithological formation accommodating at least 10% of the current wells in the GWS

According to the previous evaluation, the 40 GWSs of good quantitative and chemical status, and the 10 GWSs of poor qualitative and/or chemical status that have quantitative adequacy of monitoring sites were examined for the good spatial distribution of the monitoring sites. Only 23 of them were found to have good spatial distribution of the monitoring sites, with 2 of them not presenting good representation of the aquifer formations. It should be noted that good spatial distribution of monitoring sites means not only to be spread in the area of GWS but mainly near clustered sites of productive wells/boreholes.

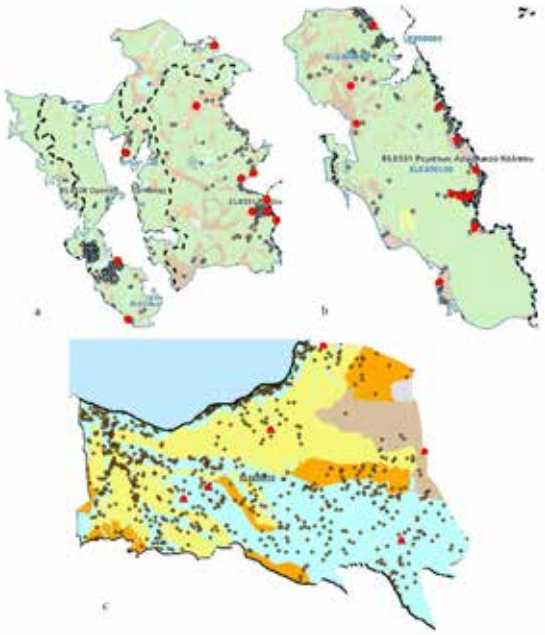

Figure 2. Example of poor (a) and good (b) spatial distribution of monitoring sites (red spots) that need to be not only spread but also near clustered sites of productive wells/boreholes (circles).

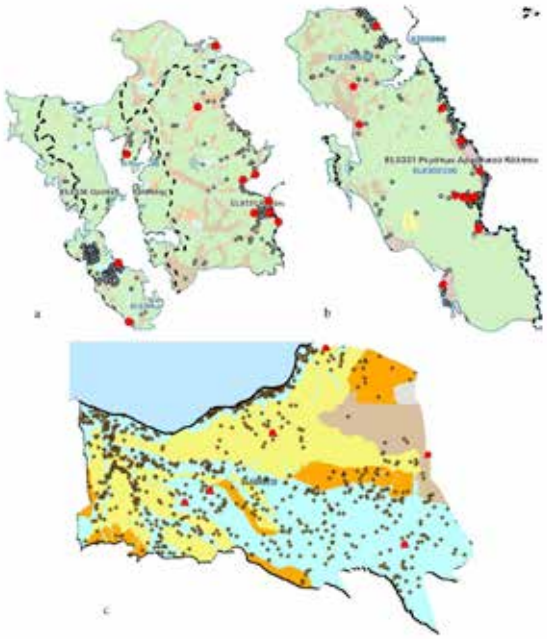

Figure 3. Example of poor representation of aquifer types, as monitoring sites (red spots) need to be not only spread in the area but also within significantly exploited hydrolithological units of the GWS.

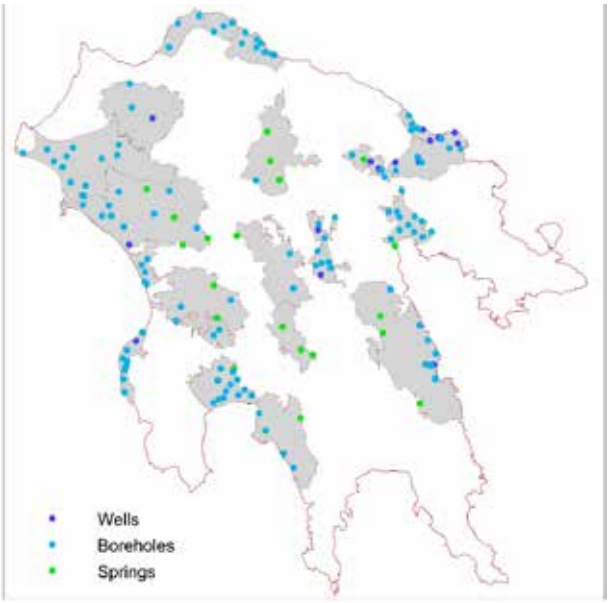

Figure 4. Three types of monitoring sites in 21 GWSs of good spatial and qualitative distribution. Only in 1 borehole measurements were conducted every hour.

Furthermore, 154 sites of the monitoring system were found in the 21 GWSs which were of good spatial and qualitative distribution of monitoring sites. Of those, 134 sites are productive wells/boreholes and only 20 of those sites are springs. However, only in 1 borehole measurements were conducted with the required frequency (eg hourly frequency). In only 4 GWSs the springs comprise the majority of the monitoring sites or are adequate in number (≥3). In the Peloponnese and Western Greece Prefectures, the number of existing productive wells/boreholes is estimated at 83,000 and in Greece at 250,000 respectively (Ntontos, 2017). These wells/boreholes can easily become unofficial monitoring sites for water level and water electric conductivity measurements. These measurements can be conducted twice a year or more frequently by geologists in the private sector who are paid by well/boreholes owners. Such an extended network, with no cost for the state, can contribute to the full understanding of the hydrogeological regime of every aquifer. This in turn can contribute to the appropriate selection of the measures necessary for the achievement of the environmental objectives of the directive.
This procedure is described in the Institution of Well Inspectors (Ntontos, 2022 (b)) and can produce hundreds or even thousands of work positions for geologists. According to the Geotechnical Chamber of Greece data for the year 2023, unemployment rates reach 40%.

Conclusions

According to the recommended methodology, after the examination of the qualitative and quantitative adequacy of the National Monitoring Network of Ground Water, it was found that, from the total of 90 GWSs that are found in the Peloponnese, only 4 of them have quantitatively adequate monitoring sites of good spatial and qualitative distribution. For it to be quantitative adequacy in all GWSs, the monitoring sites must increase in number by at 25%, selectively, and wherever this is imperative. The rearrangement of the monitoring sites is also of significance in many of the GWSs, so that they are distributed well, both spatially and quantitively. Finally, there should be water level loggers installed in all productive wells that are used as monitoring sites, to ensure the frequent monitoring of the water level according to the current European specifications.
It should also be noted that the existence of a minimum number of monitoring sites in each GWS does not, lead to the understanding of the hydrogeological status of the GWS by itself, nor does it contribute to the accurate determination of their quantitative and chemical status. Moreover, the development of a dense underwater monitoring system maintained by the state is extremely costly. Therefore, the implementation of the institution of the well inspector can contribute to the prompt development of an extensive monitoring network, which will consist of all the active wells/boreholes of the country estimated at more than 250,000. In this way, hundreds or even thousands of work positions will be created for geologists, thus the unemployment rates, which reach 40% according to Geotechnical Chamber of Greece data for the year 2023, will be reduced.

Research Highlights

Authigenic cerianite mineralization and elevated REE values in b1 and b3 bauxites at the Parnassos-Ghiona Unit and bauxite residues from the Corinth Gulf

Introduction

The Mesozoic carbonate sequence of the Parnassus-Ghiona Unit mainly attracts research and economic interest, particularly around the three karstic-type bauxite strata it hosts, namely b1, b2, b3, which were deposited between Middle Jurassic and Upper Cretaceous times (e.g. Valeton *et al.*, 1987; Kalaitzidis *et al.*, 2010; Laskou & Economou-Eliopoulos, 2013; Economou-Eliopoulos *et al.*, 2016; Gamaletsos *et al.*, 2017). Nowadays mainly b3 horizon is exploited, b2 has been the subject of mining in the past, whereas b1 was never extracted, as it occurs sporadically, with limited quantities and low grade in terms of Al. Diaspore, boehmite and gibbsite are the main Al-minerals of interest, whereas the mineralogical composition frequently includes hematite, goethite, kaolinite, chlorite, anatase and pyrite (Mondillo *et al.*, 2022 and references therein).

Although bauxite mining in Greece takes place for almost a century, nowadays the focus shifts towards the REE, which occur either within the bauxite or the bauxite residues after metallurgical processes and are a key part of the EU Green Deal, in order to transit to a greener and more sustainable future for the EU (European Commission, 2020). REE are characterized by unique electrochemical and magnetic properties, thus making them “critical metals” for technological and industrial development for both developed and developing economies around the world (Borra et al., 2016; Panda et al., 2021). For the reasons above, REE are widely used in green technologies such as electric car batteries, solar panels, special magnets for wind turbines and others (Narayanan, 2019; Deady et al., 2016; Wall, 2014). The REE are traced within the bauxite residue (BR), being enriched in comparison to the bauxite with a factor of about two (Borra *et al.*, 2016; Ujaczki, 2017). In Greece, the bauxite residue is produced during the Bayer method by the alumina and aluminum production plant “Aluminum of Greece SA”(ATE) at Aspra Spitia of Boeotia, and for several decades it was disposed in the gulf of Antikyra in the northern and central part of the Corinthian Gulf. Its discharge began in the 1970s through a submarine pipeline and it ceased in 2012. In total, it is estimated that more than 20 Mt of bauxite residue have been discharged in the Corinthian Gulf, covering up to 12% of its total surface area (Iatrou, 2013). According to Ochsenkiihn-Petropulu et al. (1994) and Borra et al. (2015) the mean value of the ΣREE in the Greek BR is approximately 974 mg/kg. In this study bauxite, from the Parnassus-Ghiona Unit, and bauxite residue samples from the Corinth Gulf were examined in order to record and evaluate their main mineralogical, geochemical and mineral-chemical characteristics, with emphasis on the REE, which has not been systematically studied till now. The aim of this study is to assess the REE mode of occurrence in bauxites and wastes from the metallurgical process of bauxites (BR) and determine their origin.

Methods

Bauxite samples represent a b1 outcrop (EL2, EL3, EL3A and EL4 samples) (in total 17 samples) from Elateia site (near the small town of Elateia, Central Greece) and two b3 outcrops from Kardarrorahi (KR3 samples) (in total 3 samples) and Vargiani (PBF1-2-2 sample) (in total 1 sample) sites (near Delphi area), whereas samples of bauxite residue (RM samples) (in total 12 samples) represent deposition within Corinth Gulf; BR samples were obtained during a drilling campaign in 1994 and 2007 as part of an environmental study.

X-Ray diffraction analysis was performed in all samples, as well as geochemical analyses for major, minor and trace elements. SEM-EDS measurements were also conducted both in bauxite and bauxite residue samples.

Results

The b3 samples mainly consist of Al_2O_3 ranging between 36.81 and 51.55 wt.-%, Fe_2O_3 in a range of 11.26-28.33 wt.-% and SiO_2 fluctuating greatly from 4.23 to 23.97 wt.-%, while the b1 samples consist of Al_2O_3 ranging within

26.39 and 63.9 wt.-%, Fe_2O_3 in a range of 4.80-25.92 wt.-% and SiO_2 fluctuating greatly from 1.85 to 12.9 wt.-%. The bauxite residue samples mainly consisting of Fe_2O_3 (9.85-25.2 wt.-%), CaO (14.85-22.2 wt.-%), SiO_2 (14.2-23.9 wt.-%), and Al_2O_3 (9-11.1 wt.-%).

The ΣREE at the b3 samples vary greatly between 771.67-1961.8 mg/kg, while at the b1 samples varies between 510.23 and 1090.73 mg/kg. Finally, the total REE contents (ΣREE) of the bauxite residue samples vary between 484 and 771 mg/Kg.

The mineralogical examination of the bauxite samples presented similar mineralogical features in the bauxite samples (for both b1 and b3 samples), with small variations among diaspore, boehmite and gibbsite, as well as for the iron oxides and hydroxides. Furthermore, rutile concentration is always low between 1-3%, while Kaolinite seem to be more dominant in the b1 samples.

EDS analysis on individual particles in the bauxite residue samples, was challenging due to the small average size of the crystals. However, several mineral phases were identified with hematite, ilmenite, quartz and calcite being the predominant ones. Various accessory minerals were also rarely detected, including pyrite, and zircon. REE minerals were also found in bauxite and bauxite residues and more specifically individual cerianite crystals.

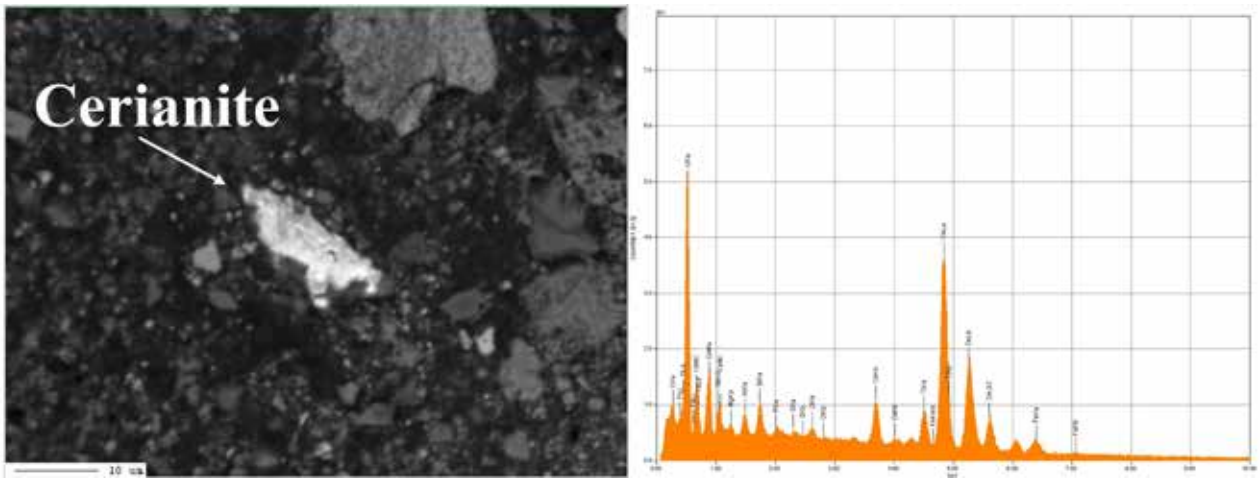

Figure 1. Back-scattered electron image of sample RM13 depicting cerianite in the bauxite residue and relative EDX spectra.

Conclusions

Both bauxite (b1 and b3) and bauxite residue samples seem to be enriched in REE, and show similar ranges in the total content of them. By comparing the ΣREE of the herein studied BR samples with those from previous studies of pure BR from Greece, the former values seem slightly decreased. This divergence is justified due to the mixing of the bauxite residue with the sediments of the Corinth Gulf. Authigenic REE-bearing minerals were identified in all samples and more specifically cerianite.

Research Highlights

The variety of microfossils identified allowed to reconstruct the original ecosystem of the lake areas of the Pululahua Volcano after its destructive volcanic events. Based on the characterization and timing of charcoal pebbles encountered within a distant but prominent ash-layer, it has been possible to identify how an ancient culture has been destroyed in coastal Ecuador, some 3,5 ka ago.

Introduction / Background

Throughout phanerozoic times, past botanic fossil records are often preserved when ironically huge catastrophic events take place, allowing the reconstruction of past evolutionary processes in the diversity and developments of plant life. These catastrophic events may include flooding of which newly deposited sedimentary material remains above previous existing vegetation, a number of volcanic events or hazards such as lava flows, ash and pyroclastic flows as well as avalanche deposits, ice or glacial deposits and also due to drought and landslides among many others (Ukraintseva *et al.*, 2014; Svoboda *et al.*, 2019; Vallé *et al.*, 2024). Nonetheless, there are a variety of studies where older plants and their corresponding flora and even fauna have been preserved in a variety of forms, due to severe volcanic events such as by even famous eruptive phases of the past (Ayala-Usma *et al.*, 2024).

As it is a challenge to encounter preserved paleoenvironmental areas with corresponding vegetation, it is even more difficult to find paleobotanic remains of wetlands, lagoonal or fluvial environments. Such environments not only preserve the flora and fauna of the given time of its existence, but they are also able to reveal the paleoclimatic and paleoecologic conditions of its time, allowing to reconstruct past events in order to understand the recent and future atmospheric behavior and their fluctuation. Such information may be reconstructed by the content of such wet environments which may include either macro or microfossils. Therefore, paleobotanic research of wet environments may be based on the findings of preserved macrofossil plants within sedimentary layers as impressions or compressions, as casts or molds, and also as petrification. However, many more details are preserved in form of microfossils, when looking with magnifying glasses, binoculars or microscopes of any kind. Such findings may be plants, algae, diatoms, fungi, pollen, spores, bacteria, biomass in general and other kind of microfossils of some animal remains. These discoveries are the basic results for a subsequent declaration of geoheritage sites.

Unfortunately, in Ecuador paleobotanic research is scarce, although there are many reports of charcoals inside of volcanic environments within a high amount of extinct and active volcanoes in the continental part of the country as well as on the Galapagos islands. However, such findings have been mostly used in past for carbon dating without further specification or characterization of the plant or wood fossil content. There are also petrified forests of the Mesozoic period, like the well-known in Puyango in the southern part of Ecuador, but also of limited information concerning paleobotanic findings (Cadena & Román-Carrión, 2018).

Based on the aforementioned context, the current study´s predominant aim has been to identify and characterize microfossil content of charcoal deposits of a fluvial-lagunar environment and a coastal site, being preserved by the volcanic activity of two volcanic complexes in north-central Ecuador. This shall be achieved by a detailed volcanic reconstruction of the catastrophic events of the past, in combination of a microscopic inventory of encountered charcoal horizons within the volcaniclastic deposits. As we deal with two different events in time, the first results may allow to establish the environmental conditions of a so far unknown humid landscape of local to regional importance within the Ecuadorian highlands, shortly after glaciation and almost simultaneously to the first appearance of human settlings, while the second results may allow to reconstruct the almost complete disappearance of a flourishing culture in the coast of Ecuador.

Geological background and study areas

The four Ecuadorian continental volcanic arcs are the result of the subduction of the Nazca oceanic plate below the Caribbean and South American continental plates. The NNE-SSW aligned volcanoes within these arcs correspond to the Western, Inter-Andean, Eastern and Subandean Volcanic Arcs or Cordilleras of Ecuador. In the central part of the Western Volcanic Arc is situated the Pululahua caldera and dome complex as well as the Pichincha Volcanic Complex (PVC), both being located just a few km outside of Ecuador´s capital Quito (Toulkeridis and Zach, 2017).

For the Pululahua volcano, at least 16 predominantly andesitic to dacitic domes have been identified, belonging to four different units (Units I-IV; Andrade *et al.*, 2021). The oldest domes are heavily eroded, porphyritic amphibole-bearing dacitic pelean lava domes of unknown emplacement ages belong to the so-called Unit I. Some further older domes (La Marca among others), belong to the Unit II yielded ages of 18 to 10 ka, while later single or major events took place at 6.75 ka, 2.6 – 2.3 ka and some 2.24 ka ago. Those events resulted into wide and thick successions of pumice-rich, pyroclastic deposits, which include charcoal rich layers, which is evidence of previous vegetation in times of volcanic activity. The most prominent outcrops with charcoal rich layers are situated on the southeastern side of the Pululahua dome complex, along the Monjas river.

A big part of the western mountain flank of the city of Quito, occupies the PVC, which is composed of five successive volcanoes, of which the first four are extinct reaching ages of 1.1 Ma to 4 ka. The El Cinto basal edifice (1.1 to 0.9 Ma) is followed by the Rucu Pichincha stratovolcano (850 to 150 ka), Guagua Pichincha stratocone (60 to 11 ka), Toaza volcanic dome complex (11 to 4 ka) within the collapsed, avalanche amphitheater of Guagua Pichincha and finally the presently active Cristal volcanic dome complex (3,700 years to present day) within the Toaza caldera. The Cristal volcanic dome complex gave rise of repeated growth and collapse of volcanic domes, which occurred in the period of 1998 to 2001 (Monzier *et al.*, 2002; Robin *et al.*, 2010).

Results and discussion

Pyroclastic flows and pyroclastic surges produced by directed, sub-plinian explosions of the outer caldera of Pululahua situated older domes, whose activity represents the second phase of its eruptive period, occurred some 12-10 ka ago. Close-by to the La Marca dome, prominent charcoal deposits of a fluvial-lagoon environment along the Monjas river have been identified and dated, correspond to this time period and event.

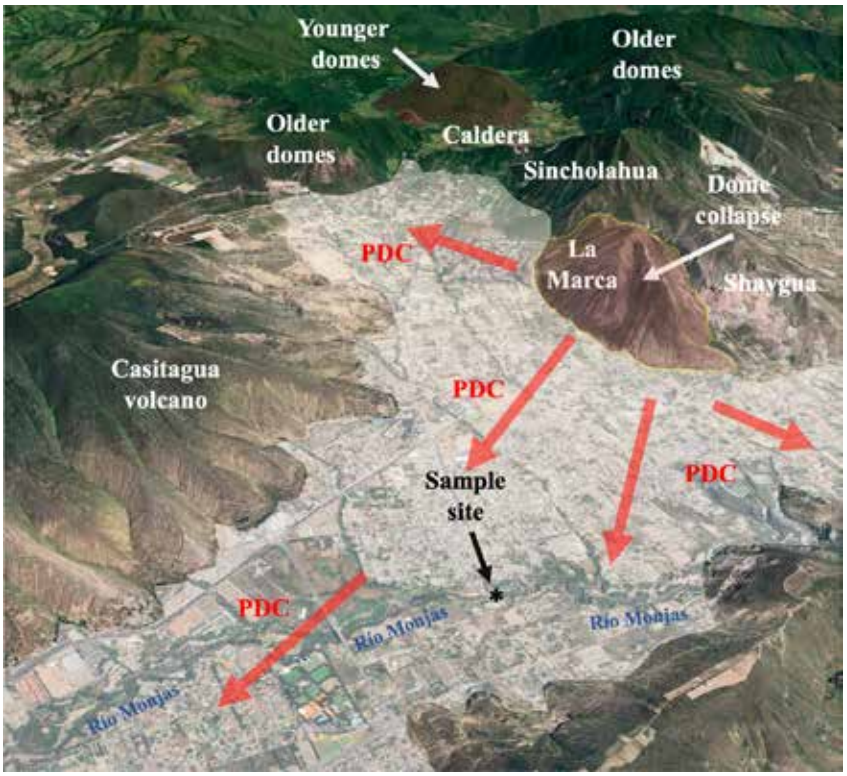

Fig. 1. South (left) to north (right) panoramic, bird-view of the result of the directed blast situation of the older collapsed domes of the Pululahua caldera and dome complex, generating pyroclastic density currents (PDC), which cover a vast area of the Inter-Andean Valley, forming what is now the base of the San Antonio de Pichincha village.

Fig. 2. Charcoal horizons of the Río Monjas type section (A-D). Note that the most prominent charcoal deposit is of about 65 cm thick (A: 45 cm plus 20 cm of the basal part), while others are mixed with pumaceous ash particles (B). Furthermore, there appear charcoal lenses within the pyroclastic deposits (C). Uppermost charcoal layers above an erosional contact (D).

We analyzed and characterized the charcoal deposits and encountered microorganisms such as benthic diatoms, saprophytic fungi and nitrogen-fixing bacteria, as well as herbaceous vascular plants such as horsetails, lycopods, bamboos, ferns, and small shrubs. These identified organisms originated from temperate and cold ecosystems, probably from flooded or seasonally flooded areas. The charcoal fragments perfectly preserved by the favorable conditions suggest that the original ecosystems of the Pululahua paleoflora correspond to areas of humid and lacustrine environments typical of swampy ecosystems, humid mountains and Andean moorlands.

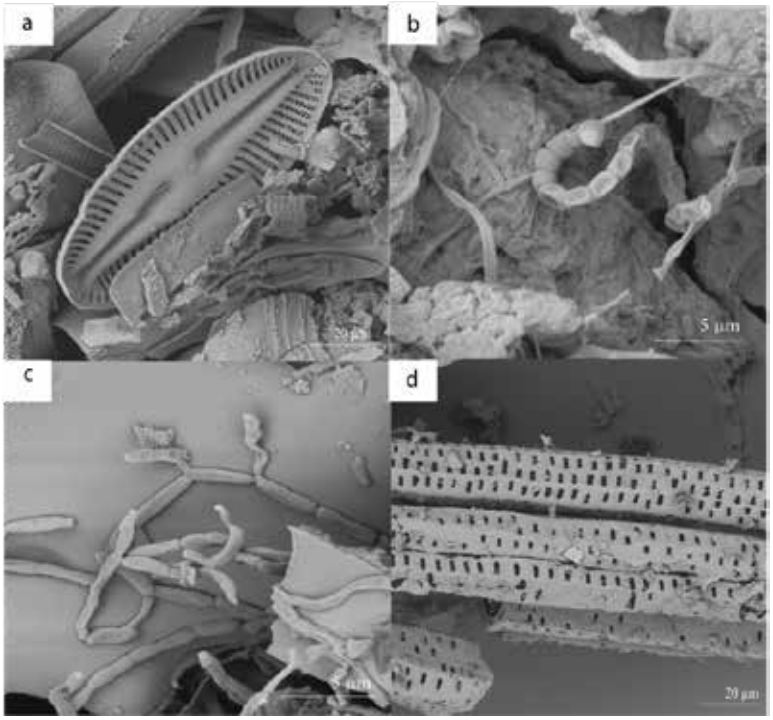

Fig. 3. SEM photomicrographs: a. Diatom Bacillariophyceae, valves oval, elongated, symmetrical, with raphe. Linear, marked transverse striations; b. Streptomyces well-developed filamentous vegetative hyphae; c. Bacillus sp., rods in branched chains; and d. Polypodiophyta, Equisetaceae adjacent nodal metaxylem tracheids.

In the coastal area of Ecuador, close to the city of Portoviejo, at the site called Papayita, an ash layer which includes charcoal pebbles (fossilized wood), with an impressive thickness of 85 centimeters was encountered above an underlying paleosol. A fact that is striking when considering that the closest volcano with sufficient eruptive power to produce such ash volumes, Quilotoa, is around 165 km away in a direct line. Nonetheless, provenance analysis based on geochemistry analysis and mineralogy revealed that the volcano responsible for the high amounts of the expelled material must have been the PVC with a distance of some 225 km in a SW direction. The stratigraphic sequence at Papayita is of significant interest, with a base consisting of geological material layer, succeeded by a paleosol and a cultural layer. The latter contains several discernible activity areas, including a hearth and small midden areas. Two separate features contained human remains associated with the Valdivia ceramics found at the site.

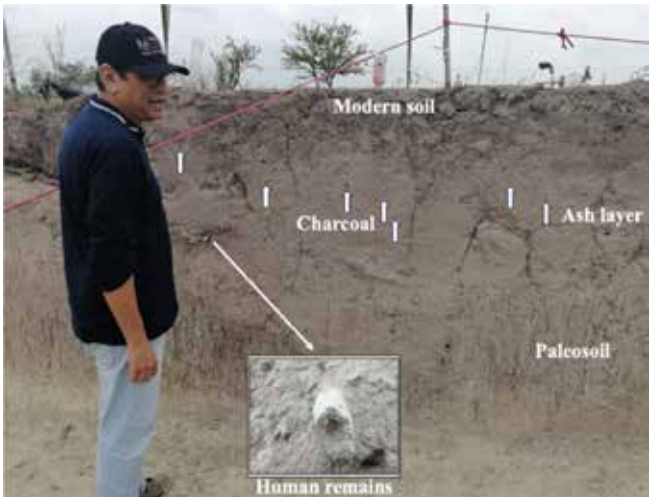

Figure 4. Exposed machine cut due to farmer's construction of a traditional water reservoir. It provided a pro file that indicates the main stratigraphic components of the Papayita site. The most important sections of the profile sequence being (from bottom to top): the paleosol, the ash layer, and the modern soil or plow zone. The position of the human remains and other artifacts, as well as several charcoal fragments, can be discerned in the profile.

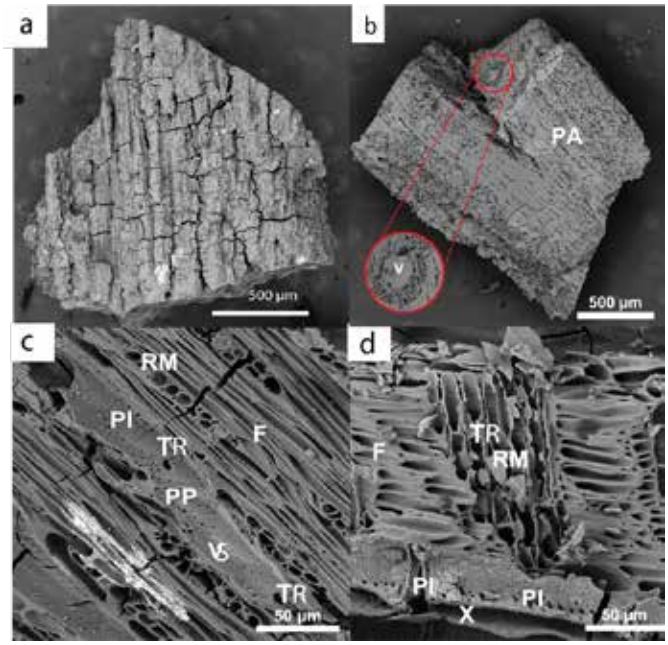

Figure 5. SEM photomicrographs of charred plant material, anatomical features of charcoal samples: A. Elongated and fusciform cells, tangential section, vascular system with septa without points, own to gymnosperms (VS), simple perforation plates (PP), medullary radius (RM), intervascular pits (PI), fibers (F) and tracheids (TR); B. Tangential cut: intervascular pits (PI), simple perforation plates (PP), medullary radius (RM), fibers (F), and xylem (X). C. Woody vascular system (VS), showing woody tracheid (TR), axial parenchyma (PA); B. Fragment of charred wood.

Interestingly, the cultural layer is sealed by a significant, uninterrupted deposit of volcanic ash reaching 85 centimeters in thickness. The features discovered, as well as the artifacts' angles of deposition suggest that this ashfall occurred while living activity at Papayita was ongoing. In other words, the site had not been abandoned at the moment the ashfall event began. The evidence of human activity after the ashfall is minimal and there is, so far, no indication of further human occupation until modern times. The mineralogical and geochemical data coincide with the geochronological outcome of the charcoal which yielded an age of 3530 ±30 years, identical to the 3560 ±70 years BP, 3540 ±30 years BP and 3549 ±30 years BP ages of previous studies (Zeidler, 1994; Zeidler, 2016; Robin *et al.*, 2008; Robin *et al*., 2010). The fossilized wood fragments collected in Papayita, were identified, thanks to their perfectly preserved anatomical structure, as a plant from the Gymnosperm group, of the Podocarpaceae family, being vegetation from temperate or cold climates in the foothills of the Andes (Páez-Barrera et al., 2024).

Conclusion

A dome collapse of the Pululahua caldera and dome complex some 10k ago, was able to cover and preserve an ancient fluvio-lagunar environment. Based on this volcanic event, it has been possible to identify several dozens of microorganisms, such as plants, diatomens, fungi and bacteria allowing to reconstruct the paleo-environment shortly after glaciation and just prior human settlements.

The species belonging to the Podocarp family inhabit temperate and cold areas of the Andes with an altitudinal distribution range between 1900 and 3800 m a.s.l., meaning that the volcanic activity of the PVC transported Podocarpus wood from a cloud forest of the high Andean zone to the Papayita site located in a coastal environment near the sea level where it was preserved. The vast ashfall and the subsequent charcoal-laden ash layer, coupled with the ensuing environmental disturbances, were probable key contributors to the ending of human occupation at the Papayita settlement and may have played a part in the termination or final metamorphosis of the Valdivia cultural tradition in this region ~3500 years ago.

Foreshock-aftershock discrimination in real-time during the 2025 seismic cluster near Santorini volcano, Greece, based on earthquake statistics and complex networks theory

Papadopoulos G.A.[1], Triantafyllou I.[2], Siettos C.[3], Spiliotis K.[4]
(1) Hellenic Mediterranean University, 71410 Heraklion, Greece, gerassimospapadopoulos2@gmail.com (2) Institute of Physics of the Earth's Interior and Geohazards, Hellenic Mediterranean University Research Center, 73133 Chania, Greece, ioannatriantafyllou@hmu.gr (3) Dipartimento di Matematica e Applicazioni "Renato Caccioppoli", Università degli Studi di Napoli "Federico II", Naples, Italy, constantinos.siettos@unina.it (4) School of Civil Engineering, Democritus University of Thrace, Greece, spiliotiskos@gmail.com

Introduction / Background

Foreshocks, aftershocks and swarms are the most common types of space-time seismicity clusters (Mogi, 1963). The real-time discrimination between foreshocks and other types of clusters is of great importance for the short-term hazard assessment but it is a challenging issue. Therefore, only *a posteriori* solutions have been proposed. During January-March 2025 a space-time seismicity cluster was recorded between Santorini and Amorgos islands, South Aegean, with the largest earthquake (M_L=5.3) occurring on 10 February 2025. This case offered a good opportunity to decipher the type of the ongoing seismic cluster based on the daily re-evaluation of the seismicity state. We utilized tools from the earthquake statistics and the complex networks theory and were able to discriminate beforehand the foreshock-aftershock nature of the ongoing cluster. Our findings were documented on time with internal reports as well as with public reports and statements.

Methods

The real-time characterization of the type of the ongoing seismicity cluster near Santorini was based on the daily monitoring of the 3D seismicity changes, i.e. in the dimensions of space, time and magnitude. Real-time means that the evaluation of a data set retrieved from the earthquake catalogue up to time t, was completed at time t+1 days. The onset of the cluster has been considered to occur on 30 January 2025 which corresponds to t=1 day. The 3D changes detected were compared with the 3D state of background seismicity (BS) in the same area in the time interval from January 2015 to January 2025. This procedure was followed up to 12 March 2025 when we realized that the cluster activity was already at very low level. The implementation of our method has been made possible thanks to the open availability of earthquake data by the Institute of Geodynamics of the National Observatory of Athens (https://bbnet.gein.noa.gr/HL/seismicity/real-time-seismicity/last-24-hours), which provides real-time updating of the national earthquake catalogue.

In the magnitude domain the monitoring of the seismicity state was performed by calculating the variation of the critical geophysical parameter b, which is the slope of the straight line in the Frequency Magnitude Distribution (FMD) well-known as G-R law expressed by (1) (Gutenberg and Richter, 1944):

$$\log N = a - b\,M \qquad (1)$$

N is the discrete or cumulative number of events of magnitude ≥M±ΔM, and a, b are parameters determined by the data. For global seismicity b is about 1 (e.g., Schorlemmer *et al.*, 2005). However, in regional and local seismic zones the b-value is sensitive in many factors the most important being the stress loading conditions (Mogi, 1963) and the crustal heterogeneity (e.g., Abercrombie and Mori, 1996). Therefore, the b-value has been considered as a stress-meter within the crustal material (e.g., Schorlemmer *et al.,* 2005). The methods of Maximum Curvature and of Fixed-M_c, both incorporated in the z-map toolbox (Wiemer, 2001), were utilized to calculate the completeness magnitude threshold, M_c, and the b-value during the BS as well as during the 2025 cluster. The significance of the b-value changes was tested with the test of Utsu (1966).

In the domain of space, we were based on the spatial distribution of the betweeness centrality (BC), which is a topological metric that quantifies the number of times a node (surface patch or earthquake epicenter) acts as a bridge along the shortest path between two other nodes. Bridging nodes that connect disparate parts of the network often have high BC value. Such nodes greatly participate in the flow of information in the network. In earthquake processes high BC indicates persistent seismic activity. From the first few days of the cluster it became obvious that the earthquake epicenters gradually migrated from SW to NE, which is the direction of the main tectonic faults in the area. Since M_c=2.9 was found for the first days of the cluster, for the monitoring of the seismicity migration we considered as zero point the epicenter of the first earthquake of M_L ≥2.9 at time t=1 day. Then we measured from

that point the mean distance, D, of epicenters of the subsequent earthquakes with an ensemble of 100 earthquakes in each measurement step. In the domain of time we analyzed the seismicity rate, r, in terms of r=n/T or r=N/T, where n=discrete number of earthquakes, N=cumulative number of earthquakes and T is a constant time interval.

Results

At time t=4 days (2 February 2025) after the initiation of the seismic cluster, we were able to recognize that the cluster was characterized by the basic properties of the foreshock sequences, i.e. acceleration of the seismicity rate, r, gradual increase of the earthquake magnitudes and significant drop of the b-value as time goes on towards the mainshock occurrence (Jones and Molnar, 1979, Papadopoulos and Minadakis, 2017). This pattern was evident until the largest earthquake (M_L=5.3) on 10 February 2025. The earthquake epicenters migrated from SW to NE towards the epicentral area of the M_L=5.3 mainshock. The maximum distance of D~25 km was found for the mainshock epicentral area. The foreshock move towards the mainshock epicenter has also been observed in other foreshock sequences. The maximum migration velocity was on the order of 3 km/day. On the 13th February we detected important drop in both the number and the magnitudes of the earthquakes. The gradual decrease of r followed power-law and was consistent with the well-known Omori aftershock decay. At the same time, a gradual increase of the b-value was detected, which was an additional evidence of aftershock activity. On the other hand, the betweeness centrality (BC) metric showed that during the stage of background seismicity although the activity was important and persistent in the Santorini-Amorgos area only weak seismicity hubs were detected in the Nea Kammeni (Santorini) and the Kolumbo volcanoes. From the first days of the 2025 seismic cluster the BC metric became quite strong in the Santorini-Amorgos seismic cluster but no seismicity hubs appeared in the two volcanic centers. This picture did not change until 12 March 2025.

During the seismic cluster in Santorini-Amorgos our findings were periodically transmitted by one of us (GP) to the competent state authorities, i.e. the Ministry for Climate Change and Civil Protection, including the Earthquake Planning and Protection Organization, and were communicated through reports (Triantafyllou and Papadopoulos, 2025) and statements in mass and social media, thus documenting beforehand the real-time foreshock-aftershock discrimination during the ongoing cluster.

Conclusions

The 2025 seismic cluster in Santorini-Amorgos area is a good example of real-time discrimination between foreshocks, aftershocks and swarms. The foreshock nature of the cluster was detected as early as the 4th day of the cluster and was verified by daily seismicity monitoring until the occurrence of the mainshock (M_L=5.3) on 10 February 2025. A few days later the aftershock sequence following the mainshock was also detected. These results disfavor the interpretation of the 2025 seismicity cluster as a swarm case. The gradual migration of epicenters with maximum velocity of ~3 km/day does not account for hydraulic diffusion and favors a cascade failure process. The findings of our analysis were documented in many ways beforehand during the ongoing seismic cluster. The area between Santorini and Amorgos acts as a long-term seismicity hub and stress concentrator.

EXTENDED ABSTRACT 236

Image-based grain size analysis of coastal sediments

Papadopoulos Th.[1], Pechlivanidou S.[1], Foumelis M.[1], Pennos Ch.[1]
(1) Department of Physical & Environmental Geography, School of Geology, Aristotle University of Thessaloniki, Thessaloniki, Greece

Abstract

In this study we show that image-based grain size analysis, could under appropriate conditions, replace the traditional grain size analysis in the laboratory, providing reliable results, especially for coarse-grained samples.

Coasts are dynamic systems affected both by natural and anthropogenic factors. Over the last few decades, the impact of climate change in coastal areas has become increasingly evident, with accelerated erosion significantly altering shorelines, threatening ecosystems, and endangering human settlements. Grain size analysis of coarse sediments (i.e. coarser than silt) traditionally held with the sieving method, remains one of the basic tools for studying coastal processes. However, this approach can be time-consuming and requires strategic sampling, particularly in extensive areas, along with a thorough understanding of geological principles. New methods, such as the use of satellite imagery and high-resolution photographs from drones or smartphones, provide faster solutions, although they often require further validation and comparison with laboratory-based grain size analysis to ensure accuracy.

Here, we investigate the effectiveness and accuracy of Buscombe's (2013) code in photographic grain size analysis techniques, both on-site and in the laboratory. We compare the grain size results obtained from this method with those from traditional sieving to draw reliable conclusions, while assessing the technical specifications and external factors affecting the accuracy of the method. The aim is to save time and resources to improve coastal zone research.

Buscombe's code is a Python algorithm that speeds up grain size analysis using sediment photos (Buscombe, 2013). It relies on Morlet wavelet to estimate the grain size distribution, by analyzing selected regions of the image to reduce computational load. This algorithm identifies patterns and frequencies in the image that correspond to different grain sizes. The results are presented as Power Spectrum Density (PSD) and, through interpolation, a complete grain size distribution is generated, eliminating the need for further adjustments.

Sampling took place in the coastal area of Kalamaria, Thessaloniki, Greece. The site was carefully selected to avoid interference from swimmers or municipal equipment. Sediment samples were collected from six different locations, based on visual observation of grain size distribution. The samples were first dried in the oven at 100°C and then sieved using 0.5Φ sieves in the Sedimentology Laboratory, at the Aristotle University of Thessaloniki. Processing of the grain size results performed using Gradistat software (Blott & Pye, 2001) following Folk and Ward method (Folk & Ward, 1957).

To evaluate the accuracy of the method for obtaining automated grain size results, we took high-resolution photographs (12MP and 108MP) of the samples in the laboratory using a Xiaomi Redmi Note 11S smartphone. Photographs were processed using the Buscombe's code and the results were compared with those from sieving. The comparison included the whole sediment samples as well as specific grain size fractions (i.e., 0 Φ).

After testing the accuracy of the code on laboratory photographs, we applied the same approach to photographs taken in the field, where external factors, such as lighting and shadows, could influence the results. Field photographs were taken of three samples (i.e., samples NOΘ-201, NOΘ-202, and NOΘ-203) in the afternoon under mild natural lighting with some shadows, and two samples (i.e., samples NOΘ-301 and NOΘ-302) at noon with strong natural lighting with minimal shadows. The grain size results from field photographs were then compared to those of the same samples photographed in the laboratory.

Table 1. Grain size results using the Buscombe's code (2013) for sediment samples sieved at 0 Φ (1 mm)

Sample	Mean grain size (mm) using Buscombe's with 108MP camera resolution	% Difference	Mean grain size (mm) using Buscombe's with 12MP camera resolution	% Difference
NOΘ-2P	0.61	39%	0.69	31%
NOΘ-3P	0.89	11%	0.89	11%
NOΘ-4P	0.94	6%	0.82	18%
NOΘ-5P	0.91	9%	0.92	8%
NOΘ-6P	0.98	2%	0.87	13%

Table 1 shows the mean grain size results for the 0 Φ fractions using the Buscombe code on photographs with 108MP and 12MP resolution. The percentage deviations range from 2% to 39% with the 108MP resolution photos and from 8% to 31% with the 12MP ones, indicating that higher resolution provides slightly more accurate results. The NOΘ-6P sample displays the smallest deviation (2%), while the NOΘ-2P sample demonstrates the largest (39% for the 108MP resolution photos and 31% for the 12MP resolution photos). Overall, both analyses yield comparable results, with the 108MP resolution offering a slight advantage in precision.

Table 2. Grain size results using the Buscombe's code (2013) for the whole sediment samples

Sample	Camera Analysis	Mean grain size (mm) using Buscombe code	Grain Size results from sieving (mm)	% Difference
NOΘ-1P	12MP	1.19	0.38	213%
NOΘ-1P	108MP	1.14	0.38	202%
NOΘ-3P	12MP	1.78	0.98	82%
NOΘ-3P	108MP	1.57	0.98	59%

Table 2 presents the mean grain size results for whole sediment samples analyzed using Buscombe's code, along with the differences compared to sieving results. For the fine-grained sample NOΘ-1P (i.e., 0.38 mm), discrepancies are substantial, reaching 213% with 12MP resolution photos and 202% with108MP resolution photos. In contrast, for the coarser-grained NOΘ-3P sample (i.e., 0.98 mm), discrepancies decrease significantly to 82% with 12MP resolution photos and 59% with 108MP resolution photos. These results suggest that the accuracy of the Buscombe code improves with higher resolution images and coarser-grained samples are used, while it exhibits greater errors with finer-grained samples.

Table 3. Comparison of the grain size results using the Buscombe's code (2013) on lab and field photos

Sample	Grain Size (mm) Lab	Grain Size (mm) Field	% Difference
NOΘ – 201	1.08	2.36	118%
NOΘ – 202	1.14	2.68	135%
NOΘ – 203	1.15	2.76	141%
NOΘ – 301	0.99	1.74	76%
NOΘ – 302	1.09	1.17	8%

Table 3 highlights variations in grain size between laboratory and field photographs, which range from 8% to 141%. Samples NOΘ-201, NOΘ-202 and NOΘ-203, photographed under less favorable lighting conditions and shadows, show the largest differences, ranging from 118% to 141%. Conversely, samples NOΘ-301 and NOΘ-302, captured under more favorable conditions with adequate lighting, show significantly smaller discrepancies, with NOΘ-302 having the smallest difference at just 8%. These findings indicate that the shooting conditions play a crucial role in the accuracy of the particle size analysis. Despite these variations, sediment classifications based on the Wentworth chart (Wentworth, 1922) differ by only one class. For samples NOΘ-201, NOΘ-202, and NOΘ-203, results from the field photos are classified as very fine gravel, while results from the lab photos as classified as very coarse sand. Similarly, samples NOΘ-301 and NOΘ-302, show even smaller discrepancies, with samples being classified as very coarse sand in both field and lab photos.

Our results show that the application of the Buscombe code to 0 Φ grain size fraction has satisfactory accuracy, when compared to the sieving data. However, in the whole sediment samples, the deviations are higher, especially in the finer grain sizes, reaching up to 200%, highlighting the need for method optimization. In the coarse grain sizes, the discrepancies decreased, with the use of high-resolution (108MP) photographs enhancing accuracy. Overall, the code proved to be effective for larger grain sizes, while its accuracy is significantly affected by the resolution of the photograph and the homogeneity of the sample.

Comparison of field and laboratory photographs highlighted the importance of external factors, such as lighting and shadows. Field photographs under good lighting conditions showed smaller differences compared to photos taken under unfavorable conditions. Coarse-grained samples showed better convergence between methods, while the use of high-resolution photographs improved the results.

Acknowledgements

Sincere gratitude is extended to the doctoral candidates, surveyors Ion and Kostas, for dedicating their valuable time to ensure the accurate and scientific acquisition of field photographs.

Introduction / Background

The Corinth Canal is a landmark of immense historical, cultural, and industrial significance, bridging the Saronic and Corinthian gulfs. It serves as a symbol of engineering ingenuity and a vital transportation route (Manolopoulou, 2024). The Corinth Canal cuts through the isthmus of Corinth, a geologically dynamic area characterized by sedimentary rock formations, tectonic activity, and steep slopes (Anagnostopoulos et al., 1991). The canal, approximately 6.4km long and 25m wide, exposes a cross-section of the region's stratigraphy, offering a unique opportunity for geological study. However, its steep walls, composed primarily of loose conglomerates and marls, are prone to erosion, landslides, and structural instability. These risks are compounded by the area's seismic activity, necessitating continuous monitoring and management. The Corinth Canal has been mapped using modern 3D mapping techniques, such as UAVs data processing and Structure-from-Motion (SfM) photogrammetry, enabling the creation of highly accurate 3D models and orthomosaics (Saroglou et al., 2019). Additionally, the canal's deformation is being monitored using SBAS (Small Baseline Subset) Interferometric Synthetic Aperture Radar (InSAR) and GNSS (Global Navigation Satellite Systems) techniques (Yaragunda and Oikonomou, 2024). These techniques have been applied to recent landslides, providing valuable insights into slope geometry, stability analysis, and risk assessment. Despite the advanced mapping efforts, a dedicated online platform for aggregating and unifying the mapping data has not yet been developed. This presents a significant opportunity to create a unified web-based mapping application that would enhance access to and utilization of these data by the scientific community and relevant stakeholders. To address these needs, this study, in collaboration with Corinth Canal S.A (A.E.DI.K) aimed to create a detailed geospatial archive of the canal through advanced UAV (Unmanned Aerial Vehicle) technologies. The initiative combined cutting-edge data collection techniques and a robust flight planning strategy to support sustainable management, promote its historical value, and enable continuous monitoring of its condition.

Objectives.

The study had three interlinked objectives:

i. **Developing high-resolution geospatial data products**: These included 3D point clouds, textured models, orthomosaics, and digital elevation models (DEMs), capable of capturing the canal's intricate details with spatial resolutions of 10-20 cm.

ii. **Implementing precise flight planning for optimized data acquisition**: A systematic and carefully designed flight plan was crucial to ensure comprehensive coverage, minimize data gaps, and maintain high geometric accuracy.

iii. **Creating a web-based mapping platform**: This platform integrates the collected datasets, enabling spatiotemporal monitoring of the canal's slopes, assessing structural stability, and supporting effective management strategies.

Methods

The data collection process between October 23-29, 2023, utilized UAVs equipped with RGB cameras, thermal sensors, and GNSS receivers. To ensure systematic coverage, the canal was divided into nine segments. Each segment was mapped using three meticulously planned flight patterns: vertical (nadir), east-west oblique, and north-south oblique. This design minimized data voids and ensured optimal image overlap (90% frontal and 80% lateral). Flight paths were pre-designed using DJI's Pilot 2 software, considering terrain variability, safety parameters, and the need for uniform data quality. The flights captured high-resolution imagery at height of flights ranging from 120 meters for general mapping, to 3-10 meters for detailed thermal scans and panoramic images at specific points of interest. Between October 23 and 29, 2023, UAV flights systematically captured high-resolution geospatial data of the

Corinth Canal. Employing UAV models such as the Mavic 3E and Matrice 300, the project utilized RGB and thermal sensors for diverse imaging needs. Each flight was executed with specific gimbal angles—typically -90° for vertical (nadir) and -70° for oblique imagery—ensuring precise coverage and minimizing data voids. The captured images featured resolutions ranging from 3.22 to 3.45 cm/pixel for general mapping to less than 1 cm/pixel for specific locations. This meticulous planning facilitated the creation of comprehensive datasets, later integrated into a web-based cartographic platform to enhance monitoring and management efforts.

Table 1: Characteristics of Flights Conducted for the 3D Mapping of the Corinth Canal

Date	October 23, 2023	October 24, 2023	October 25, 2023	October 28, 2023	October 29, 2023
Number of Flights	6	14	7	4	3
UAV Model	Mavic 3E	Mavic 3E	Mavic 3E	Mavic 3E	Matrice 300
Sensor Type	RGB Camera	RGB Camera	RGB Camera	RGB Camera	RGB + Thermal Sensors
Gimbal Angle	-90° (vertical), -70° (oblique)	-90° (vertical), -70° (oblique)	-90° (vertical), -70° (oblique)	360° Panoramic	Various
Image Resolution	3.22–3.45 cm/pixel	3.22–3.45 cm/pixel	3.22–3.45 cm/pixel		5–10 cm/pixel
Flight Patterns	Vertical (nadir), oblique east-west	Vertical (nadir), oblique east-west	Vertical (nadir), oblique east-west	Panoramic and detailed imaging	Vertical, oblique imaging

The collected data were processed using photogrammetric algorithms such as Structure from Motion (SfM) and Multi-View Stereo (MVS) (Westoby et al., 2012), producing dense point clouds, DEMs, and orthomosaics. Geometric accuracy was further validated by comparing the results with existing topographic diagrams. The photogrammetric outputs were then enhanced with thermal data to supporting the identification of potential structural vulnerabilities.

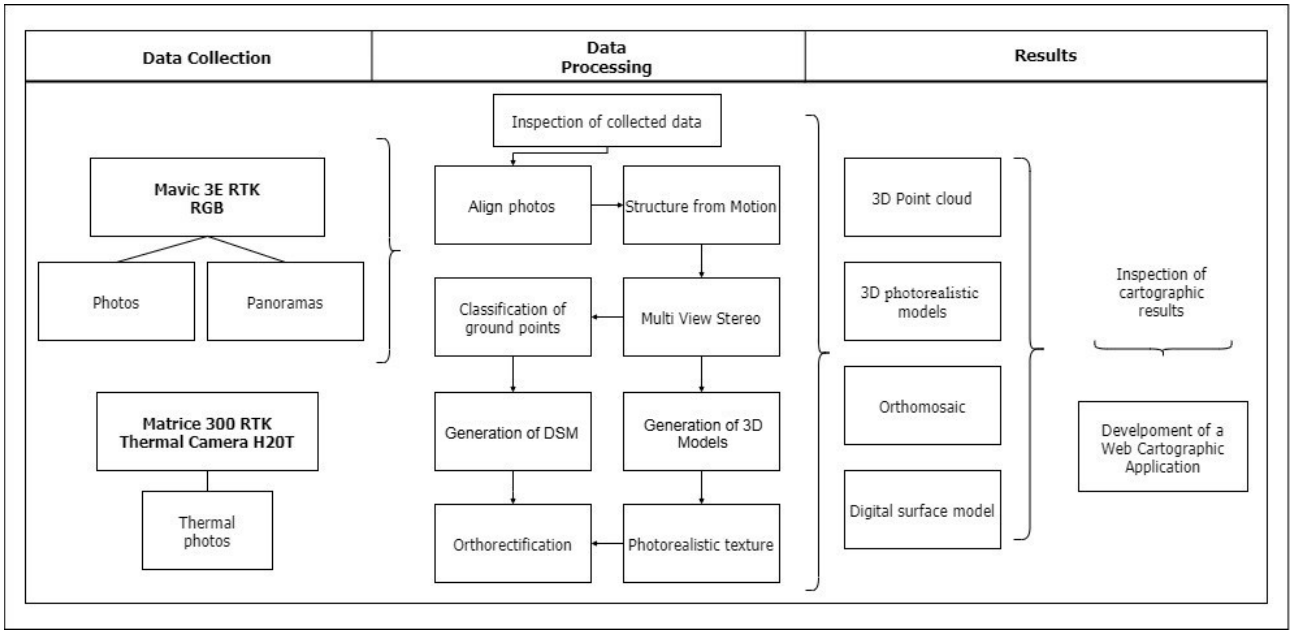

Figure 1. Flow diagram of the methodology

A key aspect of the study was the development of the “Corinth Canal” web mapping platform. This platform integrates all spatial datasets into a user-friendly interface, enabling stakeholders to visualize and interact with the canal’s digital representation. The platform was developed using GIS-based tools, such as ArcGIS Online and customized web applications, to provide functionalities including spatial analysis (distance, area, and slope measurement), thematic comparisons, and annotation capabilities. Special emphasis was placed on supporting multitemporal monitoring of the canal’s slopes, with tools designed to track changes over time, enabling early detection of risks such as landslides or structural instability.

Results

The study successfully delivered a comprehensive suite of geospatial products that offer detailed insights into the Corinth Canal's current condition. Seven georeferenced 3D models and point clouds were created, covering the entire canal and its individual segments, alongside high-resolution orthophotos, digital elevation models (DEMs), and thermal imagery. The results demonstrated high accuracy, with spatial resolutions ranging from 10-20 cm, and were validated through comparisons with existing topographic diagrams. This process confirmed the reliability of UAV-based data collection as a highly precise and efficient method for documenting such complex structures.

The integration of thermal imagery further enriched the dataset, enabling the identification of potential structural vulnerabilities, such as hotspots indicative of material stress or instability. These thermal findings, combined with detailed 3D models and DEMs, provide critical information for assessing the canal's geotechnical and structural health.

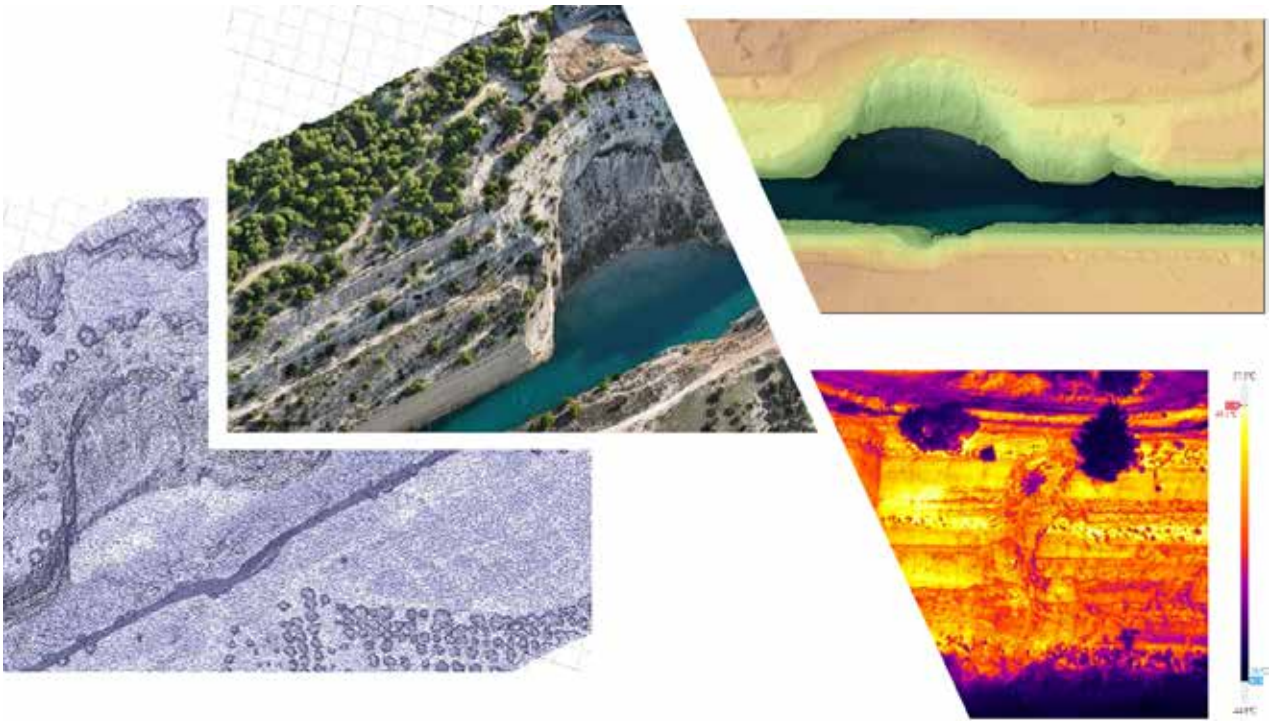

Figure 2. 3D photorealistic model, mesh of an irregular triangular network, DEM and a thermal photo of the 4th section of the Corinth Canal.

A significant outcome of the study was the development of the cartographic web application named "Corinth Canal". This interactive tool consolidates all spatial datasets, offering a user-friendly interface for visualizing and analyzing the canal's digital representation. The platform includes a variety of tools tailored to the needs of stakeholders:

- **Measurement Tools**: Users can perform distance, area, and slope calculations directly within the platform, enabling precise spatial analysis for maintenance and planning activities.
- **Thematic Comparisons**: Layers such as thermal imagery, 3D models, and orthophotos can be overlaid and compared, facilitating the identification of changes or inconsistencies over time.
- **Annotation and Note-Taking**: Users can add annotations and comments to specific areas, enhancing communication among teams and stakeholders involved in the canal's management.

The platform's design emphasizes accessibility and ease of use, ensuring that both technical and non-technical users can interact effectively with the data. Moreover, it enhances operational workflows by providing centralized access to critical geospatial information, streamlining decision-making processes. By bridging advanced UAV-based data collection with modern GIS technology, this study has laid the foundation for a sustainable, data-driven approach to the monitoring and management of the Corinth Canal. The web application not only supports day-to-day operations but also contributes to long-term preservation efforts, offering a scalable model for similar cultural and industrial heritage sites worldwide.

Figure 3: "Corinth Canal" cartographic web application.

Conclusions

The development of the "Corinth Canal" web mapping platform stands as a pivotal achievement in this study, offering an innovative and user-friendly tool for visualizing and managing the canal's digital representation. By integrating high-resolution spatial datasets—including 3D models, orthomosaics, DEMs, and thermal imagery—the platform provides stakeholders with the capability to monitor and assess the canal's structural stability in a dynamic and accessible manner. Designed with tools for distance and area measurement, thematic comparisons, and annotation, the platform supports multitemporal analysis, enabling early detection of risks such as landslides or structural instability. This interactive application not only streamlines operational workflows but also serves as a scalable model for preserving and monitoring similar cultural/industrial heritage sites or critical infrastructures worldwide.

This study underscores the transformative potential of UAV technologies in cultural heritage management. By employing precise flight planning and advanced photogrammetric methods, we achieved a comprehensive and high-resolution geospatial archive of the Corinth Canal. The integration of thermal data enriched the analysis, enabling the identification of structural vulnerabilities such as material stress and instability. UAV-based mapping it is considered a reliable and efficient method for documenting complex geological and structural settings, with centimeter-level accuracy that surpasses traditional methods in both speed and cost-effectiveness.

Future work could focus on integrating machine learning algorithms with the collected UAV data to automate the detection of structural vulnerabilities, such as cracks or erosion patterns, along the canal's slopes. Additionally, expanding the monitoring system to include real-time data acquisition using UAVs equipped with advanced sensors (e.g., LiDAR or hyperspectral imaging) could enhance the multitemporal analysis of geological and structural changes. Finally, collaborative efforts could explore creating a shared digital twin of the canal, enabling global access for research, education, and cultural preservation initiatives.

EXTENDED ABSTRACT 238

An integrated approach using Remote Sensing and the Environmental Seismic Intensity Scale ESI 2007 for three major earthquakes in the Aegean region

Papadopoulou E.[1], Chatzipetros A.[1]

(1) Department of Structural, Historical and Applied Geology, School of Geology, Aristotle University of Thessaloniki, Greece, epapadoas@geo.auth.gr

Introduction / Background

The study of earthquake impacts on the environment is important for understanding seismic hazards and reducing associated risks. Remote sensing, particularly through Sentinel-1 satellite imagery, offers an effective method for detecting ground displacement and mapping fault systems. The Environmental Seismic Intensity Scale (ESI 2007) provides a robust framework for evaluating earthquake effects on the environment (Michetti et al., 2007) with high precision (Papanikolaou & Melaki, 2017). This study combines Sentinel-1 remote sensing techniques with the ESI 2007 scale to assess seismic hazards and disaster potential by analysing recent seismic events in the Aegean region, focusing on the Kozani-Grevena 1995, Lesvos 2017 and Samos 2020 earthquakes. On 1995 May 13, Kozani and Grevena were struck by an Ms = 6.6 (Mw 6.5) earthquake, causing extensive damage. Meyer et al. (1996) reported surface ruptures over 8 km comprising open fissures and scarps on the pre-existing Palaeochori Fault striking N70◦E. It was preceded by foreshocks, causing significant impacts to buildings, and triggered environmental effects such as rockfalls, landslides, liquefaction, and surface ruptures (Meyer et al., 1998, Hatzfeld et al. 1995, Pavlides et al. 1995, Chatzipetros 1998). On June 12, 2017, a Mw 6.3 earthquake struck southeastern Lesvos Island, causing disasters to the natural environment, buildings, and infrastructure, particularly in southeastern Lesvos. The earthquake's epicentre was offshore, with a depth of ~13 km, and was associated with a NW-SE striking (Papadimitriou et al., 2017), SW-dipping normal fault along the northern margin of the offshore Lesvos basin (Chatzipetros, et. al, 2013). It triggered secondary earthquake environmental effects (EEE) (Lekkas et al., 2017) such as ground cracks, slope movements, and a tsunami in Plomari port, likely caused by offshore landslides (Karamvasis et al., 2017 Vlachakis et al., 2020). The 2020 Samos earthquake, with a magnitude of 7.0, struck the eastern Aegean Sea on October 30th, significantly impacting Samos Island, Greece, and Izmir, Turkey. Caused by normal faulting along the North Aegean Trough, it triggered substantial ground deformation (Mavroulis et al., 2020), including co-seismic uplifts and displacements and produced surface ruptures, landslides, liquefaction, coastal changes, and hydrological anomalies (Foumelis et al., 2021, Ganas et al., 2021, Sakkas, 2021). The Samos earthquake serves as a focal point in such studies.

Methods

The methodology integrates advanced remote sensing techniques and field-based analyses to investigate ground displacement and environmental effects caused by seismic events. Sentinel-1 Synthetic Aperture Radar (SAR) data were utilized for pre- and post- seismic periods, with differential interferometric SAR (DInSAR) processing, employed to measure co-seismic deformation. The analysis involved co-registering SAR images, removing the topographic phase using Shuttle Radar Topographic Mission (SRTM) data, unwrapping phase data using SNAP Desktop software. Vertical (up-down) displacement component was calculated from ascending and descending LOS data and was visualized within a GIS environment. Using published and field information about the distribution and magnitude of surface effects and the ESI 2007 scale, the study evaluates environmental impact, such as uplifts, surface ruptures, slope failures, and liquefaction, by mapping and digitizing these data in GIS, producing isoseismal maps with the method of kriging that illustrate intensity patterns. The final step involves an analysis of remote sensing data and traditional field measurements to validate their consistency and potential data overlap.

Results and Conclusions

The analysis of ascending Sentinel-1 data (Fig. 1 and Fig. 3) and descending Sentinel-1 SAR data (Fig. 2 and Fig. 4) for the Lesvos and Samos earthquakes demonstrated significant ground displacement, accurately captured through interferometric synthetic aperture radar (InSAR). Moreover, the ascending and descending Sentinel-1 data showed similar results for both seismic events. Field measurements used for the ESI 2007 scale and the seismic intensities ranged from IV to IX, which are broadly in agreement with other studies (Lekkas et al., 2017, Papanikolaou & Melaki, 2017, Mavroulis et al., 2021), reflecting the widespread impacts of all three events. Moreover, the use of the Environmental Seismic Intensity (ESI-07) scale demonstrated its effectiveness in evaluating primary and secondary earthquake environmental effects (EEEs), such as slope failures, liquefaction, and ground cracks, particularly in inaccessible areas.

The maps (Fig. 1, 2, 3, 4) of surface co-seismic deformation fields obtained by analysis of interferometric synthetic aperture radar (InSAR) images have significantly improved the description of earthquake effects. The seismic intensity was visualized in isoseismal maps to illustrate the spatial distribution of impacts for the Kozani-Grevena (for which no InSAR data was available Fig. 5), Lesvos (Fig. 6) and Samos (Fig. 7) earthquakes present the spatial distribution of seismic intensity and highlighted areas

of heightened risk, enhancing seismic hazard assessment and disaster preparedness for future applications. This integrated approach offered valuable insights into the environmental impacts of seismic events and improved hazard assessment. It also emphasized the complementary roles of remote sensing in covering inaccessible areas and field data for high-resolution, localized studies. The multidisciplinary response shown in these studies demonstrates the growing integration of advanced geospatial technologies, field observations, and historical data in seismic risk assessment.

In conclusion, this study underscores the effectiveness of combining Sentinel-1 SAR imagery with the ESI 2007 scale to assess environmental impacts of strong earthquakes. It enhances our understanding of seismic risks by detecting concealed faults and quantifying ground displacement, especially in remote or inaccessible areas. The findings contribute to the ESI 2007 database and highlight the critical role of remote sensing in earthquake research. This integrated framework has the potential to strengthen disaster preparedness and response strategies, providing a foundation for future advancements in seismic risk assessment.

Introduction

The purpose of this work is to study the specifications required for developing or improving a quality label for products and services offered by businesses in the regions of the four collaborating geoparks (Vikos-Aoos UNESCO Global Geopark, Sitia UNESCO Global Geopark, Chelmos Vouraikos UNESCO Global Geopark, Psiloritis UNESCO Global Geopark).

The project involves the design of a special label for local agrotourism products and services in the cooperating areas, based on global market quality standards and UNESCO principles for Global Geoparks. Additionally, it includes the design of the specifications and evaluation criteria for the products and services of each region, which will carry this special label, in alignment with UNESCO's principles for Global Geoparks.

This expertise is conducted within the framework of the Interterritorial Cooperation Plan entitled "EMPOWERMENT, PROMOTION, AND NETWORKING OF UNESCO GEOPARKS" and, more specifically, as part of the project "Expertise on Specifications – Evaluation Criteria and Design of a Special Label for Local Agrotourism Products and Services."

Fig.1: Presentation of the project partners

The Interterritorial Cooperation Plan is implemented under the local CLLD/LEADER program, Submeasure 19.3 of Measure 19 of the Rural Development Program (RDP) 2014–2020, by the coordinating Local Action Group (LAG) ACHAIA S.A. – DEVELOPMENTAL ANONYMOUS COMPANY OF LOCAL AUTHORITIES, in collaboration with the following participating partners: EPIRUS DEVELOPMENTAL S.A. – Developmental Organization of Local Authorities, LASSITHI DEVELOPMENTAL S.A. – Developmental Organization of Local Authorities, AKOMM – PSILORITIS DEVELOPMENTAL S.A. – Developmental Organization of Local Authorities (Fig.1).

Methodology

The design of the quality label and the proposals for improving the existing ones (Psiloritis and Sitia UGGps) were based on several aspects:

- Study of Criteria and Application of 1st Generation Quality Labels: Examination of standards like AGRO (Hellenic Agricultural Organization–DIMITRA) and the EU's Eco-Label for environmental certification of products and services.

- Study of 2nd Generation Quality Labels: Investigation on labels such as the certification for the Samaria National Park, the "CRETE" quality label, local cultural support agreements like the Epirus Ancient Theaters Cultural Route, the PINDOS quality pact (no longer in effect), and the Special Quality Label for Greek Cuisine (E.S.P.E.K.).
- Study of Quality Labels for Geoparks: Analysis of existing labels from participating geoparks (Sitia and Psiloritis) and international geopark labels such as "Naturtejo Geopark Geoproduct," "Qualità parco" from Adamello Brenta Geopark, and "Naturally Tasty" from Beigua Geopark.
- Study of GEOfood Label Standards: Inspection of the guidelines and specifications of the GEOfood label.
- Review of Literature including research on the history and philosophy of quality label development, as well as other public surveys (e.g. Ilbery and Kneafsey, 1998; Henchion and McIntyre, 2000; Eckardt, 2007; Marques, 2007; Carpenter and Larceneux, 2008; Lorenzini, 2011; Ramos and Garrido, 2014; Košičiarová Kajima et al., 2016; 2017; Hutagalung et al., 2024 and other).
- Discussions with Project Partners and Geopark Representatives Five online meetings were held, including one kickoff meeting and four individual meetings with each partner. These meetings focused on expectations and challenges regarding quality label use.
- Online meeting with Lassithi Developmental S.A., Sitia Geopark, and Local Businesses: Local businesses shared their experiences, challenges, benefits, and suggestions for improving the label's operation. A survey conducted by the Psiloritis Geopark also provided insights from businesses using its quality label.
- Contractor's experience and discussions with local businesses and geopark representatives
- Designing of a customized questionnaire (Google Forms) aiming on a) obtaining general information about the participating businesses, information about the promotion methods and sustainable practices they use and information about their level of knowledge about geoparks and quality labels in general and b) in assessing the intentions of geoparks that do not implement certification as well as to evaluate the experiences of already certified businesses. The questionnaire was distributed to relevant businesses in all four areas and the results were analysed and validated.

An analysis of the needs of the co-operating partners was also conducted.

Results

The research resulted in proposals regarding the improvement of the already existing quality labels and the drafting of a regulation which sets out the conditions that must be followed by beneficiaries who wish to use this quality mark. The aim of granting this quality mark is to certify the suitability of the product-service to represent the geopark area as a genuine expression of its identity.

Additional objectives for applying the quality mark to products and businesses are:

- To certify the locality of the product-service
- To create added value to the product-service by providing or enriching the identity of the region and leveraging participation in the UNESCO Global Geoparks Network
- To connect the products-services with the geodiversity elements of the geopark area
- To provide differentiation to the products-services in relation to similar products by leveraging the uniqueness of the region and the experiences provided
- To enhance the credibility of the product/service
- To promote local products-services at a national and international level
- To strengthen relationships between producers, entrepreneurs and other interested parties
- To ultimately strengthen the local economy either directly or indirectly.
- To enhance the feeling of "belonging" in the collaborating businesses

The quality mark is aimed at businesses related to agro tourism, agriculture and rural tourism.

Eligibility criteria

The eligibility criteria are divided into general criteria, specific criteria and proportional coverage criteria. The general criteria are applied in their entirety to all enterprises and regard the legality, locality and mode of operation of the enterprise. The specific criteria are applied per type of enterprise (catering and accommodation businesses, manufacturing businesses -inside or outside the geopark area-, tourist-ecotourism offices, use of organic products etc.). The proportional coverage criteria constitute a set of criteria, the application of which can substantially contribute to the achievement of the objectives of the certification but are more specialized and difficult to apply practices (e.g. ISO or other certifications, minimizing the consumption of natural resources and waste in at least one way etc). For this reason, it is not recommended to cover all of these criteria, but it is required to cover at least 5 of them.

The coverage of the required criteria is confirmed by the presentation of the corresponding supporting documents.

Code of conduct

The "identity" of a region is not shaped solely by measurable characteristics, and for this reason, granting the current certification requires, in addition to meeting specific criteria by the interested businesses, a commitment to a set of **ethical rules**. This involves a collection of principles and rules that the parties involved must fully adopt as a way of life. These cannot function as criteria because their evaluation by individuals is inherently subjective. The signing of a **Code of Conduct** is proposed as a way to operate with integrity and commit to common values.

The proposed quality label regulation also determines obligations of both the participating businesses and geoparks, as well as of the certification process (application, evaluation, inspections and audit, issuance and monitoring) and proposes actions in order to maximize the impact of the quality label.

Discussion and Conclusions

The establishment of a quality label for geopark products and services represents a significant step towards promoting sustainable development and the responsible management of natural and cultural resources. Through this initiative, the high quality of offered products and services is ensured, while simultaneously the visibility of geoparks as exemplary areas that integrate tourism, education, and environmental protection os enhanced.

The implementation of the quality label can make a crucial contribution to the economic development of local communities by offering incentives for innovation while protecting and showcasing the unique natural wealth of geoparks. Strict adherence to the criteria established for the quality label will guarantee its reliability and strengthen the trust of visitors and consumers.

Finally, collaboration among various stakeholders—such as local communities, producers, management bodies, and educational institutions—serves as the foundation for the successful implementation and continuous improvement of the quality label. This will enhance the sustainability and uniqueness of geoparks in the long term.

Introduction / Background

The Lesvos Petrified Forest is a geological heritage site of global significance, featuring silicified tree trunks, fossil leaves and volcanic deposits dated back to the lower Miocene. Initially brought to scientific attention in 1844, it gained broader recognition in late 19th and early 20th centuries, with pivotal research in the 1990s elucidating its formation processes (e.g. Velitzelos & Zouros, 1997). Designated as one of the first European Geoparks in 2000, and Global Geopark in 2004, the Lesvos Petrified Forest is the main geological heritage area of international significance for the recognition of Lesvos island as an UNESCO Global Geopark in 2015 (https://www.lesvosmuseum.gr/en/node). Recognized as one of the first 100 IUGS geological heritage sites in 2022, the Lesvos Petrified Forest is a hub for research, education, and sustainable tourism.

Recent construction works of the Kalloni-Sigri road brought to the light new fossiliferous localities hosting thousands of fossils including fossilized trees and leaves (Zouros et al., 2022). The road cuts at the new fossiliferous sites enable detailed stratigraphic analysis of the Sigri pyroclastic rocks and a reevaluation of the area's stratigraphy and palaeoenvironmental evolution. This study focuses on the analysis of West Akroheiras section (39.230107°, 25.905465°, 320 m section length, Fig. 1) following a pilot multi-proxy approach and aiming to establish the most effective methods for palaeoenvironmental reconstruction of the Lesvos Petrified Forest monument.

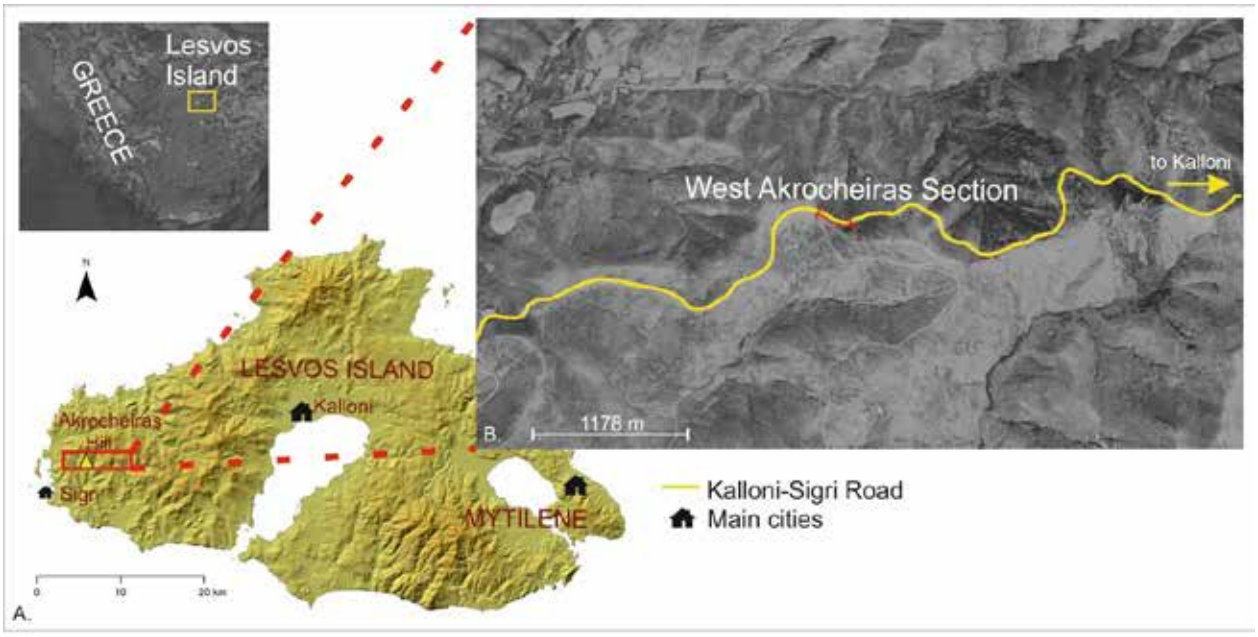

Fig. 1: A. DEM image of Lesvos Island. Main cities and main points of interest are noted. The study area is noted with the red rectangle. B. Satellite image of the study area, where the studied section (red line) is noted.

Geological setting

The volcanic rocks of Lesvos have been extensively studied and mapped, with notable contributions from researchers such as Hecht (1972, 1974a,b), Pe-Piper (1978, 1980) and Pe-Piper et al. (2019), who established the stratigraphic framework and identified key volcanic structures. These formations lie at the top of Permian schists (Katsikatsos et

al., 1982) and marbles, and include the Sigri Pyroclastic Formation, which features pyroclastic and volcaniclastic deposits rich in silicified tree trunks and fossilized leaves (Velitzelos & Zouros, 1997, Zouros, 2021). The Sigri pyroclastics derived from an early Miocene stratovolcano chain (Hecht, 1972; 1974a, b; Pe□Piper, 1980), dating between 21.5 and 18.4 Ma ago (Pe-Piper et al., 2019), with stratigraphic divisions inferred from adjacent geological formations. The volcanic chain follows a NNE-SSW orientation influenced by the dextral strike-slip tectonic regime of the Aegean-Anatolian microplate (Yilmaz et al., 2000). Over geological time, this regime evolved, giving rise to various fault systems, including dextral, sinistral and normal faults during Neogene and Quaternary times. These findings highlight the complex tectonic and volcanic history of the island, contributing to a deeper understanding of its geological evolution.

Material and Methods

Stratigraphic logging was performed in several places of the studied section as the lateral continuity of the layers was interrupted by faults, in addition to the many lateral changes in the nature of the pyroclastic material. The lithological characterisation of the pyroclastic rocks followed Fisher & Schmincke (1984) and Francis & Oppenheimer (2003). The most prominent fallen or standing tree trunks and fossil leaf horizons were noted along with basic sedimentological characteristics. Taphonomic observations of the fossil leaves were made in situ. Bed by bed sampling was also conducted.

Generalised stratigraphic cross sections containing the most important features (characteristic horizons, major faults etc.) were compiled and photos were taken. The sections were digitised later on (using CorelDRAW Graphics Suite), and the respective stratigraphic columns were drawn (using Strater 5 software) (Figs 2 and 3) and correlated. Moreover, very high-resolution Images acquired through Unmanned Aerial Vehicles were used to generate: i. a 2D orthophotomap and ii. 3D textured model, both used for digital stratigraphic measurements (e.g. layer thickness).

A number of rock samples were picked up for selected pilot analysis methods (XRD, organic petrography, micropalaeontologic analyses, and organic geochemistry, as well as systematics and taphonomy of fossil leaves). Powder XRD analysis was conducted on three palaeosoil samples (B6, B13, B23; Fig. 2) in the Department of Geology, University of Patras. Organic petrographical analysis was conducted on five samples (B3, B6 and B12; Fig. 2) also at the Department of Geology, University of Patras. Micropalaeontological analysis for aquatic organism remains (e.g. ostracods, diatoms) was conducted in fifteen samples (A1, A2, A3, A4, A5, B1, B2, B9, B10, B12, B13, D1, D2, Fig. 2) (Department of Geology, University of Patras). Samples B1, B6, B9, B12, B13, B19, B20 and D1 (Fig. 2) were subjected to organic geochemistry analysis at the Birmingham University. The systematic classification of the fossil leaves was based on their macro-morphological characteristics and was performed at the Natural History Museum of the Lesvos Petrified Forest.

Results

West Akrocheiras section consists mainly of coarse tuffs, lapilli tuffs and less of tuff breccia layers intercalated with palaeosoil horizons, with a total thickness of 22 m (Figs 2 and 3, columns C8.1-C8.13). Volcaniclastic layers are also included. Several strike slip faults exist with vertical displacements < 2 m, uplifting the western parts of the section. After correlating the stratigraphic data from the combined study of several sections along the Akrocheiras Hill roadcuts, seven palaeosoil horizons have been recorded in this section (Figs. 2 and 3, PS8.1-PS8.7), separating it in eight units (Units 8.1-8.8, Figs 2 and 3).

Standing fossil trunks were recorded in three palaeosoil horizons (Figs. 2 and 4 - PS8.3, Fig. 3 - PS8.5 and PS8.6). Fossil leaves were recorded in great numbers in many horizons throughout this section (units U8.1, U8.3 and U8.4), both as leaf litter between different layers and also oriented in different directions, mixed with the pyroclastic materials. The lower part of the section (units U8.1-U8.4) exhibits intense volcaniclastic characteristics (conglomerate lenses mostly at the western part).

Unit U8.2 possibly represents deposition of volcaniclastic material in a water body, as implied by the massive unconsolidated pyroclastic coarse ash layer with thickness around 1 m (column C8.1, Fig. 2). In this unit transported coal were found (column C8.2). Unit U8.4 bears a series of pyroclastic flows with leaf litter in at least five horizons (columns C8.2 and C8.3).

XRD analysis in the soil samples revealed that they consist mostly of crystalline intermediate feldspars and clay minerals or/and zeolites. Amorphous inorganic or/and organic material is also included.

Maceral analysis of sample B3 (unit 8.2) obtained from the 1-m-thick coarse pyroclastic ash layer at the bottom of the sequence, proved containing partially charred biomass derived from fresh and/or slightly peatified organic matter, probably of arboreal origin. Several organic fragments display a gelified texture and are heat-affected, as the relatively high mean random vitrinite reflectance values (0.47-2.0%) and the cracks indicate. These partially or totally-

carbonised peaty, and woody fragments may be air-borne transported from the surroundings and deposited there. Sample B6 (unit 8.2) represents a thin black layer, which contains charred particles (semifusinite and degradofusinite) with plasticized edges and displays a mean reflectance of 0.85%. In the same strata, charred particles with thin cell walls (pyrofusinite) are also common, with reflectance values ranging up to 1.4%. Interestingly, several particles display a pre-charring gelification, whereas the in-situ growth of the precursor plants is evident by the included charred corpohuminite particles. Sample B12 (unit 8.3) is characterized as a carbonaceous or sapropelic coaly layer (i.e. elevated liptinite content), with limited thermal affection and VR of 0.5%; the mode of deposition seems to be in a short-lasted water-logged limnic/limnotelmatic environment; an epigenetic thermal influence is evident only by some cracks.

All the samples that were micropalaeontologically examined, were barren. This implies either a non-aquatic environment, unfavorable life conditions (e.g. anoxic) or/and unfavorable preservation conditions (e.g. low pH values).

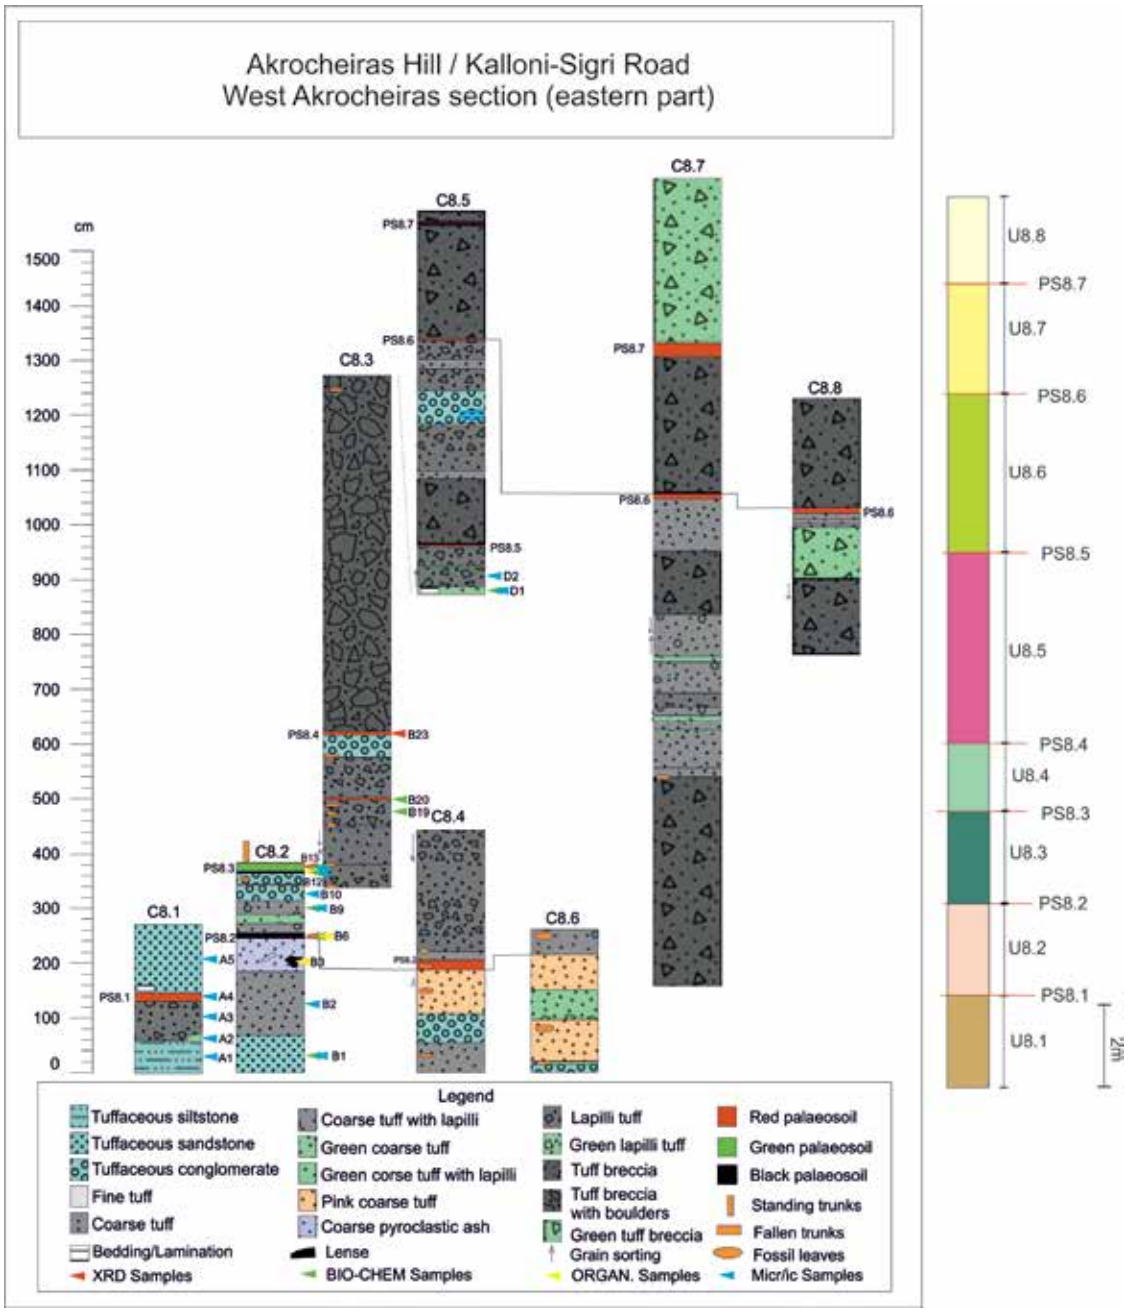

Fig. 2: Stratigraphic columns presenting the logged sequences from the eastern part of West Akrocheiras section. On the right, the units are schematically presented.

Pilot biomarker analyses of the eight samples revealed that the majority of them have plant wax n-alkanes in with only one showing an absence of these compounds. Some samples show some signs of thermal/diagenetic impact (B1), but overall the samples show high potential for organic geochemical work, including sufficient concentrations for compound specific isotope analyses. Some samples appear exquisitely well preserved, comparable with extract leaf matter of modern or very recent age (Holocene). Alkane response varies from 0-91% (samples D1 and B1/B20, respectively). Total Lipid content (TLE) varies from 0.6 mg (sample B19) to 5.8 mg (sample B9). No correlation was found between TLE and the abundance of n-alkanes in the samples. Sample B20 shows a very distinctive pattern where alkanes are persistent but a cluster of broad peaks is observed around C26-C29 alkane response time.
To date, the systematic taxonomy of the fossil leaves has revealed more than 55 plant taxa from West Akrocheiras. The palaeoflora consist of bryophytes, ferns and several angiosperms (including herbaceous and woody monocots, dicots). Among the identified plant taxa, *Daphnogene polymorpha* (A. Braun) Ettingshausen, *Laurophyllum* sp., *Phoenicites* sp., *Rosa* sp., *Nerium* sp., *Myrtophyllum* sp., *Pungiphyllum cruciatum* (A.Braun) Frankenhäuser & V.Wilde and members of Fagaceae family are abundant floristic elements.

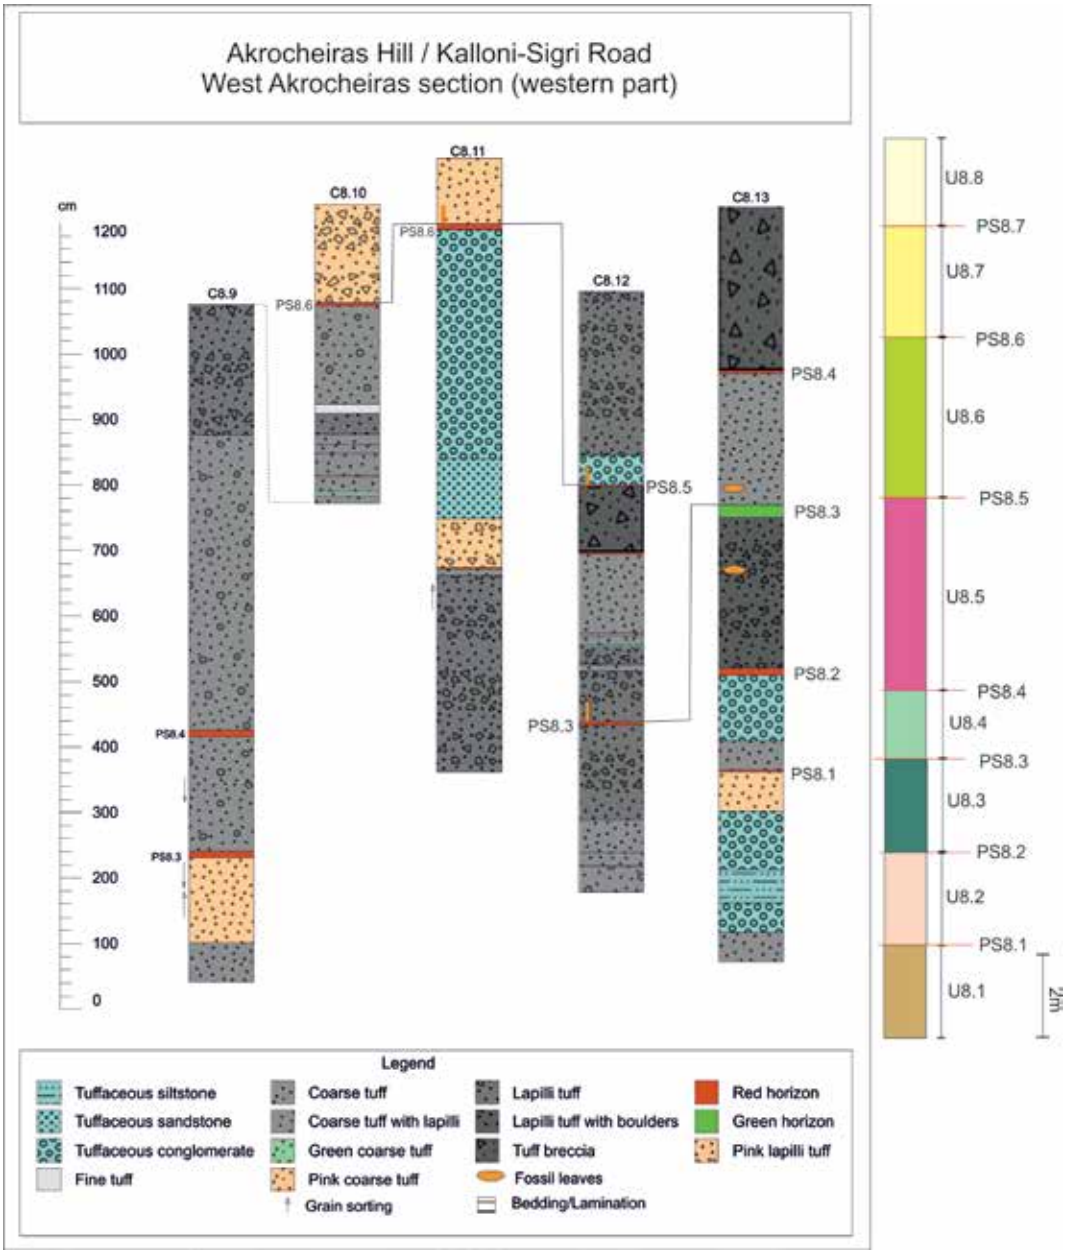

Fig. 3: Stratigraphic columns presenting the logged sequences from the western part of West Akrocheiras section. On the right the units are schematically presented.

Discussion

Palaeosoil horizons were examined in order to distinguish the different eruption phases. In West Acroheiras section at least 8 different eruption phases have been recognized corresponding to units U8.1- U8.8 (Figs 2 and 3).

The pilot studies on the palaeoenvironmental evolution of West Acroheiras section gave encouraging results. The lithology of some layers of the lower part (units 8.1 and 8.2) provides evidence of a water body (layer of samples B1-B2), nevertheless, the micropalaeontological analysis gave no results implying unfavorable life or preservation conditions. The organic geochemical analysis of sample B1 revealed high content of thermally matured organic matter, possibly rapidly deposited under anoxic conditions. Thus, if there was a water body there, then a hot pyroclastic flow must have entered it. This is in agreement with the results of the organic petrography analysis for sample B3, which reveals organic matter charred in various degrees, representing roots and arboreal plants, possibly deriving from a nearby peat-forming environment. The combined analysis of sample B6 from palaeosoil horizon PS8.2 (which marks the end of unit 8.2) reveals a palaeoenvironment with high organic matter content, partially affected by thermal alteration and buried rapidly under anoxic conditions. The very good preservation conditions of alkanes can be also attributed to clay minerals as was shown by the XRD analysis of the same sample.

Unit 8.3 shows volcaniclastic lithological characteristics. The fossil leaves scattered in the layer, reveal the deposition of transported material. Both organic petrography and organic geochemistry analyses of palaeosoil horizon PS8.3 show preservation of organic material (samples B12/B23). The palaeoenvironment is characterized as water-logged with limited thermal affection. On this palaeosoil horizon a remarkable fossilized standing tree trunk has been preserved (possibly a giant *Sequoia* tree, typically thriving on soils with good moisture retention). It is worth mentioning that the layers of units 1-3 show limited lateral continuity.

Fig. 4: Fossil giant *Sequoia* trunk standing on palaeosoil horizon PS8.3 in West Akrocheiras section.

Unit 8.4 bears a lot of fossiliferous layers. Fossilized leaf litter (fossil leaves laid on fine-grained horizons) were found at various levels along with transported fossilized leaves and trunks scattered in the pyroclastic material. Organic geochemical analysis of sample B19, deriving from a lapilli tuff layer with scattered fossilized leaves and trunks, gave low values of alkane response and TLE relatively to samples from palaeosoil horizons such as sample B20 but still includes organic remains. According to Retallack (1984), the preservation of leaves and wood in non-calcareous environments is only possible in water-logged environments with $0<Eh<200$ mV and pH 2-5. Thus, the pyroclastic flow that generated this specific layer contained a sufficient amount of acidic water for the preservation of fossilized plant material and thus the depositional environment was anoxic. Sample B20, from a small palaeosoil horizon, gave evidence for a dry climate and a terrestrial environment (where waxy coatings on plants were more prominent) possibly consisted of vascular plants, trees, shrubs and herbaceous elements.

The systematic taxonomy of fossil leaves indicates a rich flora dominating different habitats such as riparian and mesophytic forests in the lowlands and adjacent surroundings. Several plant taxa including ferns, diverse palms (e.g, *Phoenicites* sp.), *Daphnogene polymorpha* suggest proximity to a water source, while others such as *Laurophyllum* sp., *Nerium* sp. and Fagaceae spp. are indicative of well-drained soils.

Units 8.5 to 8.8 present more thick and coarse-grained, organic matter-lean layers.

Conclusions

- The stratigraphic analysis of West Akroheiras section allowed the identification of at least eight different eruption phases recorded in the layers of this section (units 8.1-8.8). Based on standing fossil trunks at

least three forests had developed on some of the palaeosoil horizons of this section. Detailed stratigraphic analysis of the volcaniclastic sequence serves as a basis for the synthesis of the results from all methods and for palaeoenvironmental reconstruction.

- The taxonomy of the fossil leaves so far has revealed a mosaic of habitats such as riparian and mesophytic forests occurring in the broader area. The high alkane response and/or TLE implies decomposition and chemical transformation of organic matter (plants, algae or/and microrganisms) and favourable conditions for organic matter preservation (e.g. anoxic conditions, rapid burial and presence of clay minerals).
- The preservation of leaves and wood in non-calcareous environments is only possible in water-logged environments with 0<Eh<200 mV and pH 2-5 (acidic environments). Thus, evidence for the physicochemical conditions of the water-saturated layers is provided.
- Organic petrography on palaeosoil horizons gave evidence for water-logged environments amongst others.

The diverse methods revealed that there is a great potential in clarifying the Miocene palaeoclimatic and palaeoenvironmental conditions of the Lesvos Petrified Forest and this potential is multiplied when these methods are applied in combination. In the future more systematic and detailed analyses are needed in order to fully unravel the history of the area, its palaeoclimatic and palaeoenvironmental evolution.

Acknowledgements
We would like to sincerely thank Ass. Prof. Lambropoulou Paraskevi for the XRD analysis.

Comparing broadband and strong-motion data using collocated sensors in the HP network, Greece

Papageorgiou A.[1,2], Ktenidou O.-J.[1], Pikoulis E.-V.[1], Sokos E.[2]

[1] *National Observatory of Athens, Greece*

[2] *University of Patras, Greece*

Introduction and motivation

High-quality seismic data is of great importance in a wide range of seismological applications and studies, whether focusing on the source, path or site effect. Errors related to the sensors (calibration, orientation, or installation issues) or erroneous metadata may produce unreliable data that do not reflect true ground motion, either in all or in part of the frequency range of interest. We select stations of the Hellenic Unified Seismic Network (HUSN), and in particular the two networks that possess a significant number of co-located broadband and strong-motion sensors, namely HL (National Observatory of Athens; DOI:10.7914/SN/HL) with 24 co-located stations, and HP (University of Patras, DOI:10.7914/SN/HP) with 11 co-located stations. Our aim is to scrutinize their data over their frequency band during all periods of joint operation, in order to understand to what extent, the data from the two sensors agree and investigate potential discrepancies. In the abstract at hand, we focus on the HP network (Figure 1. black diamonds represent the collocated stations of HP network).

Figure 1. Map of collocated stations in Greece. HP stations appear as black diamonds.

Methodology

To perform a detailed analysis, we developed a targeted in-house code for data processing. We compiled a dataset of more than 1000 recordings from a total of 11 collocated sensors for the time period 2012-2023. Our records are of events with magnitudes M4 or larger, out to distances depending on magnitude. Our starting point was the NGA-West2 and NGA-East processing protocols by PEER, UC Berkeley (Kishida et al 2016) and the recent automated processes of Cauzzi et al. (2022). After inspecting the raw waveforms and identifying clipped data, we manually process them in the time and frequency domain, considering both horizontal components per event.

First, in the time domain we: perform visual inspection and detect issues such as lags (Figure 2. left) or amplitude discrepancies (Figure 2. right) in the time domain, manually pick P and S arrivals to select signal and noise windows, calculate peak-to-peak ratios (Figure 2. bottom) and inspect them with time. After that, in the frequency domain we perform visual inspection of S-wave and noise FAS (Fourier Amplitude Spectrum) of acceleration, examine the usable bandwidths, and calculate FAS ratios (Figure 3.).

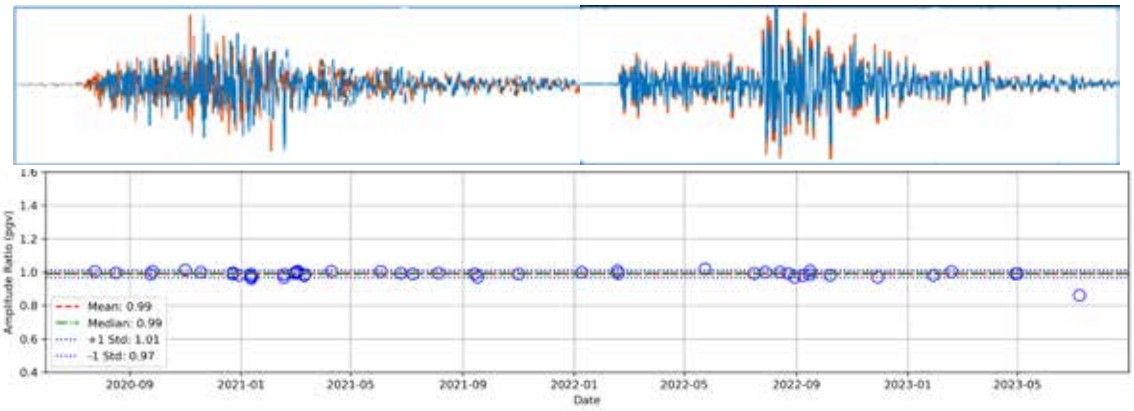

Figure 2. Top: Comparison of waveforms and problem detection in time (left) and amplitude (right). Bottom: peak amplitude ratio for a single component with time: no discrepancy observed.

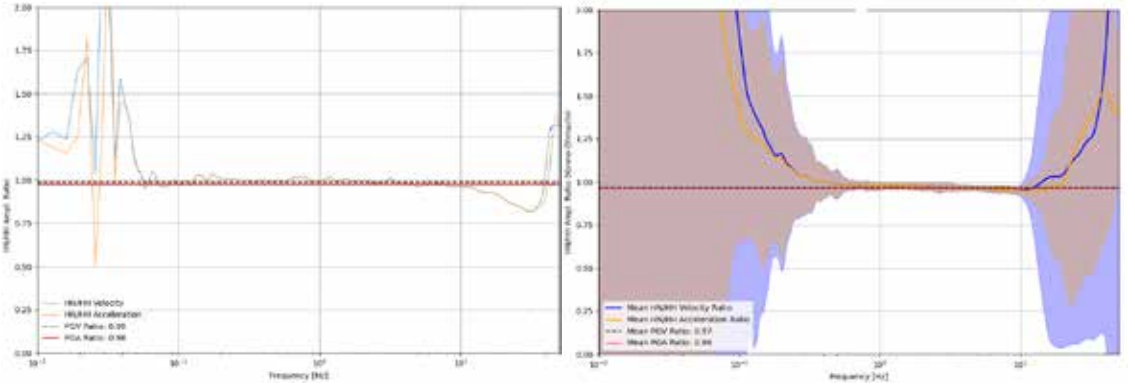

Figure 3. FAS ratios (SM/BB) for a single event (left) and average ratios for a station (right).

Results and conclusions

In this work we attempted a careful visual inspection of data from the collocated stations of the HP network in both the time and frequency domain, with the aim of compiling parameters that describe and assess data usability. By examining the observed discrepancies, we identify and amend certain underlying errors in sensor response. We compare the usable frequency between channels, per station, and assess data reliability and usability in the frequency domain. We calculate peak amplitude ratios for the 2 sensors per component and investigate if this deviates from unity, either persistently or sporadically. We identified GPS problems (time lags), component errors (amplitude discrepancies due to hardware), and metadata issues. Issues detected are fed back to the operator, so these findings contribute to network health monitoring and highlight potential for system improvement. Studies such as this one can help underline the potential impact that amplitude or time issues may have on several methods, including event location, tomographic studies, source analysis (moment tensor, slip inversion, etc.), as well as strong-motion applications, shakemaps, and dynamic analyses of structures.

EXTENDED ABSTRACT 242

Groundwater changes and induced seismicity influencing surface deformation in post-mining landscapes

Introduction

In this study, we employed advanced interferometric time series analysis to explore the relationship between water level variability, seismicity, and induced surface motion over the Gardanne coalfield (Figure 1), while also accounting for potential long-term contributions. A spatio-temporal investigation of surface motion measurements was therefore conducted using data from the Copernicus Sentinel-1 mission, ultimately aiming to attribute the observed motion to a deformation mechanism.

The Gardanne coalfield, located in southern France between Marseille and Aix-en-Provence, was mined from the 17th century until 2003. Different techniques were employed along the basin with the deepest exploitation reaching up to 1300 m depth to the west of the basin (Dominique *et al*., 2022). The gradual progression of the mine workings to the west of the basin was affected by groundwater flow and pumping was considered essential to lower the water level and allow access to deeper levels. After mining ceased in 2003, the ending of pumping led to the flooding of the mine, with groundwater levels stabilizing around 2010. Since then, water level is relatively stable by pumping, with annual fluctuations of about twenty meters (Dominique, 2016).

With the gradual rise of the underground water level microseismicity was felt by the population in 2010 and a strong seismic swarm occurred in November 2012. Since then, swarming seismic activity lasting a few days has been re-appearing periodically in the same area, especially in November 2012, December 2014, November 2016 - March 2017 and August 2017. Prior analysis of seismic data revealed apparent connection of seismic activity with seasonal changes of underground water level in the mine, as well as with pumping rates (Dominique, 2016). Further analysis showed that swarming activity is related to the reactivation of minor fault segments being favorably oriented with respect to the local tectonic stress field (Dominique *et al*., 2022). However, no impact on the surface has been observed in post mining period that would indicate collapses of underground mining works (Namjesnik *et al*. 2022).

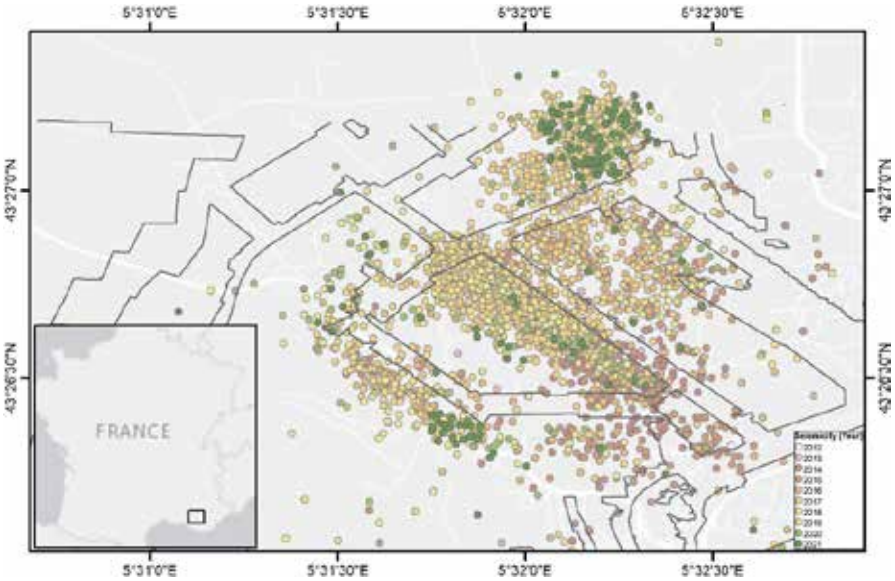

Figure 1. Gardanne coal mine area with observed seismicity (Ineris, BRGM). In the background the coal mine workings are depicted with black lines.

Methods / Results

Post-mining surface deformation detected from multi-temporal interferometric processing for the period from April 2015 to December 2022 via the SNAPPING service (Foumelis *et al*., 2022) revealed deformation patterns spatially correlated with the epicentral area of the 2016-2017 Gardanne micro-seismic activity (Figure 2). The temporal evolution of surface motion shows a signal attributed to induced seismicity, evidenced by a clear change in the displacement time series during this specific period.

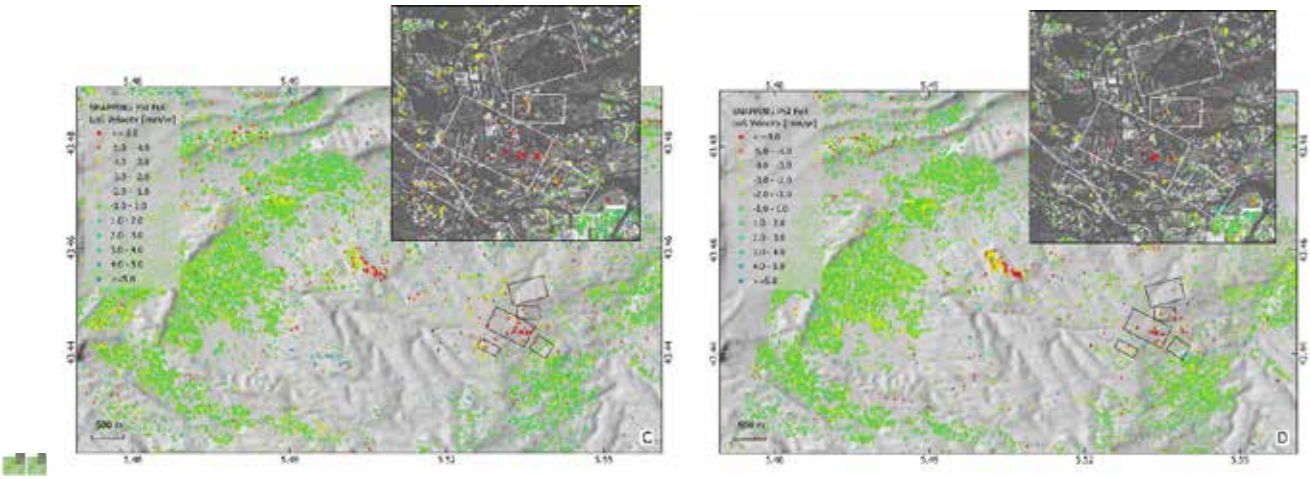

Figure 2. Surface motion rate along the LoS considering the period 2015-2022 and SNAPPING PSI processing schemes for ascending (a) and descending (b) satellite tracks. The rectangles outline the clusters of seismicity.

Geometric decomposition of the ascending and descending LoS measurements confirms the above observation, showing prevailing vertical motion with a negligible E-W component. This is also consistent with the focal mechanisms of major recorded events, which indicate normal faulting, typical of post-mining sites.

To investigate the relationship between seismicity locations and observed surface motion, we performed spatial clustering of micro-seismicity using the k-means algorithm. This process resulted in 5 distinct clusters (Figure 2), which accounted for ~80% of the total number of events in the catalogue within the epicentral area. It is apparent that seismic activity increased after each pumping phase, with a notable correlation between the magnitude of water table lowering and the frequency of seismic events. The consecutive drops in the water table during 2015 and 2016 contributed to the largest seismic swarm of late 2016 - early 2017, also coincided with the largest surface motion signal. An overall consistency was observed between the timing of micro-seismic events and the occurrence of surface displacements across the various seismic clusters.

Although the interpretation of the measurements until early 2017 is straightforward, it becomes more complex when examining the seismic activity and related surface motion for the August 2017 swarm. This signal seems to extend well beyond the main epicentral region, representing a seasonal subsidence component observed in the inter-annual displacement time series from 2015 to 2022. This seasonal signal might mask the maximum motion, potentially impacting the assessment of deformation caused by post-mining seismic activity during this period.

Conclusions

Our findings suggest that the observed surface motion is likely a result of energy released by both seismicity and aseismic motion caused by fluctuations of the mine's water table. The onset and variability of surface motion may also be controlled by the heterogeneity of the mine workings, such as differences in the gallery dimensions and the lithological composition of the overlying lithology.

Introduction

The groundwater system of Larissos has poor chemical status due to human activities in the area. Due to the high-water needs of the population, aquifers have been underused for many years and have degraded the quality and quantity of groundwater. As a result, aquifers have been in a state of over pumping for decades, which has led to a reduction in the water table, which has reached negative absolute altitudes, and to the occurrence of seawater intrusion, particularly in the northern and north-eastern part of the region. In addition, the aquifers are also affected by the agricultural activity taking place in the study area, resulting in locally elevated nitrate (NO_3^-) values. Through sampling and chemical analyses carried out in the laboratory, these phenomena of seawater intrusion and increased nitrate values are observed and are shown in the graphs. Chemical analyses were carried out for the determination of major cations (Ca^{2+}, Mg^{2+}, Na^+ and K^+ and major anions (HCO_3^-, SO_4^{-2}, Cl^-, NO_3^-, NO_2^-, NH^{4+} and PO_4^{2-}). In the Laboratory of Hydrogeology of the Department of Geology at the University of Patras, all analyses were carried out in accordance with the suggested procedures and standards. The Na^+, K^+, Ca^{2+}, Mg^{2+} were measured using a Perkin Elmer atom absorption spectrometer. The HCO_3^- were determined by indicator H_2SO_4 titration. The other main anions were measured by a Hach® DR 4000 spectrophotometer.

Study Area

The study area is located in northwestern Peloponnese, and specifically in the prefecture of Achaia, and occupies an area of approximately 163 km^2. The main river in the study area is the Larissos river. The main riverbed of Larissos is 19,5 km long, originating from mountain Movri and emptying into the Prokopou lagoon. It is one of the most important sources of surface runoff in the area and collects water from various streams along its course. In addition, the river also receives overflows and excess water from the irrigation ditch from the Pinios river. The Larissos groundwater system is mainly developed in deposits dating back to the Neogene and Quaternary periods.

According to data from the “River basin management plan”, the groundwater system of Larissos is estimated to have an average annual supply of approximately $26 \cdot 10^6$ m^3/y and the total annual water withdrawal is $33 \cdot 10^6$ m^3/y. These quantities are used to fill the supply needs of irrigation and water supply. Furthermore, the hydraulic characteristics of the system, such as hydraulic conductivity and storage coefficient, also have been calculated and equal $3{,}5 \cdot 10^{-5}$m/sec και 5-8% respectively.

Geology

The Larissos groundwater system is structured by rock formations of the tectonostratigraphic zone of Ionian and is mostly covered by sediments dating back to Neogene and Quaternary periods. In particular, the Ionian zone includes limestones of Upper Jurassic to Palaeocene age and Eocene flysch. The postalpine sediments include sands, screes, recent cones of scree, eluvial formations, terrestrial and torrential deposits and alluvial deposits dating from Quaternary period and friable sandstones, sandy clays and yellowish to grey clayey marls from the Neogene (Figure 1). Geomorphologically, the study area is divided into flat zone (79,23%), semi-mountainous zone (13,42%), hilly zones (4,95%) and lagoons (2,40%). It is observed that the transition from flat to the hilly and mountainous zones is gentle and smooth (Stavropoulos, X., 1992).

Hydrogeology

In the study area there are two types of aquifers, the first is found in carbonate rocks and the second in sediments that are dating in Neogene and Quaternary periods (Stavropoulos, X., 1992). The hydropermeability of geological formations depends on the porosity, the size, the shape and the distribution of the grains. The geological formations of the area are classified into three categories based on their hydro-lithological behavior. The first category concerns hydropermeable formations which allow water to penetrate and circulate and include formations of the Holocene age such as scree, recent cones of scree and alluvial deposits. The second category includes semi-hydropermeable formations which have low permeability and can store and allow water to flow but at a low rate. These include formations dating from the Pleistocene and contain pebbles, sandstones, clays and clay marls. The third category includes impermeable formations, such as flysch, which do not allow the flow of water.

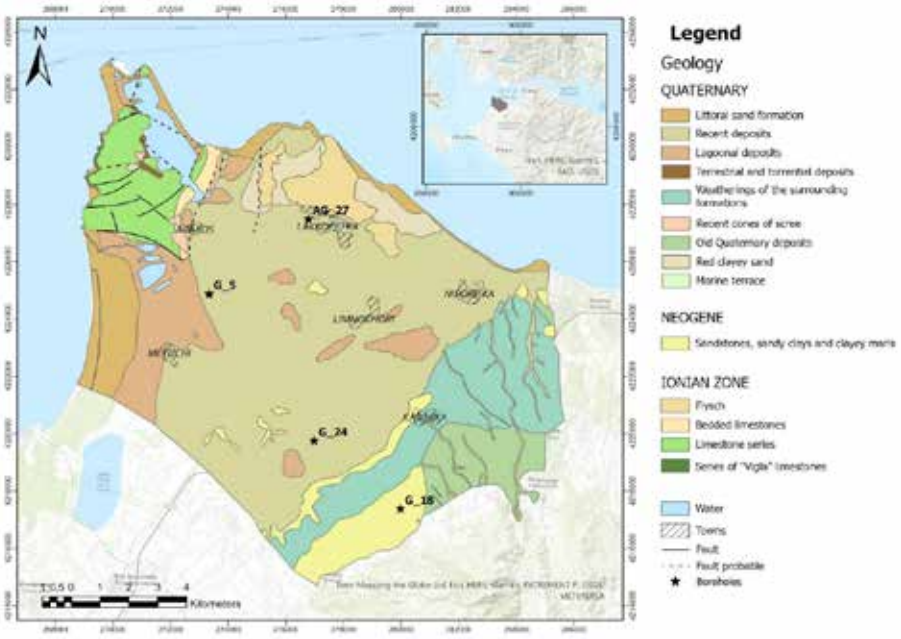

Figure 1. Geological map of study area (modified from I.G.M.E., 1977-1980)

Results and Discussion

Characteristics of groundwater hydrochemistry

Table 1 indicates the physicochemical characteristics of water samples. Especially, the electrical conductivity depends on the temperature and the amount of dissolved salts in the water. When high values of electrical conductivity occur then there is likely to be water pollution (Kazakis N., 2013). It is observed by Figure 2 that in boreholes G_24, G_5 and G_18 the values of electrical conductivity range from 630 μS/cm to 1600 μS/cm, while in borehole AG_27 the values are very high and exceed 2000 μS/cm. The pH expresses the concentration of hydroxide cations (H3O+) in an aqueous solution. The solution is neutral when pH = 7, acidic when pH < 7 and alkaline when pH > 7. It is observed that in boreholes G_24, G_5 and G_18 the pH values increase with depth and the water solution can be classified from acidic to alkaline, while in borehole AG_27 there is a decrease in pH values. The Oxidation Reduction Potential (ORP) gives information about the oxidation state of the elements in an aqueous solution. The water is called reductive when the values are negative and oxidative when it shows positive values (Mandhlaras, D., 2005). It is observed that borehole G_24 shows negative values, borehole G_5 has both positive and negative values and boreholes G_18 and AG_27 have positive values. Dissolved Oxygen (DO) provides informations on the exposure of groundwater to atmospheric air. When the values are zero or very low then the water is old and non-renewable. It is observed that all boreholes have low values ranging from 1.5 mg/l to 5.8 mg/l. The total dissolved solids are a parameter that related to electrical conductivity and depends on the type of rock through which the water and its flow velocity. For values of TDS<1000 mg/l the water is classified as fresh (Davis – DeWiest, 1966). It is observed that in boreholes G_24, G_5 and G_18 the values of TDS range from 270 to 575 mg/l, while in borehole AG_27 the values reach 857 mg/l. The increase in calcium ions is associated with the initial stages of salinization where cations are exchanged as Ca^{+2} is released and Na^{+}, Mg^{+} and K^{+} are absorbed from seawater (Walraevens et al. 1993). It is observed that all boreholes show high values and in borehole AG_27 the values reach 310 mg/l. Sodium ions are associated with the infiltration of seawater and its mixing with fresh water. The concentration of Na^{+} increases with the continuous pumping of aquifers. It is observed that boreholes G_24 and G_18 have values ranging between 20 mg/l and 32 mg/l, while boreholes G_5 and AG_27 have higher values up to 134 mg/l (Figure 3). Cloride ions are associated with seawater infiltration and their high value indicates high pumping conditions. It is observed that in boreholes G_5 and AG_27 the values are >100 mg/l and in boreholes G_24 and G_18 they range between 40 mg/l and 51 mg/l (Figure 4). Nitrate ions in groundwater are associated with agricultural activities that cause contamination of the aquifer (Figure 5). It is observed that all boreholes have high nitrate values while boreholes G_18 and AG_27 have the highest. The Revelle factor is a parameter for the identification of salinization. For seawater it takes values >150 and for good water the index has values <1 (Kalergis, G., 2000). It is observed that the water of boreholes G_24, G_18 and AG_27 is good while the water of borehole G_5 is slightly contaminated.

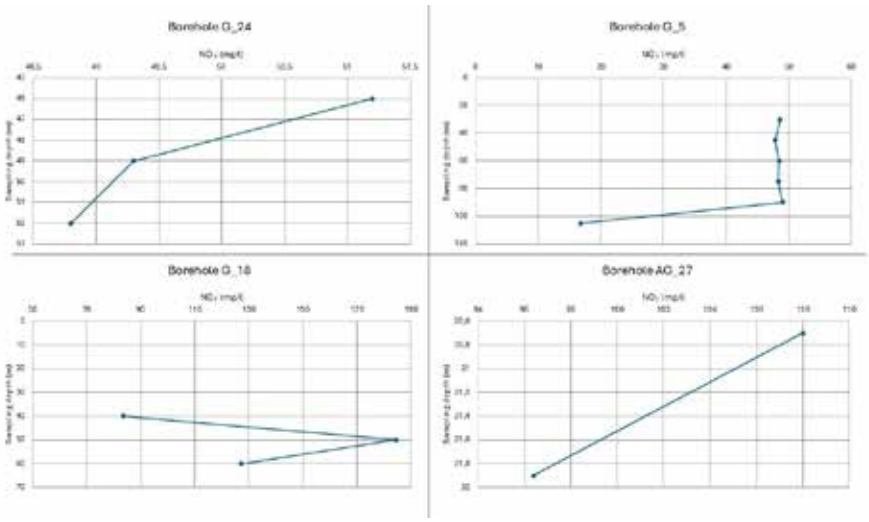

Figure 5. Profiling of NO_3^- in the four boreholes of study area

Study of hydrochemical facies

With respect to the main cations and anions in solution, it was determined that the hydrochemical facies changed from the low salinity Ca^{2+}-HCO_3^- type to the Na^+-Cl^- type as salinity increased (Mahlknecht et al., 2017). Typically, samples with higher salinity have been identified close to the coast or in areas that had been severely affected by the hydraulic gradient inversion, while samples with lower salinity were found further from the coast (Tamez-Meléndez et al., 2016). The Piper diagram at Figure 6 (a) shows the two main water chemical types of Ca-HCO_3 and Ca-Mg-Cl. Also, the samples from boreholes G_18 and three samples from G_5 is mainly dominated by type Ca-Mg-HCO_3 or types of Mg-Ca-HCO_3. The samples from boreholes AG_27 and the other samples from G5 appear to be enriched in Cl. According to the results figure 6 (b) shows the Schoeller Berkaloff diagram. This diagram shows the groundwater samples in different depths of mains cations and anions respectively. Moreover, in the Schoeller diagram the water samples show high concentrations of Ca, Na, Cl, and NO_3 in relation to low concentrations of SO_4 and Mg. For borehole G_24 the diagram shows that with increasing depth the concentrations of the elements decrease. Also, in borehole G_5 the lines of the samples in depths 30, 45 and 60 m appear almost parallel. In addition, in relation to the next three sampling depths 75, 90 and 105 m the samples are enriched in all elements. Regarding borehole G_18, the concentrations of the elements are low at the depth of 40 m compared to the next two depths, and specifically the NO_3 at the depth of 50 m are increased compared to the depth of 60 m. In addition, all major ions except nitrate increase with increasing depth.

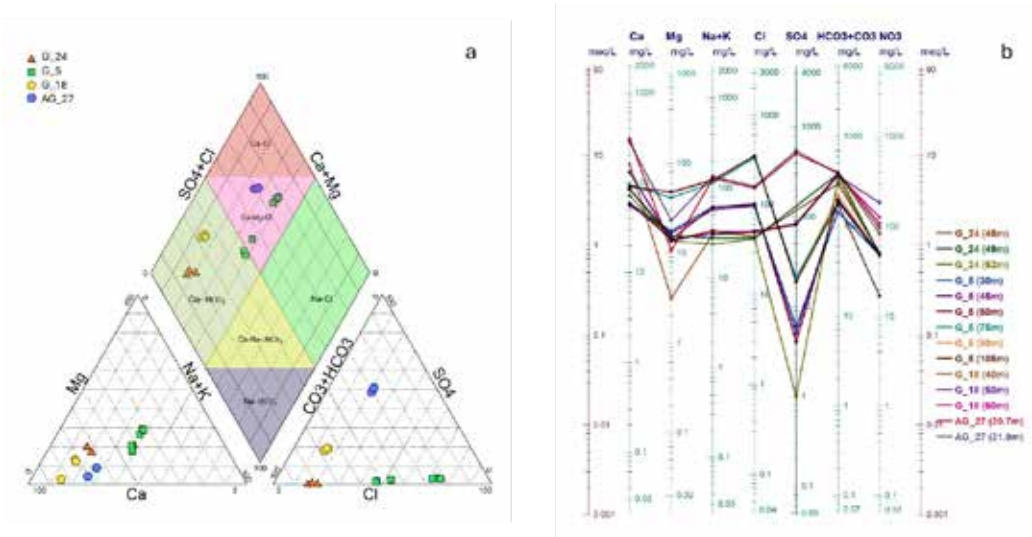

Figure 6. (a) Piper diagram showing the water type; (b) Schoeller Berkaloff diagram

Conclusions

The samples were collected from different depths and analyzed for physicochemical parameters, major cations, and anions. The interpretation was carried out using Piper and Schoeller–Berkaloff diagrams. During the cation exchange phenomena with seawater intrusion, the hydrochemical facies of groundwater evolves from Ca–HCO_3 to Na–Cl. Ion exchange is one of the fundamental geochemical processes occurring during the salinization of groundwater. The seawater intrusion leads to an increase in Na^+, Mg^{2+}, and SO_4^{2-} concentrations due to ion exchange. The geochemical processes controlling groundwater chemistry in the research area include ion exchange, carbonate production, mineral precipitation, and seawater intrusion (Salem and Osman, 2017). Moreover, the dissolution of gypsum in coastal aquifers containing gypsum beds results in more complex water–rock interactions when freshwater mixes with saline fluids or seawater (Campana and Fidelibus, 2015). Two groups of groundwater were identified on the Larissos groundwater system of Ca-HCO_3 and Ca-Mg-Cl according to Piper diagram. As the above results show that the borehole AG_27 faces the most serious problem regarding seawater intrusion. The borehole AG_27 exhibited high electrical conductivity values, with elevated concentrations of Na^+, Cl^-, and SO_4^{2-}, indicating possible influence from seawater intrusion or interaction with evaporate formations. In contrast, borehole G_5 showed dominance of Ca^{2+} and HCO_3^-, classifying it as a Ca–HCO_3 type, particularly at lower depths. At greater depths, however, an evolution toward a mixed Ca–Mg–Cl type was observed. The gradual increase in ion concentrations with depth in borehole G_5 can be attributed to the fact that deeper groundwater has a longer residence time within the aquifer and comes into contact with rock formations richer in soluble components, leading to ion enrichment in the water. The sudden decrease in electrical conductivity was created at lower depths in G_24. Borehole G_24 exhibits stable physicochemical parameters, with minor variations among the samples collected at depths of 46, 49, and 52 meters. The major ions show consistent concentrations, with a dominance of Ca^{2+} and HCO_3^-, classifying the water as Ca–HCO_3 type. The concentrations of Na^+, Cl^-, and SO_4^{2-} are low, with no indication of seawater intrusion. Moreover, in all boreholes, the concentration of NO_3 decreases with respect to the depth, except for the borehole G_18, where at the intermediate depth their concentration is increased. In addition, the concentration of Cl increases in relation to the depth of the borehole, and in particular the boreholes which are located near to the coast have high concentrations of Cl. Consequently, the borehole sample logging helps to find out the interactions of freshwater and saltwater in coastal areas. This strategy is expected to support a much wider range of coastal aquifer research. The study highlighted the importance of vertical sampling and multiparametric analysis in understanding the qualitative evolution of aquifers and identifying zones of contamination or salinization. The results contribute to the management of groundwater resources in areas with complex geological and hydrogeological conditions.

Assessment of the groundwater vulnerability using DRASTIC method in Larissos watershed, Greece

Papailiopoulou Maria., Chrisanthakopoulou K., Stavropoulou V., Pouliaris, C., Kazakis, N. and Zagana, E.

(1) Faculty of Natural Sciences, Department of Geology, University of Patras, Greece

Introduction

Especially in the world's arid areas, groundwater provides the only source of water because of its extensive supply, low sensitivity to pollution compared to surface water, and storage capacity (Zghibi et al., 2016). In addition, as groundwater is the primary supply of drinking water, it is crucial to determine how vulnerable it is to anthropogenic contamination (Iqbal et al., 2015). Therefore, nitrate contamination of groundwater due to agricultural practices and an important increase in the use of fertilizers is becoming an increasingly serious problem (Zghibi et al., 2016). The probability with which a contaminant introduced into the ground surface might enter and spread throughout groundwater due to human activity is known as inherent vulnerability having consideration given to the region under research's natural geological, hydrological, hydrogeological, and hydrogeochemical characteristics (Zghibi et al., 2016). In most parts of the world, groundwater reservoirs are the only supply of water that is drinkable, yet they are rapidly transforming into a resource that is not renewable (Udosen et al., 2024). Aquifer vulnerability has been evaluated using DRASTIC, a reliable and validated vulnerability model (Aller, n.d.) (Kazakis and Voudouris, 2015). The acronym DRASTIC originates from the parameters that the model is intended to assess: depth to groundwater (D), net recharge rate (R), aquifer media (A), soil media (S), topography (T), impact of vadose zone (I) and hydraulic conductivity rating (C). The study proposes to develop and carry out an assessment tool that uses a geographic information system (GIS) and the DRASTIC model to control the groundwater vulnerability of the watershed of Larissos in Greece. Assessing the relative importance of the DRASTIC criteria for determining aquifer vulnerability is an additional objective of this study.

Study area

The study area is located in the north-west part of Peloponnese, which is located in Greece (Fig.1). The mean annual precipitation is approximately 781 mm, and the temperature it is observed in the months of July and August reaches approximately 27.4°C, while the minimum is placed at month of January with rising around 10.2°C is 10.2 °C these values were estimated based on five years of records (2020–2024) which collected in the study area. The study area is characterized to numerous rivers, from east to west with the main river being the Larissos. Characteristic of the Ionian series in the Lower Cretaceous is the plunge of the watershed that originated due to the taphrogenesis and the deposition along it of Vigla limestones-rich in planktonic organisms-due to the high rate of sedimentation (Karakitsios, 1995). Also, the overlay of "Pantokrator" limestones is found from the Vigla limestones, a fact attributed to a large extent erosion of the stratigraphic sequence. In the deposition phase of limestones of the Upper Senonian, the conditions of carbonate sedimentation they are homogenous until the Eocene, with characteristic features the low rate of sedimentation and the partial supply of material from the Pro-Apulias to the west and Gavrovou-Tripoli to the east, favorable for him formation of micro-breccia and micro-conglomerate limestones with Nummulitidae. Finally, like any sequence, likewise the sequence of Ionia Zone ends with the presence of the flysch. These are clay exchanges, marls, sandstones, siltstones and conglomerates, starting from their deposition in the Eocene, which also reflects its change sedimentation from carbonate to clastic (appearance of Pliocene deposits and Quaternary deposits). It is observed that a wide range of faults in its northwestern and southeastern parts of study area with dominant directions W-E, N-S and SW-NE respectively. The majority of faults occurring within the boundaries of our study area are recorded in the carbonate series and in alluvial deposits.

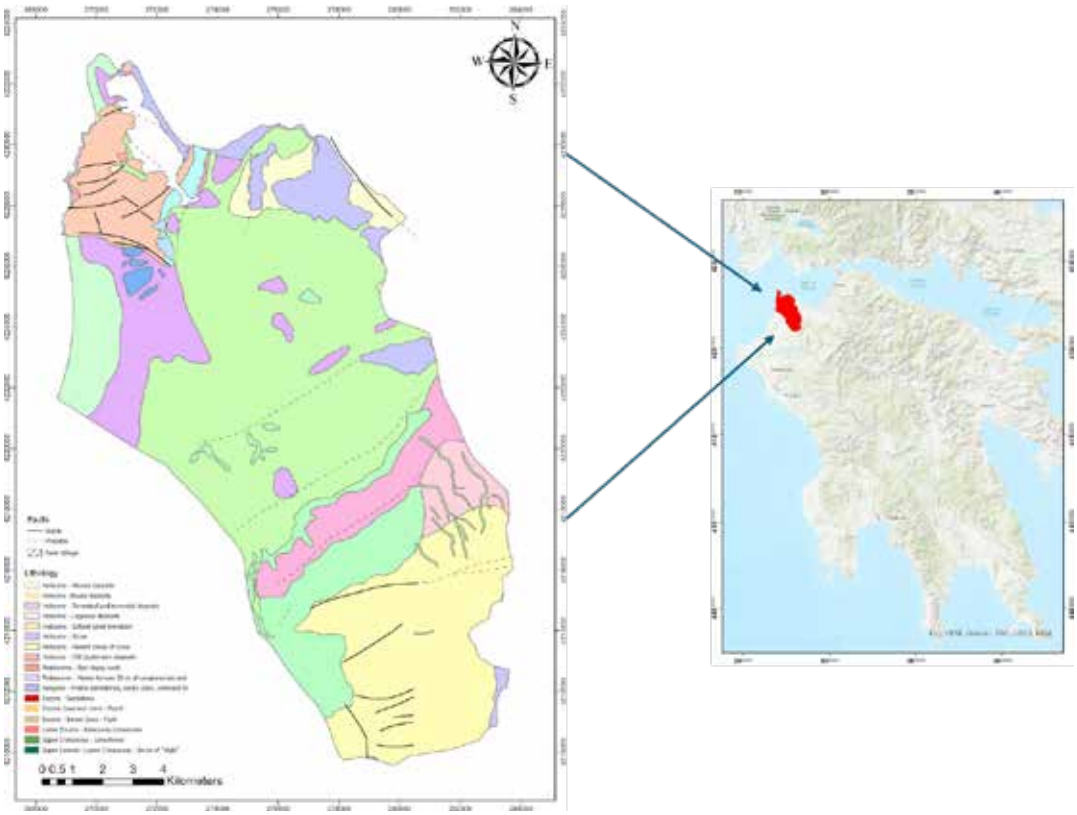

Figure 1. Geological map of study area (modified from I.G.M.E., 1977-1980)

Materials and methods

This is one of the most important parameters in the methodology DRASTIC (Table 1) as it determines the time required until the pollutant reaches the aquifer. Great depth of groundwater indicates a long-time transport interval of the contaminant in the groundwater and sufficient thickness of it unsaturated zone resulting in the weakening of the pollutant and the greater aquifer protection. The hydrological parameters that are widely used for the application of the method in areas with granular formations is seven in number and are also the acronyms of the term DRASTIC and are as follows:

The DRASTIC index is calculated as follows:

DI=DrDw+RrRw+ArAw+SrSw+TrTw+IrIw+CrCw

r index is the value of the parameter

w index is the weight of each parameter

Table 1. DRASTIC weighting and ratings for every DRASTIC parameter (Aller et al., 1987)

Results and discussion

This work analyzed the DRASTIC model to accurately and effectively assess groundwater vulnerability (Ozegin et al., 2024). The primary factor influencing aquifer vulnerability is water table depth, which is the height between the thickness of subsurface earth components and the water level (Rahman, 2008). The distribution of the parameter in the bounded area differs from point to point, as seen in the groundwater depth thematic map (fig. 2a). Low values of the depth are observed in the NE part of the area, while the high values of this dominate the SW side of the watershed. Moreover, high recharge indicates a higher

vulnerability to contamination. This is due to the fact that increased internal water movement could transport more pollutants (Jesiya and Gopinath, 2019). High values of recharge dominate in the NW part of the watershed, on both sides the lagoon Kalogria, characterized by gentle slopes and the heavy rains (fig. 2b). Conversely, low values of R occur in the NE, NW and N part of the study area, with its prevailing large slopes and small amounts of rain. Aquifer media are different kinds of geological formations that serve as pathways for the transmission and storage of water. The aquifer's media shows a lower vulnerability to groundwater when the grain size is smaller (Saha and Alam, 2014). The distribution map of parameter A the prevailing type of aquifer in the study area is lithological consisting of sand and gravels (fig. 2c). As most of the area consists of the specific combination of materials, the study area calibrated mainly with 8. However, the study area indicates different aquifer material. In the NW part of the watershed karstified limestone and sandstone layers are noted and limestones with layers of clay in the southern part of it. The study area at these positions is rated with 10 and 6 respectively. The soil media affect the area's replenishment and have a greater impact on the movement of contaminants across the geologic layers (Bhuvaneswaran and Ganesh, 2019). In the case of this parameter, the data is not sufficient and consequently the map of soil cannot be carried out. An inclined gradient angle increases the intensity of water discharge and reduces pollution susceptibility, but a small slope angle supports significant contaminat migration with water, which is absorbed through a vertical channel (Ozegin et al., 2024). According to the map of the T parameter the study area in almost its entire extent is represented by gradients >18%, so it is rated as 10 (fig. 2d). However, the distribution of slopes it is different in the NW and SE part of the watershed and in a limited part of that in the NE, because of the increase in altitude. Also, with the territory of gentle slopes favoring active infiltration. The domain that extends before the water table and is an aeration zone is known as the vadose zone (Ahmed et al., 2015). For the study area, in the case where clay minerals dominate in the unsaturated zone and its thickness is large, the length of time the contaminant remains in the unsaturated zone increases and this results in its weakening and preventing the infiltration to the groundwater. According to the results are observed 3 different lithologies (fig. 2e). Almost completely the unsaturated zone in the watershed of Larissos consists of sand and gravel with significant percentage of silt and clay. Also at the center of it are places where the unsaturated zone consists of sand and gravel and the value of parameter is 8. On the contrary, to the west of the watershed is observed the value 3, indicating that the material of the unsaturated zone is detailed. By indicating the aquifer's capacity to transport water, C affects the rate at which contaminated material moves through the groundwater system (Aller et al., 1987). In addition, the size of an unconsolidated aquifer's pores and the interconnected of its intergranular void spaces affect its hydraulic conductivity. As particle size increases, hydraulic conductivity decreases (Ozegin et al., 2024). High water values hydraulic conductivity corresponds to high values of water permeability. The different calibration of values is shown in while the distribution of the parameter in the watershed is shown with the distribution map (fig. f).

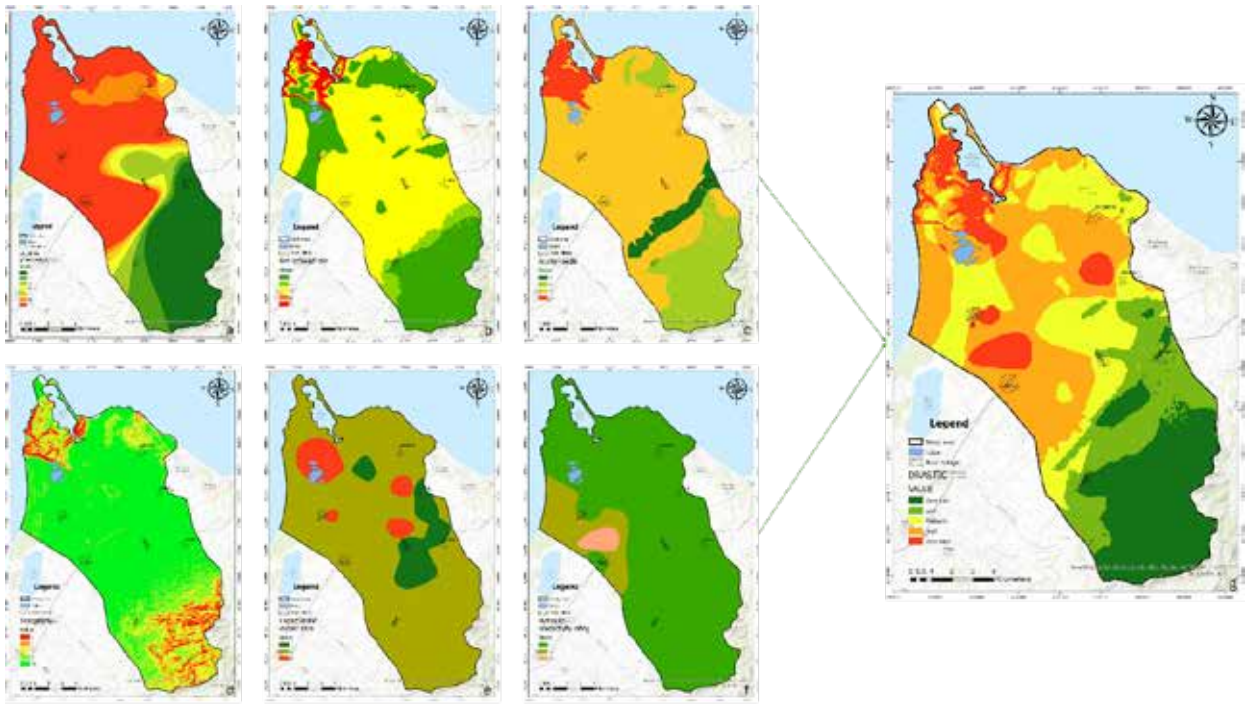

Figure 2. (a) Map of depth to groundwater; (b) Map of net recharge rate; (c) Map of aquifer media; (d) Map of topography; (e) Map of impact of the vadose zone; (f) hydraulic conductivity rating; (g) Map of DRASTIC method

Conclusions

It is crucial and necessary for investigation into the vulnerability of aquifers, which are groundwater resource systems. Throughout the research area, aquifer formations are still in risk from pollutants that are both naturally occurring and caused by humans. The results of six distribution maps, which correspond to the six parameters of the DRASTIC methodology contributed to the drafting of the final DRASTIC map (fig. 1g) that indicates the distribution of its vulnerabilities study area in terms of external pollutant. The maps were produced using the ArcGIS Pro program as well as the value of the gravity of each parameter. According to the final vulnerability map almost completely the SW part of the watershed it appears in green as the least sensitive part of the study area. This is reasonably explained as this section characterized by a large depth of the aquifer, high slopes, low rainfall and clay material that is impermeable, preventing the infiltration of the pollutant. Instead, highly vulnerable positions within it defined area are in red in the NW part of it, on both sides of the Kalogria lagoon, and in some places in the central part of the basin, which are characterized by gentle slopes, shallow depth of groundwater, intense rainfall and the presence of karstic limestone. The above features favor active recharge and the infiltration of pollutants. Finally, the other areas in the central and NW extent of the study area are characterized by high to moderate vulnerabilities as well present intermediate characteristics. Due to its ability to adapt to specific hydrogeology and human (land use) factors, this model-based technique can be used to study and manage groundwater resources. The pollution hazard map provides the data sets and model predictions required for land use and water resource management and strategic planning.

Research highlights

How can we protect European cultural heritage from climate change, natural hazards and other stressors such as pollution and over-tourism?

Introduction

RescueME (Resilient Cultural Landscapes) is a Research project funded by the Horizon Europe programme where five Resilience Landscape Laboratories (R-labscapes) are working with 12 consortium research and technology partners to create new approaches of protecting coastal cultural heritage and landscapes, implementing innovative resilience solutions and culture-focused strategies. The project started in February 1st, 2023, lasts for 42 months and focuses on the enhancement of the resilience of coastal cultural landscapes (CLs) in Europe.

The five case studies (Psiloritis UGGp in Greece, the island of Neuwerk in Germany, Portovenere, Cinque Terre & the Islands in Italy, L'Horta in Spain, and the city of Zadar in Croatia) have been selected carefully as complementary representatives of European coastal landscapes. They act as resilience landscape laboratories (R-labscapes) to validate the results and ensure their replicability. For these five target areas, RescueME is going to produce digital tools and innovative solutions for climate change adaptation and natural disaster risk management.

Regarding Psiloritis UGGp located at the island of Crete, Greece, planned actions focus on shielding of its northern coast (parts of the Municipalities of Mylopotamos & Rethymnon) from the impacts of extreme weather phenomena such as heatwaves, droughts, water shortages and, secondarily, floods. Also, Psiloritis UGGp has set as priority to enhance heritage resilience, raise awareness among local stakeholders and make RescueME project results actionable in the local framework.

Common heritage is a central element of our communities and economies, and a principal but vulnerable dimension of our common identity as Europeans. It has been proven that cultural heritage contributes to well-being, social cohesion, identity, local economy, territorial attractiveness, and environmental sustainability (European Commission, 2021), but the climate crisis and natural hazards threaten this heritage. RescueME is going to take immediate action to demonstrate how an innovative data-driven, community-based and heritage-centric actionable landscape approach for resilience enhancement can protect our cultural heritage and landscapes, while supporting the transition toward a green society and economy that sustains resilient, cohesive, nature-connected communities. RescueME proposes a call for broadening the scope, triggering actions, untapping and mobilizing resources, engaging actors, and facilitating the decision making and the implantation of co-created just resilience solutions to protect our common heritage.

RescueME is developing, testing and demonstrating the effectiveness of an Actionable Framework based on the Resilient Historical Landscape approach (RHL) complemented by data, models, methods, and tools able to assess risks and opportunities, co-develop inclusive and just resilience strategies and innovative solutions to protect European cultural heritage and cultural landscapes from climate change, disaster risk, as well as other stressors (such as pollution and over-tourism) with special focus on European coastal landscapes (FUNDACION TECNALIA RESEARCH & INNOVATION, 2023).

Methodology

Figure 1: Map of RescueME area. This area applies to the semi-mountainous and lowland part of the Municipality of Mylopotamos as well as part of the old Municipality of Arkadi of the current Municipality of Rethymno.

For project implementation, the study area of Psiloritis UGGp (Figure 1) has been determined as well as the main hazards the area faces due to climate change, while stakeholder task forces have been set. These, comprise of local CCSIs (Creative & Cultural Sectors and Industries) and other businesses, experts with local knowledge, researchers as well as civil society, and participate in the co-creation process of the project that entails the collaborative engagement of diverse local stakeholders in the development of resilience measures and strategies in the R-labscape.

For the purpose of co-creation of local measures and solutions, these local stakeholders have already been engaged in an intensive Resilience Baseline Assessment for a better understanding of the local knowledge/awareness. The assessment has been conducted via a questionnaire of 78 quantitative and qualitative questions which was distributed amongst targeted users as well as stakeholders based on the RescueME indicator approach. This approach implements a GLOCAL (global and local) strategy blending global and local factors alongside top-down and bottom-up approaches, as well as the adoption of the concepts of Socio-Ecological Systems (SES) and a landscape approach, as described in the Deliverable “Actionable framework for resilient historic landscapes”. By this way, weak spots and strong points have been identified in Psiloritis R-labscape and the most appropriate approach is going to inform the co-creation of resilience measures.

Stakeholders have also participated in two “impact chain” workshops (Impact Chains) to address the impacts from heatwaves and temperature rise and possible adaptive measures, on the sectors of agriculture and tourism. At a first step, these impact chains identified first the main hazards that threat the R-labscape, analyzed the potential capitals (build, natural, cultural, economic, social etc.) that might be affected, and determined the specific impacts that might occur. In a second step, the focus was concentrated on the impacts in tourism and agricultural activities, identifying the vulnerabilities, the weaknesses and the potential drivers for enhancing local resilience.

Based on the Impact Chains, a predictive impact model which is going to be defined to model and quantify the impacts of the considered hazards and stressors, specifically addressing the aspects of ecosystems services and local heritage values. Especially in Psiloritis UGGp, the model is going to focus on the impact of changes in temperature and precipitation patterns on agriculture and tourism. As a start, a Multiscale risk and resilience assessment of the

R-labscape has been developed through a questionnaire and bilateral meetings with the R-labscape in order to analyze the possibilities of the development of the final model. Following, local quantitative data have been selected, such as the population number of the area, tourism turnover in euros and agricultural area in m^2 etc., in order to have a selection of indicators for the spatial analysis of the impact model.
After thorough analysis of the results obtained by the Impact Chains, the Resilience Baseline Assessment and the Multiscale risk and resilience assessment a long list of issues and common findings between them was created by the relevant work package leaders which were categorized in capitals and key elements according to the SES Framework. This list was validated by the R-labscape in order to understand what matters most and what needs to be addressed urgently to enhance resilience. Currently, resilience issues have been further categorized in a reduced list and prioritized via a prioritization exercise by assessing their impact on resilience, complexity and effort required to address them. By this way, the Psiloritis UGGp focuses on the most critical issues when co-creating resilience measures and solutions.
Moreover, a RescueME resilience meta-repository as well as local policy tools have been created which show existing knowledge and solutions on community- or system-based resilience in order to define measures, solutions and conditions to guide Cultural Landscapes in building their transformative resilience strategies. Also, RescueME research partners are starting the development of the first steps of a social innovation and co-creation tool, the Resilient Landscapes Serious Game for resilience strategy development. By this way, compatible solutions are going to be adapted in a local context with in-person workshops with local stakeholders. Currently, the structure of the game Board mock-up game, game steps, resilience strategy objectives and possible scenarios are being built.
RescueME aims, also, to deliver a set of advanced digital solutions, easily accessible through a single application portal (RescueME One-stop Shop). The design and development of all foreseen digital solutions will follow a human-centred approach, based on a common set of definitions, including a comprehensive multi-scale data model. The digital solutions will include a geospatial and interoperable Data Lake, a geospatial Data Intelligent Platform for heterogeneous data aggregation, processing, and visualization, and a set of AI-based tools and solutions (crowdsourcing, satellite mapping, AR app). Currently, in order to deliver a set of advanced digital solutions, social media posts are being analyzed and available local actionable data sources are being gathered to be inserted in a Data Lake of AI based tools. Also, already calculated by Psiloritis UGGp geographical, demographic and, economic data at the Multiscale risk and resilience assessment phase, are going to be selected and displayed through the Geospatial Data Intelligent Platform, to allow the users further use of such data sources if necessary.
Last but not least, the project is going to produce a digital One-Stop-Shop (OSS) that will include advanced tools for the protection and promotion of coastal cultural landscapes of Europe.

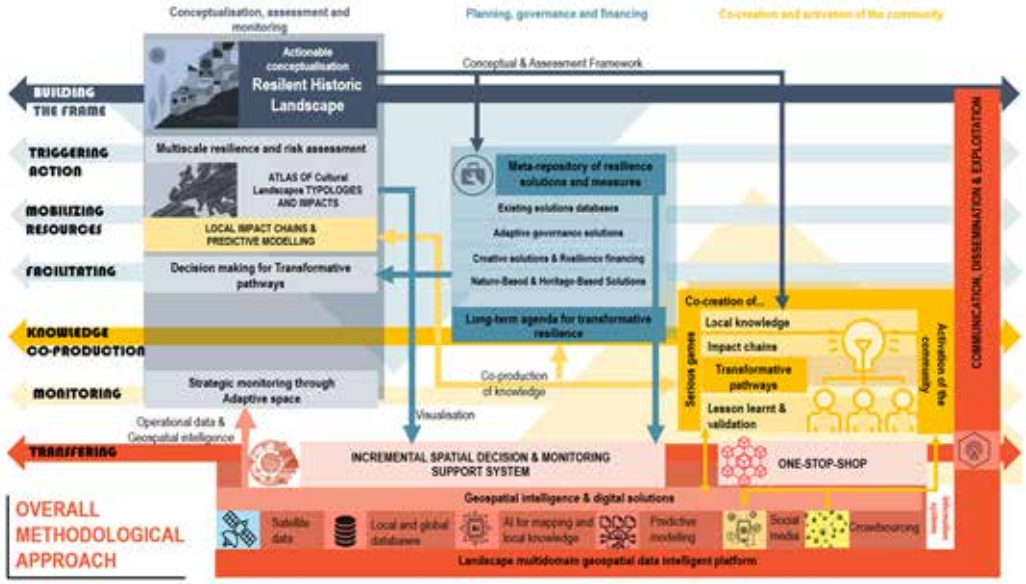

Figure 2: RescueME methological approach

For all the above, the RescueME methodological approach (Figure 2) interconnects the conceptualisation of approaches and quantification of values and impacts with the development of resilience solutions and measures to create long-term transformative strategies. From a bottom-up approach, these strategies are being co-created with the R-labscapes and for the top-down approach, they are implemented in the decision-making tools to facilitate the transference.

Results

Key conclusions have been drawn by the local stakeholders at the two local Impact Chains. In specific, on 11th October 2023, at the 1st Impact Chain, 13 local stakeholders from the public and private sector gathered at Panormos in Crete in an interactive group session to discuss how they perceive the existing and potential future climate-related hazards in the region. The workshop's results revealed how the selected area's climate-related hazards, such as the rise of winter temperatures, may cause impacts on agriculture, culture, ecosystems, infrastructure, people, tourism and Crete's economy. At the same time, the participants' discussions explored how the impacts are affected by exposed elements of the Cultural Landscape, apparent sensitivities and capacities in these sectors. Therefore, the workshop concluded in an effort by the stakeholders to propose potential adaptation measures. For instance, the rise of winter temperatures may cause diseases that affect both livestock and agricultural production as well as public health. As a sub-effect, less products are available on the market, the income is getting lower, the welfare state gets weakened and rural communities are being abandoned. At the same time, there is an apparent sensitivity: the lack of civic engagement and participation of citizens in planning & implementation. Workshops/seminars were, therefore, proposed for good practice exchange at the local level.

On 2nd February 2024, at Aggeliana in Crete, a deeper review and analysis of the same topic was made by 12 different local stakeholders from targeted sectors. This time, the focus of 2nd Impact Chain was only on agriculture and tourism, since these are the main driving forces in the economy of Crete. At that workshop, new adaptation measures were also addressed. For instance, climate related hazards such as heat waves may increase the time spent inside hotel units, the energy and water consumption but also reduce travel agencies income due to the lack of tourist mobility. The promotion of off-season alternative tourism could be one of the adaptation measures.

Figure 3: Impact Chain Workshop 2

This task supported the next steps of the project along with the results obtained by the Resilience Baseline Assessment and the Multiscale risk and resilience assessment developing the list of all related resilience issues. As a result, the prioritized list of issues has been created in order to focus on the issues which are most critical for the co-creation of resilience measures and solutions, having in mind the main co-creation aims of Psiloritis UGGp (enhancing heritage resilience, raising awareness among stakeholders and making RescueME project results actionable in the local framework). Examples of those issues include the lack of agricultural training which may pose challenges in terms of implementing sustainable farming practices, adopting modern agricultural techniques and ensuring the long-term viability of traditional farming methods. This is of relatively high impact but also feasible to address. Also, climate impacts on crop productivity and water resources may pose concerns regarding water availability and management, highlighting vulnerabilities to drought and over-pumping with significant risks to agricultural productivity and livelihoods, a challenge highly complex but also with a high impact if addressed. Lastly, facing the reduced attractiveness of the destination for tourists due to the impacts of natural hazards on the cultural landscape (e.g. coastal erosion), human health (heatwaves) and recreational outdoor activities, may become a "Big Project" having relatively high impact, requiring also to address quite intensive resource efforts.

All these actions are part of a long co-creation and decision-making process that is taking place with the collaboration of project partners and local actors in order to enhance the common heritage resilience from climate change, natural hazards and other stressors.

Introduction

To enhance geotourism and public awareness, the Vikos-Aoos Geopark launched the "Enhancement of Geosites and Geological Formations" project (2022–2024). This initiative integrates modern technology and infrastructure to improve visitor experience and promote sustainable tourism. Key components include a mobile app offering interactive geological and cultural content, visitor centers providing in-depth interpretation, and outdoor viewing platforms showcasing geosites through strategic placements and aerial imagery. Additionally, a visitor tracking system at eight major sites has provided valuable data on geotourism trends. These efforts strengthen conservation-focused tourism and serve as a model for balancing heritage preservation with visitor engagement.

Methods

The Vikos-Aoos Geopark, in collaboration with the Hellenic Ministry of Environment and Energy, has undertaken a comprehensive initiative to enhance geotourism, visitor engagement, and public awareness of its geological heritage. This project, titled "Enhancement of Geosites and Geological Formations and Evaluation of Visitability of Geosites and Landscapes of High Aesthetic Value in Vikos-Aoos UNESCO Global Geopark", is funded by the Natural Environment & Climate Change Agency (N.E.C.C.A.) under the framework of a cooperation memorandum signed between N.E.C.C.A. and the Hellenic UNESCO Global Geoparks Forum in 2022. Spanning from 2022 to 2024, the project implements a strategic, multi-faceted approach to improving visitor services and sustainable tourism development.

The first major action (Action 1) of the project focused on enhancing information and geosite interpretation services through the development of a web-based digital mapping application. Designed for use both within visitor centers and on mobile devices, this platform allows for interactive exploration of the Geopark's geological, environmental, and cultural heritage. The application provides dynamic, user-friendly access to geosite data, enabling visitors to engage with scientific information through maps, multimedia content, and interactive tools.

The second action (Action 2) centered on the installation of Outdoor Viewing Spots (OVS) at carefully selected locations within the Geopark. These platforms were strategically placed to highlight key geosites and landscapes of high aesthetic value, offering visitors enhanced vantage points to appreciate and understand the region's unique geomorphology. This intervention not only improves the geotourism experience but also reinforces the Geopark's educational mission by making significant geological formations more accessible and visually interpretable.

The third action (Action 3) involved the installation and operation of a visitor counting system, aimed at collecting real-time data on tourist activity within the Geopark. By monitoring visitor numbers across key sites, this system provides valuable insights into seasonal tourism trends, site popularity, and the overall impact of geotourism initiatives. The collected data supports future planning efforts, ensuring that conservation strategies align with sustainable tourism growth. Together, these actions contribute to a more immersive and informative visitor experience while supporting the long-term management and conservation goals of the Vikos-Aoos UNESCO Global Geopark.

Results

Action 1 was titled "Improvement of Information and Geosite Interpretation Services" and was implemented to enhance the educational and awareness-raising capacity of the Vikos-Aoos Geopark, two modern Information Centers were established (Action 1.1) in the municipalities of Zagori (Vitsa) and Konitsa. These centers serve as key hubs for visitors, providing structured insights into the Geopark's geological, environmental, and cultural heritage. Their design prioritizes accessibility and engagement, utilizing modern technology to improve visitor interaction with geosite information. By centralizing interpretive resources, these centers strengthen the Geopark's role as an educational destination, promoting geotourism and fostering appreciation for natural landscapes.

A web-based digital mapping application was developed (Action 1.2) to complement the Information Centers and extend accessibility to geosite data (Figure 1a-d). This interactive platform presents the entirety of the Geopark's

geological, cultural, and environmental assets through a user-friendly, two-dimensional map. Accessible via web browsers on desktop and mobile devices, the application allows users to navigate geosites, explore categorized information on geoheritage, culture, and geotourism, and interact with multimedia content. Developed in collaboration with geologists, biologists, and historians, the platform ensures scientifically accurate and engaging content delivery. Its digital format modernizes geosite interpretation, allowing visitors to plan their routes, visualize geodiversity, and interact with the Geopark's rich heritage beyond the physical boundaries of the information centers.

To maximize the effectiveness of these digital tools, specialized IT equipment was installed (Action 1.3) at both Information Centers (Figure 1a,b). In Konitsa, a digital presentation screen wall system, an interactive info kiosk, and a dedicated computer provide visitors with dynamic, on-demand access to geosite information (Figure 1a,b). Similarly, the Vitsa Information Center features a digital screen wall system, a smart interactive table, and a computer, fostering an immersive educational experience (Figure 1c,d). These installations modernize the visitor experience by integrating smart technology into geotourism services, enabling real-time exploration of geological data and supporting sustainable tourism development in the Geopark.

The digital screen wall systems installed at Konitsa projecting the web-based digital mapping application developed for the Vikos-Aoos Geopark. c. Top view of the smart interactive table at Vitsa. d. The smart interactive table during installation at Vitsa.

To enhance visitor engagement and raise awareness about the geological and geomorphological features of the Vikos-Aoos Geopark, a series of outdoor viewing areas were installed at carefully selected locations, under Action 2: "Installation of Outdoor Viewing Areas at Significant Geosites in Landscapes of High Aesthetic Value". These viewing platforms were designed to provide strategic vantage points where visitors could appreciate geosites, geological formations, and landscapes of exceptional beauty while simultaneously accessing educational interpretative panels. The primary goal of this initiative was to merge the aesthetic appreciation of these landscapes with scientific knowledge, helping visitors understand the forces that shaped the region.

Each outdoor viewing area features a specialized prefabricated canopy structure equipped with exhibit panels that highlight key geological, environmental, and cultural aspects of the surrounding landscape. The structures maintain a uniform design, but the content of each panel is tailored to the specific geosite, ensuring site-specific interpretation. The panels, measuring three meters in length, present information in both Greek and English and include photographs, diagrams, and explanatory texts. The selection of these locations was based on their scientific, educational, and touristic value, ensuring that visitors have access to some of the most iconic geological features within the Geopark. Three major outdoor viewing areas were established at critical geosites, two in the eastern-southern section of the Geopark (Municipality of Zagori) and one in the western-northern section (Municipality of Konitsa). Each location was selected to showcase significant geological formations, offering visitors an immersive experience that blends scenic beauty with

scientific exploration.

The first outdoor viewing area, located at Kapesovo fault (geosite 12) and the Stone Stairway of Vradeto, provides a remarkable perspective of the Kapessovo fault and its role in shaping the regional geomorphology. The mountainous landscape of Tymfi, composed primarily of limestone formations dating from 145 to 15 million years ago, is revealed through aerial photographs and diagrams. The interpretative panel at this site highlights nine distinct geological features, including the effects of glacial activity during the Pleistocene epoch, which sculpted the area's characteristic U-shaped valleys (Telbisz *et al.,* 2019). Visitors can gain insight into the tectonic and erosional forces that shaped the terrain while admiring the rugged beauty of the surrounding cliffs and gorges.

The second viewing area, is related to the Voïdomatis river Valley and Astraka Fault (geosite 9), offers a spectacular panoramic view of the Vikos Gorge and the surrounding mountain formations. The Towers of Papigo, a striking set of vertical limestone formations, dominate the landscape, shaped by the Astraka fault and karstic erosion processes (Chatzipetros *et al.,* 2024). This site also provides insight into the hydrological system of the Voidomatis river, which emerges from the karst springs of Mount Tymfi before flowing towards its confluence with the Aoos river. The exhibit panel at this location presents nine key geological features, allowing visitors to explore the interplay between faulting, river dynamics, and mountain-building processes.

The third viewing area, positioned at Prophet Elias Hill (1071 m) near Konitsa fault (geosite 8), provides an unparalleled panoramic view of the Konitsa plain and the surrounding mountain ranges. This location offers vistas of Lapatos, Trapezitsa, Gamila, and Astraka, with the Aoos river flowing through the valley, shaping the landscape through continuous erosion and sediment deposition. Visitors can trace the 24-km long Konitsa fault and learn about the structural features of this active seismogenic fault (Chatzipetros *et al.,* 2024). Furthermore, they can explore the sedimentary processes of the Aoos river, learn about the sulfur caves of Sarantaporos river valley and admire the Smolikas (2497 m) and Gamila (2497 m) peaks (Lazaridis *et al.,* 2024). The panel here showcases seven distinct geological features, explaining how the tectonic forces responsible for the formation of the Konitsa fault have influenced the region's topography. From this vantage point, visitors can also observe the Nemerçika mountain range, marking the natural border between Greece and Albania, as well as the ophiolite peaks of Smolikas (2637 m), Greece's second highest mountain.

These outdoor viewing areas provide an unparalleled opportunity to connect with the geological past while enjoying breathtaking landscapes. Visitors gain a deeper appreciation of the region's dynamic geological history, from ancient fault movements and glacial sculpting to modern river systems and ongoing erosional processes. By merging scientific interpretation with stunning natural beauty, these installations reinforce the Geopark's mission of education, conservation, and sustainable geotourism, offering an immersive and enriching outdoor experience.

The third action implemented under this project was tilted "Installation and Operation of a Visitor Counting System at Geosites". Its scope was to effectively manage visitor traffic and ensure sustainable tourism in the Vikos-Aoos Geopark. A visitor counting system was installed at key geosites and geomorphological formations (Figure 3a-c). This system aims to collect data on the number of hikers in specific areas, such as the Vikos and Aoos Gorges and the Dragon Lakes of Tymfi and Smolikas. By analyzing visitor numbers and movement patterns, park authorities can develop informed strategies for conservation, infrastructure planning, and visitor experience enhancement. The system utilizes passive infrared sensors to count visitors discreetly. Counters were placed at eight strategic locations along major hiking trails, ensuring coverage of high-traffic areas like the Vikos Gorge and its branches, the Aoos Gorge, and popular scenic viewpoints such as the Oxya (Stone Forest) in Monodendri. These bidirectional sensors not only track the number of hikers but also identify their direction of movement (Figure 4a). Additionally, the counting data can be co-evaluated in relation with real time weather and extract information on how weather may affect or not visitor traffic (Figure 4b). The collected data is transmitted to a central unit, where it is processed using specialized software for further analysis. The placement of the sensors was carefully designed to minimize their visual impact on the natural landscape while maintaining accurate and reliable data collection (Figure 3a,c).

A significant example of the system's effectiveness is the monitoring of visitor numbers at the Agkastromeni Spring (geosite 4), located at the exit of the Vikos Gorge (Figure 4a). This site marks the main springs of the Tymfi karst system, where water emerges from limestone and dolomitic limestone formations with black chert. The spring, formed due to the Astraka fault, has an intermittent flow that varies with seasonal water availability. Nearby, an 18th-century church, once a monastery, serves as a cultural landmark and a resting point for hikers. The results from the counter at this site indicate that approximately 16,000 visitors pass through annually, with a steady flow throughout the year. The highest visitor numbers occur on weekends and holidays, peaking during the summer and early autumn months, particularly in August, when around 4,000 hikers visit the site.

The implementation of the visitor counting system provides invaluable insights into hiking trends and seasonal variations in visitor traffic. This data will help park managers maintain a balance between accessibility and conservation, ensuring the long-term protection of the geopark's natural and cultural heritage while enhancing the visitor experience.

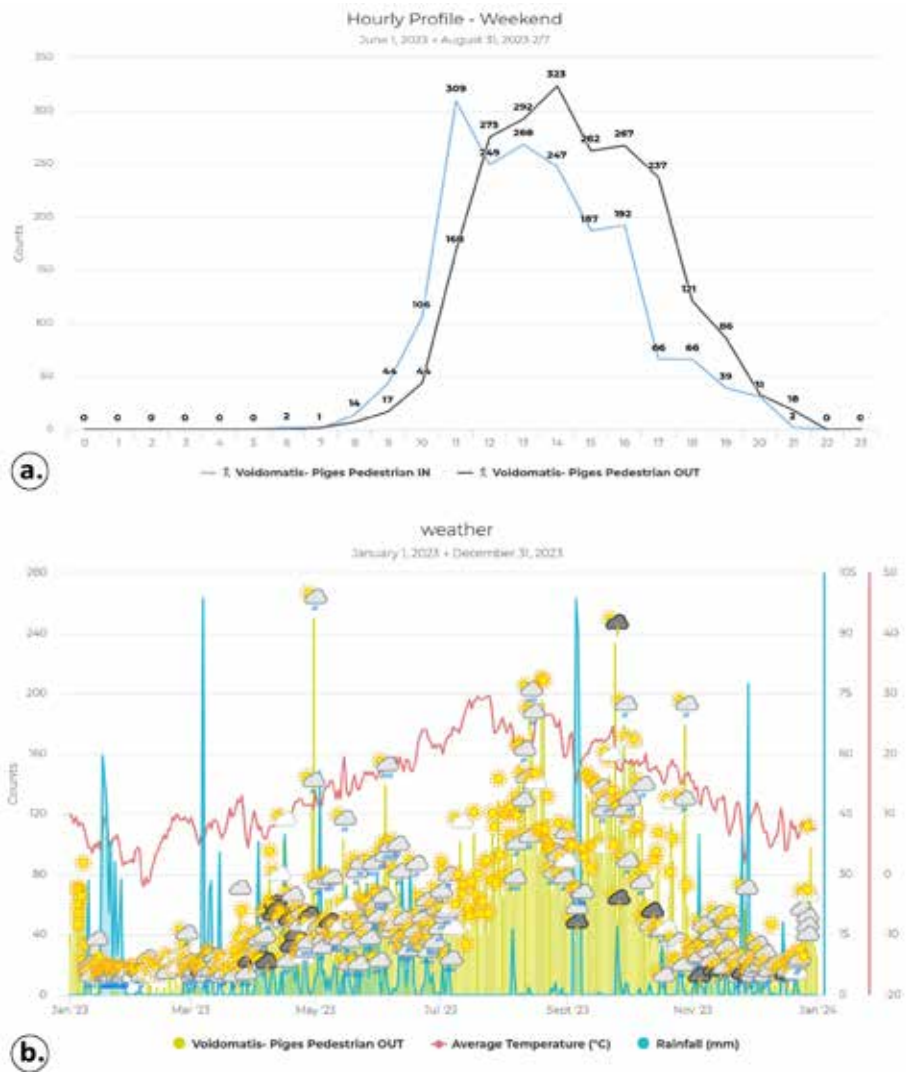

Figure 4. a. Diagram showing the hourly allocation of incoming and out coming visitors to the Agkastromeni spring of Voidomatis river. b. Visitors counts coupled with weather conditions from January 2023 to January 2024.

Conclusions

The implemented actions in the Vikos-Aoos Geopark enhance visitor experience while promoting geoconservation and awareness. The outdoor viewing areas provide panoramic insights into key geosites, while the new interpretation panels educate visitors on geological processes shaping the landscape. Additionally, the visitor counting system enables sustainable management by monitoring foot traffic across major trails. These efforts contribute to preserving the park's natural and cultural heritage while fostering appreciation for its geological significance. Through these initiatives, the Geopark strengthens its role as a model for responsible geotourism and environmental stewardship.

Volcanism and the metamorphic core complexes of Rhodope and Cyclades

Papanikolaou D.[1], Nomikou P.[1] & Lambridou D.[1]
(1) Department of Geology and Geoenvironment, National and Kapodistrian University of Athens, Greece

The four active volcanic centres of the Aegean arc and another ten inactive volcanic centres, activated during Oligocene – Middle Pleistocene, following its southward migration are described with emphasis on their tectonic signature. They are all localized within tectonic grabens, resulting from the back-arc extension of the Hellenic arc throughout its Late Eocene – Present evolution. Our study was based on geological maps and the transverse tectonic profiles both onshore and offshore. The material presented is either from our own publications (usually modified) or new. The orientation of the tectonic grabens depends on the extensional stress field of each period and region. The existence of Late Miocene granitic rocks in the Cyclades without outcrops of Late Miocene volcanics is probably due to the considerable uplift of the Cycladic metamorphic core complex that has denudated the upper geological formations together with the volcanic rocks. The volcanic activity is observed within the arc parallel marine molasse of the North Aegean – Rhodope back arc basin during Oligocene – Early Miocene and within the Plio-Quaternary marine arc parallel tectonic grabens/basins of the South Aegean. Middle-Late Miocene volcanic rocks are observed within continental tectonic grabens/basins only in the lateral margins of the Cycladic metamorphic tectonic window.

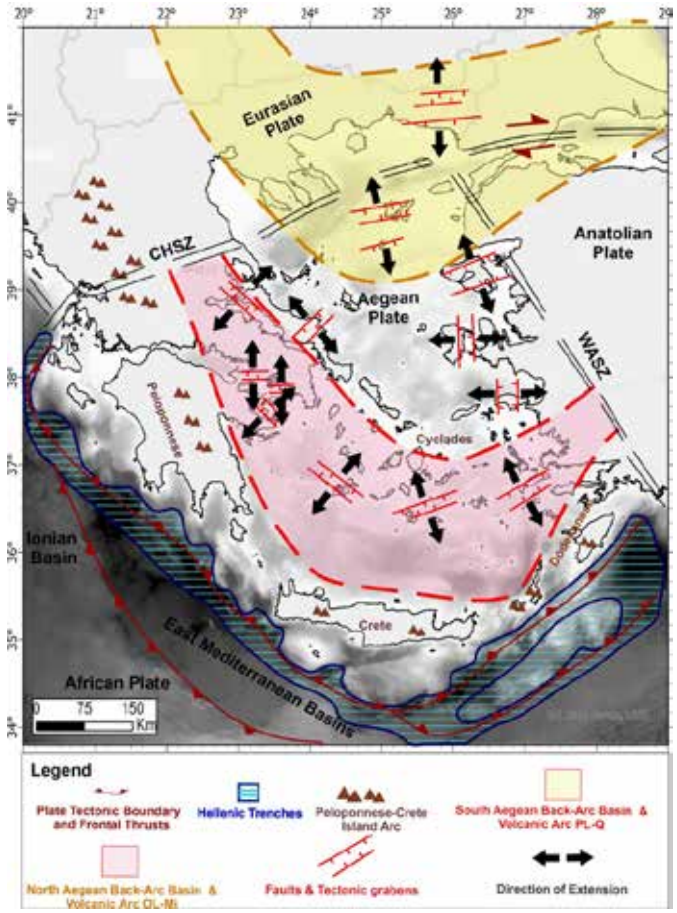

Fig. 1. Map showing the dominant tectonic trend and stress orientation in the 14 volcanic fields studied in this paper. The volcanism during Oligocene – early Miocene is observed within the molassic back arc basin of Rhodope – North Aegean Sea (No 11, No 12, No 13, No 14) whereas the Plio-Quaternary volcanism is observed in marginal marine basins along the northern border of the present back arc Cretan Basin (No 1, No 2, No 3, No 4, No 6). Exceptions are observed in the eastern Aegean islands (No 8, No 9) with N-S tectonic trend during the Middle – Late Miocene and W. Attica-Corinth (No 5, No 7) with E-W tectonic trend during Late Pliocene – Early Pleistocene.

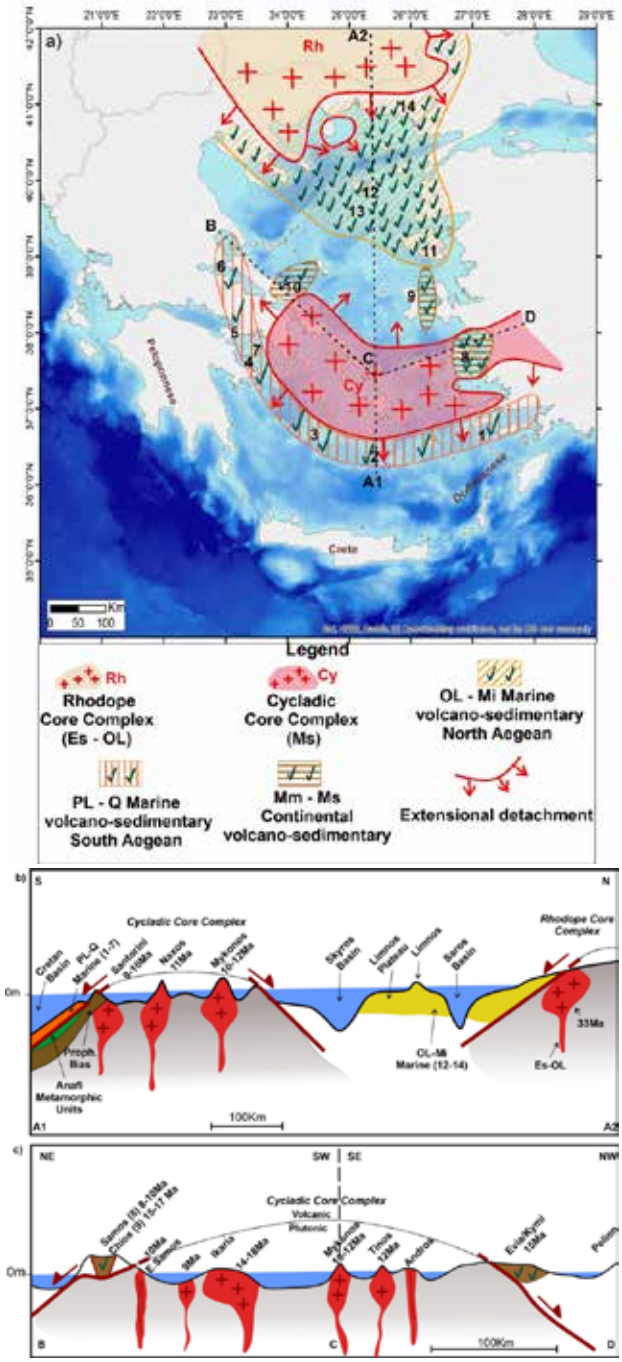

Fig. 2. a) The location of the 14 studied volcanic outcrops of the Hellenic arc within the Aegean tectonic structure. The volcanic outcrops are related to the Rhodope and Cycladic metamorphic core complexes with marine outcrops in the molassic basin of the North Aegean during Oligocene – Early Miocene and marine outcrops during Late Pliocene - Quaternary along the southern border of the Cycladic belt. Middle – Late Miocene continental outcrops are observed at the margins of the Cycladic core complex in Evia and Samos-Chios. b) N- S- schematic cross section A1-A2 through the Aegean Sea showing the volcanic outcrops in relation to the two metamorphic core complexes. Miocene granites of the Cyclades are indicated in Mykonos, Naxos and Santorini. c) Longitudinal schematic section B-C-D along the Cycladic core complex from Pelion – Northern Evia to Samos. The Miocene granitic rocks are shown within the core complex (Samos, Ikaria, Mykonos, Tinos) and the volcanic rocks within Miocene continental sedimentary basins at the two margins (Evia/Kymi and Samos, Chios).

Conclusions

In conclusion, almost all volcanic outcrops of the evolving Hellenic arc throughout the Late Eocene – Present are related to extensional tectonic graben structures associated with sedimentary basins, either marine or continental. Exceptions to this rule are very few, such as the Skyros andesite of Middle Miocene age about 15 Ma (Fytikas et al., 1980), which intruded the Alpine basement rocks of marbles, tectonically emplaced ophiolites and Cretaceous limestones. The role of the metamorphic core complexes in the distribution of the magmatic and volcanic products of the evolving Hellenic arc is documented and it is shown that the overall image of the upwelling magmas can be obtained only by combining the plutonic with the volcanic products.

EXTENDED ABSTRACT 248

The influence of stratigraphy for the generation of surface evidence of liquefaction phenomena; case study Piniada, Greece

Papathanassiou G.[1], Valkaniotis S.[1], Taftsoglou M.[2]
(1) School of Geology, Aristotle University of Thessaloniki, Greece, gpapatha@geo.auth.gr
(2) Department of Earth Science, University of Ferrara, Italy

Introduction / Background

The present study focuses on the assessment of liquefaction potential in an area where numerous liquefaction phenomena were triggered by the 2021 Damasi, Greece, earthquake. The liquefaction features were reported during a field survey conducted few hours after the event along the Piniada Valley (Papathanassiou et al. 2022). They were classified as i) sand craters, as singular features as well as aligned ones, ii) ground fissures, from where a mixture of water and fine sandy and silty material was ejected, and iii) lateral spreading phenomena. According to eyewitnesses, the phenomena occurred during the March 3rd mainshock, locally caused mixed fluid fountaining as high as 1 m from the topographic surface. The total area covered by the ejected material (sand blow) at Piniada Valley was estimated as 0.0325 km^2, approximately 0.5% of the zone that is delimited by the village Piniada, to the north, and the present-day river channel of river Pinios, to the south (Papathanassiou et al. 2022).

This area is covered by Holocene sediments deposited along the meandering fluvial system of Pinios. The characteristic evolution of Pinios River dictates the depositional process of the sediments and contributed to the lateral and vertical heterogeneity of the surficial soil material. That was clearly shown during the 2021 event since liquefaction phenomena preferred to concentrate in specific location forming clusters of liquefaction-induced ground disruption such as sand boils, craters and ground fissures (Valkaniotis et al. 2024). In addition, it is highlighted that within a short distance, the severity of ejecta was totally different.

Methodology

For the purposes of this research, we investigated the role of the stratification of soil deposits for the generation (or not) of liquefaction-induced surface evidence and to the relevant ejecta severity. In order to achieve this, we used data derived by six CPTu tests conducted on an area where liquefaction phenomena were mapped. The liquefaction potential at each site was estimated following the method proposed by Hutabarat and Bray (2022), who concluded that the layer stratification can lead to not producing ejecta.

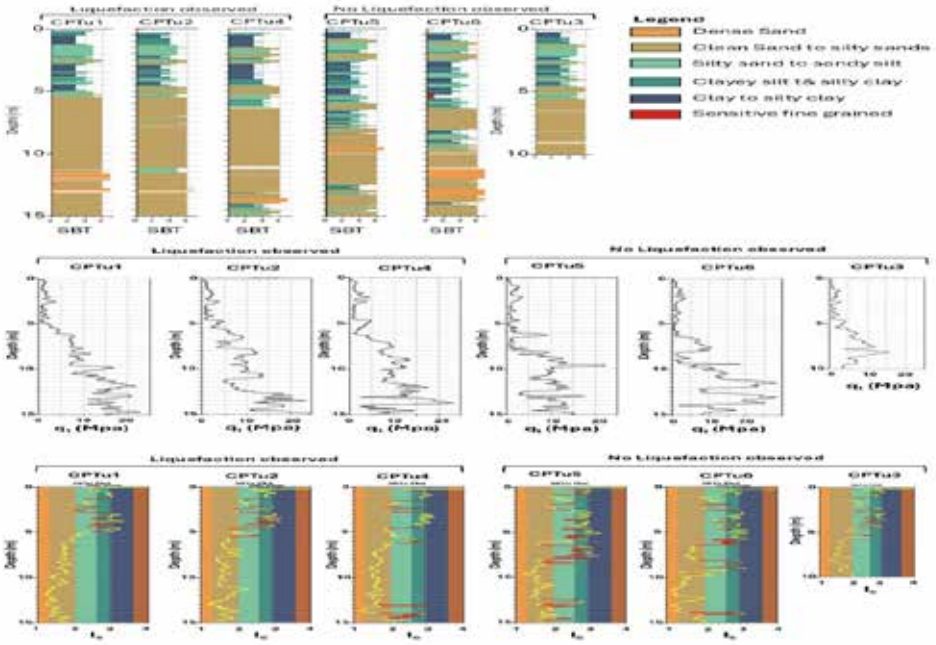

Figure 1. Soil stratigraphy of investigated sites, classified as liquefaction and non-liquefaction ones (Papathanassiou et al. 2025)

Thus, they developed a methodology aiming to address the prediction of the liquefaction-induced ejecta severity by quantifying two new factors: the liquefaction ejecta demand (L_D) and the crust layer resistance (C_R). The former considers the soil layer beneath the crust layer that may contribute to ejecta production and captures the hydraulic conductivity contrast, while the latter one (C_R) is related to the non-liquefiable crust layer that prevents liquefied material to eject and is estimated by taking into account the shear strength and thickness of this surficial stratum. According to Hutabarat and Bray (2022), this new method considers the system response of the soil column and captures the liquefaction-induced upward seepage that can erode the crust layer resulting in the generation of ejecta.

Conclusions

The outcome arisen by our study is that partially or highly stratified soil deposits are not expected to generate artesian flow pressure capable of producing liquefaction surface evidence, i.e. ejecta. This is due to the fact that i) the thickness of liquefiable sand-like layers is usually too small to produce large value of excess hydraulic head h_{exc}, while ii) in case this happens, the interbedded low-k_v soil layers impede the upward seepage. On the other hand, soil deposits where thick continuous sand-like material is encountered, are expected to produce excess hydraulic head that can lead the soil-water mixture onto the surface, i.e., ejecta. It is pointed out that this type of soil deposit can produce ejecta even when the thickness of the crust layer is larger than 4 m.

EXTENDED ABSTRACT 249

Monitoring the Santorini Volcano for 3 decades (1995-2025) by ISMOSAV and its role for the early detection of the 2011-2012 and 2024-2025 intra-caldera unrests

C. Papazachos[1], G. Vougioukalakis[3], S. Bitharis[2], Ch. Pikridas[2], M. Foumelis[1], Ch. Ventouzi[1], Ch. Kkallas[1], E. Karagianni[1], D. Vamvakaris[1], and E. Papageorgiou[1]

(2) Aristotle University of Thessaloniki, School of Rural and Surveying Engineering, Thessaloniki, Greece

(3) Institute for the Study and Monitoring of Santorini Volcano, Santorini, Greece

Introduction

The Institute for the Study and Monitoring of Santorini Volcano (ISMOSAV) was established in 1995 as a non-profit entity, with the main purpose of continuing the operation of the Volcanological Observatory and the volcano monitoring networks (seismological, geodetic, geophysical and geochemical) in 1993 in the framework of a European research program. A secondary objective of ISMOSAV was to promote volcanological research in Santorini, contributing significantly to the improved assessment of volcanic hazard and improving the ability to predict any volcanic activity or unrest in a timely manner. In this way, ISMOSAV has filled the gap left by the lack of a public body in Greece (e.g. research institute, etc.) that is responsible for the study and management of volcanic hazard, striving to protect Santorini by maintaining a reliable monitoring system that increases the likelihood of early warning of the volcano's reactivation, while also refuting, when necessary, any unfounded rumors and/or speculation. As a result, over the past 30 years and mainly with the support of the island's local authorities, ISMOSAV has managed to overcome several problems related to the lack of permanent research infrastructure on the island, maintaining and upgrading installed networks, replacing obsolete equipment, and processing real-time and near-real time information.

We present information on the early detection of the 2011-2012 and 2024-2025 volcano-tectonic intra-caldera unrests in Santorini. The presented results verify the critical role of ISMOSAV for the identification of these unrests, as well as on the measures that were taken to handle them. Moreover, they strongly suggest the need to establish the first permanent Volcanological Observatory on the island, operated by a local or other state authority, that will rely on and "assimilate" the existing ISMOSAV infrastructure, as well as monitoring sensors operated by other institutes, allowing to continue and expand on the ISMOSAV's 30-year legacy.

Data and Analysis

During the first 15 years of operation, ISMOSAV mainly relied on monitoring microseismicity to assess volcanic activity. This was mainly performed in collaboration with the Seismological Station of the Aristotle University of Thessaloniki (AUTh), gradually evolving and improving on the initial network of 5 analogue seismological stations. The recordings of the first analogue seismological network, initially recorded on paper in a local acquisition facility in Profitis Ilias, where later locally digitized and transmitted via the internet to AUTh. Until 2010 (Figures 1) these data showed continuous but relatively low seismic activity, mainly in the area of the submarine volcano of Koloumbo, as well as in several tectonic faults to the north and northeast of Santorini (e.g., an **M**5.1 sequence in June 2009), but also along the active tectonic line Koloumbos-Anydro-Amorgos area (e.g., Dimitriadis et al., 2005). These results, which showed little variability between 1995 and 2010, were in agreement with the findings of local seismological networks periodically installed on the island, as well as in the broader Santorini area (e.g. Bohnhoff et al., 2006; Dimitriadis et al., 2009).

As a result of this monitoring, ISMOSAV was able to detect the 2011-2012 volcanic unrest as early as February 2011. Figure (2) depicts the very early intra-caldera seismicity distribution, as presented in a confidential report submitted to the Earthquake Planning and Protection Organization in March 2011. From

this map, it was evident that the seismic activity began in January 2011 on the NE coast of Nea Kameni and expanded towards the NE (and less towards the SW) in February, continuing both to the northeast (Firostefani-Imerovigli) and southwest (Palaia-Nea Kameni area) in March 2011. From these early results it was evident that the activity was mainly concentrated at depths of 2-6 km, with shallower depths (2-4 km) in Palaia and Nea Kameni, increasing towards the mainland (Firostefani). The small hypocentral errors (0.7 km and 1.4 km for the horizontal and vertical coordinates) showed that this unusual seismicity was a reliable feature. This unrest was further supported by the temporal evolution of this low magnitude seismicity (Figure 3), that showed clear indications of significant temporal variations, increasing in late February 2011, as well as independent data (sea temperature increase, sea level changes, etc.).

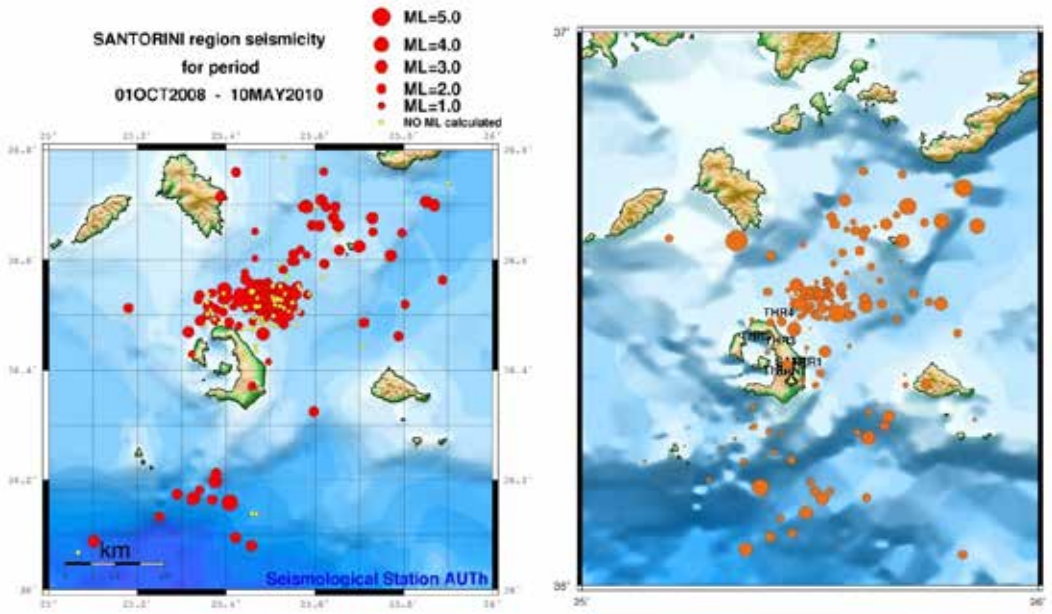

Figure 1. Seismic activity in the volcanic center of Santorini between October 2008 and May 2010 (left) and January 2006 and October 2008 (right).

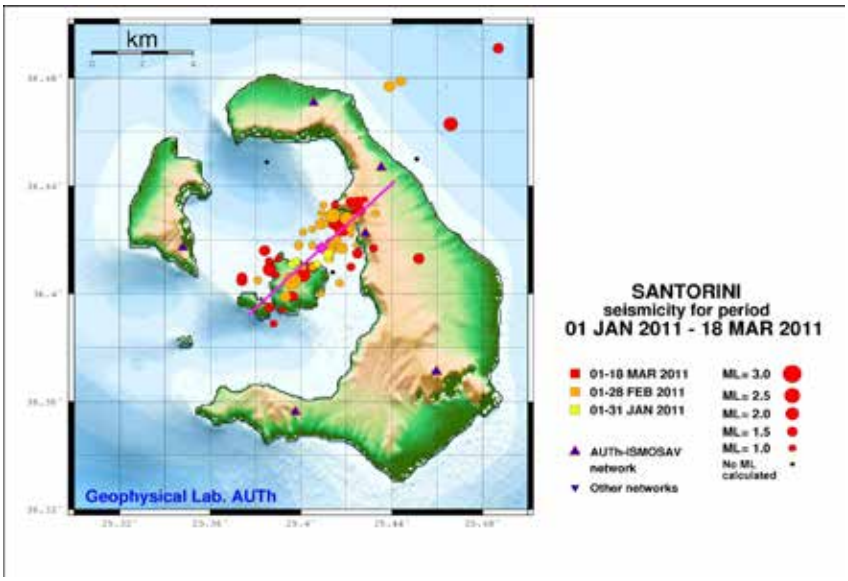

Figure 2. Seismic activity in the volcanic center of Santorini between January 9 and March 18, 2011, as originally reported in March 2011.

The moving average is shown by a red line for the left figure, while colored lines depict the rate (number of events per day) in the right figure.

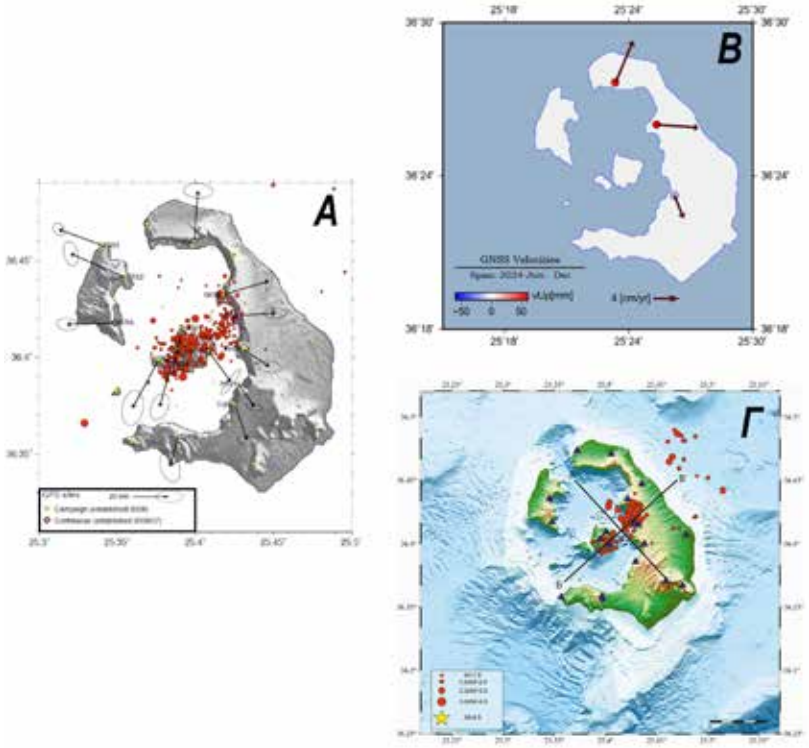

Figure 4. A) Earthquakes (red circles) in the Kameni fault and related displacements from GPS data in the Santorini caldera during the 2011–2012 seismic–volcanic crisis (Newman et al., 2012). B) Relative movements in the Santorini caldera from late June to early December 2024 for the three real-time GPS stations of ISMOSAV. Γ) Best located epicenters of earthquakes with magnitude M_L≥1.1 in the Santorini caldera during the second half of 2024 (mid-September-19 Dec. 2024).

While the 2011-2012 unrest was later extensively studied using a combination of earthquake, GPS, InSAR and geochemical data (e.g. Newman et al., 2012; Foumelis et al., 2013; Parks et al., 2012, 2013, 2015; Saltogianni et al., 2014; Tassi et al., 2013, Papadimitriou et al., 2015 among others), and while a large number of instruments were additionally installed during the unrest, within a few years the monitoring of the island returned to its previous state, with a small number of permanent seismographs and a single GPS station operating in real-time after 2016. To handle this situation, ISMOSAV installed three new GNSS receivers along with the corresponding ancillary equipment in October 2919, establishing a new modern geodetic network to monitor changes in the Earth's relief caused by possible volcanic activity. Furthermore, it continued to monitor seismicity, improving the network coverage and quality. Finally, it also relied on the use of the SNAPPING PSI operational service for InSAR data to further monitor surface deformation. This platform is integrated into ESA's Geohazards Exploitation Platform (GEP) and has been used for automated updates at regular intervals, providing an additional monitoring option for the volcano.

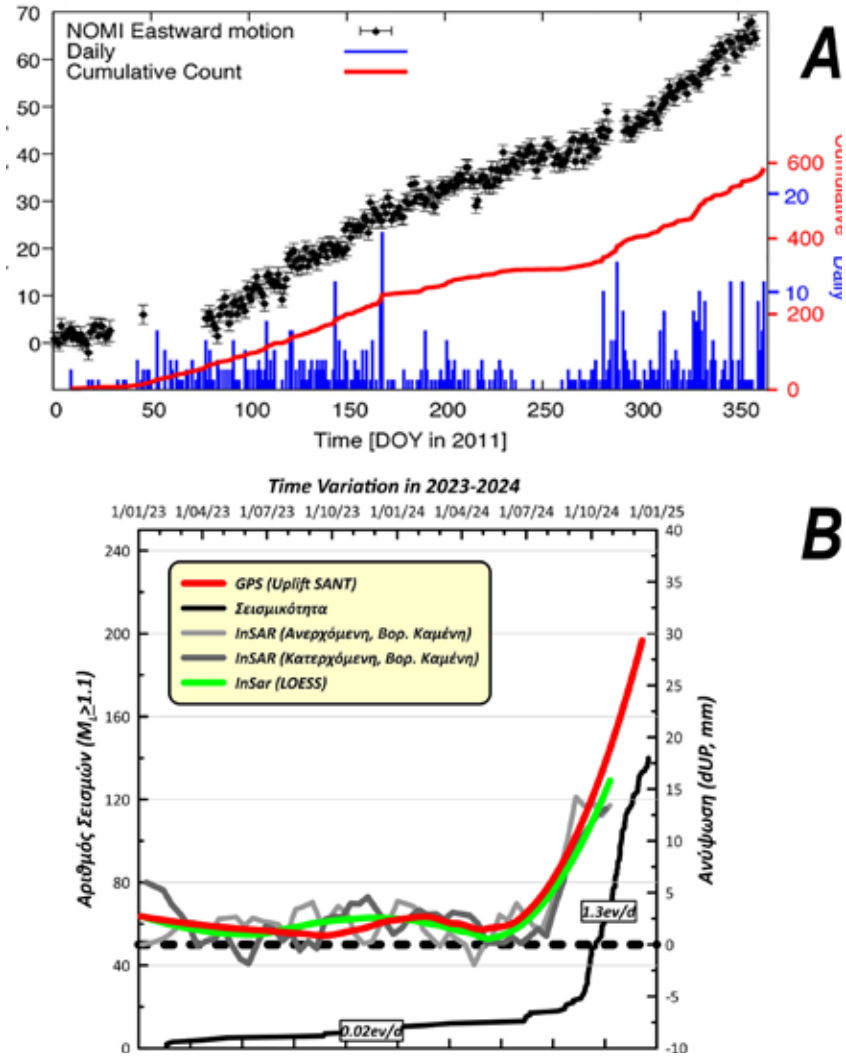

Figure 5. A) Eastward motion of GPS station NOMI station (black circles) and seismicity at the Santorini caldera from the 2011-2012 earthquake-volcanic crisis (Newman et al., 2012). B) Relative elevations at GNSS station SANT station and the northern segment of Nea Kameni (InSAR data) and seismicity rate at the Santorini caldera since January 2023, as originally reported by ISMOSAV. The island's caldera uplift is evident from June 2024 and seismicity has increased by almost 2 orders of magnitude during the period September-December 2024.

This persistent and systematic monitoring has allowed ISMOSAV to detect and inform the Greek government (Civil Protection, Earthquake Planning and Protection Organization) on January 2, 2025, for the on-going (at the time) intra-caldera unrest, as this was identified by seismicity, GNSS and InSAR data (Figures 4 and 5). More specifically, the ISMOSAV network detected since mid-September 2024 an anomalous seismic activity on the central fault of Kameni (Figure 4Γ). Analysis of geodetic data (Figure 4B) confirmed that this activity was accompanied by strong deformation, which started earlier (end of June 2024). This activity was almost identical to the 2011-2012 unrest, where more than 15 million cubic meters of magma rose to a depth of ~3-4 km, north of Nea Kameni. As shown by Figure 4, the displacements detected in northern Santorini and the relative seismic activity from mid-September 2024 were almost identical to the corresponding 2011-12 activity. This was verified by Figure (5), which presents the variation of seismic activity and relative deformation from GPS and InSAR data, as well as its comparison with similar data from the 2011-2012 crisis. From these figures it became evident that from the end of June 2024 (for deformation) and from mid-September 2024 (for seismicity) an unrest very similar to the 2011-12 phenomenon was evolving in Santorini.

Discussion and Conclusions

It is worth noticing that the continuous (for more than 3 decades) monitoring of the Santorini volcano by ISMOSAV did not only lead to the identification of the important 2011-2012 and 2024-2025 unrests, which had a significant impact on the island, but also led to important developments in volcanic risk management in Greece. These developments involved the publication of the TALOS Civil Protection plan for volcanic hazard in Santorini, as well as the creation of a Permanent Scientific Committee for the monitoring of the Greek Volcanic Arc under the auspices of the Earthquake Planning and Protection Organization, both motivated and realized after the 2011-2012 unrest. It is evident that the recent 2024-2025 caldera unrest should also be used as a platform to further strengthen and support the development of the necessary volcanic hazard policy in Greece. As noted in the Jan 2, 2025, letter of ISMOSAV to the Civil Protection and EPPO, this can be realized by adopting several measures, such as:

a) Strengthening of the role of the Permanent Scientific Committee for the Monitoring of the Greek Volcanic Arc of EPPO by creating permanent working research groups, with appropriate support for the volcanic arc monitoring and evaluation.

B) The allocation of the necessary resources (financial and other) for the permanent improvement (upgrading) and densification of the monitoring networks in Santorini, to improve the scientific and operational response, especially if there is an adverse evolution of tecto-volcanic activity.

C) The review and refinement of the TALOS plan, especially with respect to other volcanic centers (Koloumbo), as well as regarding the possible actions that will be required for the residents and visitors of Santorini in case of unrest or eruption.

D) Establishment of a permanent Volcanological Observatory of Santorini supported by the state. This observatory, for which a suitable site has been already selected and allocated by the Municipality of Thera, could “assimilate” existing monitoring networks to provide continuous volcano monitoring and reliable assessment of the associated volcanic hazard and risk, especially in periods of unrest.

Acknowledgements

The authors would like to acknowledge the help of Geothira MAE, the Municipality of Thera, EPPO, Greek Civil Protection, as well as ISMOSAV members and Santorini locals for their continuous support during the 30+ years of Santorini volcano monitoring by ISMOSAV. We would also like to thank a) Metrica SA for the donation of 3 GNSS stations that are permanently installed on Santorini, b) the Research Committee of the Aristotle Univ. Thessaloniki for partly funding 4 wide-band seismological and 1 GNSS stations, that are also permanently installed on Santorini, c) the IRIS technical company operating in Santorini, for providing valuable assistance regarding the permanent ISMOSAV network maintenance during the last 10+ years.
