**ABSTRACT.** For the first time in Greece, we investigated the prevalence of *Coxiella burnetii* antibodies in milk and sera from dairy cattle herds located at central and northern parts of the country. Eighty herds were initially voluntary enrolled in the study and a bulk milk sample from each farm was assayed by ELISA for *C. burnetii* antibodies. According to antibody titre, herds were classified into 5 categories: negative and grades 1, 2, 3 and 4 (ascending scale). To assess the prevalence within farms, two herds from each category were selected and blood samples were collected for antibody assessment. In these herds, some reproductive indices were compared between farms; in addition, comparisons were made in paired seropositive and seronegative animals from one grade 3 herd. Twenty three herds (35%) were found positive, 21 being in categories 3 and 4. The prevalence of seropositive animals between herds varied from 4.9 to 46.3%, even from farms initially characterized as negative, some positive animals were detected. Between farms, no differences were detected in the abortion rate or in the mean number of artificial inseminations (AI) per pregnancy. Some differences were found in other reproductive indices that were impossible to be biologically interpreted under the light of *C. burnetii* level of infection. From the results presented here, we infer that *C. burnetii* infection is likely asymptomatic in dairy cows causing minimal –if any– economic losses to farmers. However, since the disease is a zoonotic one, its spread can easily occur, a systematic surveillance, in all ruminant species, for the restriction or eradication of the disease should be undertaken in national level.

**Keywords:** *Coxiella burnetii*, antibodies, reproduction, cow
**Introduction**

*Coxiella burnetii* is an obligatory intracellular, Gram-negative, very resistant, ricketsial microorganism that replicates in host monocytes and macrophages. It was first reported in 1938 by two independent groups; the organism was later named after the family names of the two senior researchers, Cox and Burnet (Burnet and Freeman 1937, Cox 1938). The organism is endemic all over the world except New Zealand (Hilbink et al. 1993) and *C. burnetii* infections have been reported to a wide range of hosts such as domesticated and wild mammals, birds and arthropods (Maurin and Raoult 1999, Hirai and To 1998). The life cycle of the bacterium has two forms - both of them are infectious - the large cell variant (LCV) and the spore-like small variant (SCV), which is extremely stable to the environment and can induce reproductive failures, such as abortions, delivery of weak newborns, retention of fetal membranes, endometritis and reduced fertility, with the clinical signs being more prominent in small ruminants than in the bovine (Van der Brom and Vellema 2009, Rodolakis et al. 2007). Ruminants are the main reservoir from which humans are infected by *C. burnetii* that gives the ubiquitous zoonosis called Q fever. Usually, the disease has non-specific clinical manifestation, with an onset as a flu-like febrile infection accompanied by severe headache. Atypical pneumonia with non-productive cough and chest pain is very common, but acute infections can cause meningitis, pericarditis, thrombophlebitis, arthritis and pancreatitis, with a mortality rate up to 2% (Gikas et al. 2010, Mazokopakis et al. 2010, Hartzell et al. 2008).

In ruminants, the prevalence of the disease varies between countries; for example seropositivity in Korean, Canadian and Danish dairy herds was 25.6%, 67% and 59%, respectively, while, in the USA, this figure goes from 1 up to 94% depending on the state and the method used (Agger et al. 2010, Kim et al. 2005, Kim et al. 2006, Lang 1988).
While we know that Q fever is endemic in some parts of our country (Pape et al. 2009, Antoniou et al. 1995, Tselentis et al. 1995), very little is known on the prevalence of the disease in Greek ruminant population; only Pape and co-workers studied the prevalence of C. burnetii in small ruminants in northern Greece (Pape et al. 2009).

Hence, the aim of this study was to assess, on the basis of antibodies in bulk milk, the prevalence of C. burnetii infection in cattle dairy farms in central and northern Greece (the area with the highest concentration of dairy farm) and then to correlate some basic reproductive indices with seroprevalence.

Materials and methods

Eighty farms from the regions of Macedonia, Thrace and Thessaly were voluntary enrolled to the study. Each day 20 samples were collected in sterile 100ml containers, from the outlet of the milk tank; to minimize cream concentration, the mixer was stopped 15 to 30 min prior to collection. Samples were transferred ice-cold in the lab, they were centrifuged to remove fat and the non-fat fraction was stored at -20°C until tested for antibodies.

Milk antibody titres against C. burnetii were assayed using an initial 1/20 dilution, by a commercial indirect ELISA kit (LSIVET RUMINANT, Milk/serum Q fever, INRA, Lissieu, France) according to the manufacturers instructions. The antibody titre was expressed as S/P value X100, according to the equation:

\[ S/P = \frac{(OD \text{ sample} - ODN C)}{(OOPC - ODN C)} \]

where S = sample, P = positive, OD = optical density, NC = negative control, PC = positive control.

A titre ≤ 30 was considered negative, while positive samples were categorized into 4 grade scale according to their titres: 30 to 100 grade 1, 100 to 200 grade 2, 200 to 300 grade 3 and > 300 grade 4.

On the basis of milk antibody titres, two farms from each category were selected to screen the seroprevalence. These farms were located at the regions of South Macedonia and Thessaly, they had similar husbandry practices and they were keeping reliable reproductive records. All farms enrolled in the serological studies were free of brucellosis, they had conducted a BVD-MD eradication program, they were routinely applying vaccination program against BVD-MD, IBR, BSRV and PI3 and the reproduction management was implemented in co-operation with staff members of our Clinic.

For the determination of serum antibody titres, 526 blood samples (102, 100, 116, 100 and 108 from negative and categories 1, 2, 3 and 4, respectively) were collected from the tail vein in plain vacutainers; blood was allowed to clot and serum was separated and stored at -20°C until it was assayed as it is described above, using an initial dilution 1/400.

To assess possible effects of infection on reproductive performance, comparisons were made 12 months after the initial laboratory detection of antibody titres.

Based on farm records, reproductive indices of individual cows were calculated. To compare possible effects of C. burnetii infection on reproductive parameters pairs of seronegative – seropositive cows were made in a category 3 farm, using as a criterion the calving date.

Pregnancy diagnosis was performed 35-42 days after AI and it was confirmed 60 to 75 days later. Abortion was defined any premature expulsion of a dead fetus or the failure of a cow to retain the pregnant status in both pregnancy examinations. As extended cycles were defined the interestrus intervals that exceeded 25 days, but they were not the product of multiplication by 20 to 24.

Statistical analysis

The number of AIs/pregnancy and calving interval among groups were compared by ANOVA followed by Duncan’s new multiple range test. The results are expressed as mean ± SEM. Among groups, chisquare analysis was used to compare the proportion of abortions, the proportion of cows with enlarged estrous cycle length, with retained fetal membranes or with uterus infection. Statistical differences were considered significant when P < 0.05.

Paired data within the same herd were individually analyzed by student’s t-test.

Results

Twenty eight out of the 80 tested herds had antibodies in the bulk milk sample (prevalence 35%). According to the antibody titre, 3, 4, 16 and 5 herds (3.25%, 5%, 20% and 6.25%) were allotted to the categories 1, 2, 3 and 4, respectively.

Table 1 shows the distribution of animals with different seropositivity in each farm category. Seropositive animals of category 1 were detected in the farms that according to the bulk milk analysis were initially characterized as being negative.

Among groups, no differences were detected in the required number of AIs per pregnancy. Significant variations were detected in calving interval that was the highest in category 3 herds (table 2). No differences were detected in the proportion of abortions, while significant variations were found in proportion of: non-physiologically extended estrous cycle length, animals with retained fetal membranes and uterine infections (table3).

When reproductive indices of seropositive and seronegative cows in the same farm were studied, no statistical difference was detected between the two groups and, hence, the data are not presented in detail.

Discussion

Here, we report for the first time the prevalence of *C. burnetii* infection in Greek dairy cattle farms. We provide evidence that antibody positive herds are prevalent in Greece; however, the disease had been underestimated so far. The prevalence of infection was 35%, which falls within the range reported in the international literature (Agger et al. 2010, Kim et al. 2005, Kim et al. 2006, Paiba et al. 1999, Lange et al. 1992, Lang 1988).

The sensitivity and specificity of the ELISA assay used in the present study are unknown and, hence, the true prevalence of the disease may be different from what is reported herein. Nonetheless, most research groups utilize either ELISA or complement fixation test for bulk milk antibody detection, which appear to be similar in terms of sensitivity and specificity (Hansen et al. 2011, Schalch et al. 1998). Seropositive animals were found in herds that were characterized as negative on the basis of antibody presence in the bulk milk. In these herds, the prevalence and the titre of seropositive animals were low, indicating that animals with low serum antibody titre excrete minimal antibody concentration in milk, which being diluted in the milk tank, further lowered milk titre to the negative zone of the assay. Similar findings have been reported by others (Hansen et al. 2011).

According to the answers we received during the farmers’ interview (data not shown), no diagnosed human cases were reported in the personnel of farms enrolled in this study. This is either because, in fact, no infections have occurred or people had been infected, but the disease was mild and, hence, no medical consultancy was required.

No associations were found in prevalence between herds having importing replacing animals and those using exclusively own replacement heifers. This is possibly because the bacterium is highly contagious and can be carried for long distances by the dust and winds. In addition, infection could have occurred from small ruminants that graze in short distances in almost all farms.

In the present study, it appears that the prevalence of *C. burnetii* titres is not associated with reproductive disturbances. In fact, in the statistical analysis between farms, there were significant differences, which, nonetheless, could not be biologically interpreted under the light of antibody titre. For example, in negative and grade 4 farms, incidence of uterine infection was not different, but in both groups it was lower than that of grade 2 farms. Similarly, negative and grade 4 farms had similar calving intervals that were lower from that of grade 3 farms. On the other hand, no differences were detected on the number of AIs per pregnancy or in the abortion rates. These findings suggest that the differences reflect either different management practices or the existence of obscure pathological conditions between farms that were not evaluated in the present study or, finally, that the disease is asymptomatic in cattle. The latter hypothesis is a matter of controversy. Some researchers have reported that *C. burnetii* infection can cause or is associated with abortion in cattle (Bidfell et al. 2000, Arricau-Bouvery et al. 2006, Cabassi et al. 2006). In the latter study, antibody against *C. burnetii* were detected both in aborted cows (44.9%) and in cows that carried pregnancy to term (22%). Others have reported that the infection in cattle is subclinical and rather asymptomatic (Hansen et al. 2011, Rodolakis et al. 2007, Paiba et al. 1999, Behymer et al. 1976). The pathophysiology of abortion includes either the death of the fetus and/or placental lesions caused by placentitis as a result of colonization by the infectious agent. In goats, after experimental infection, *C. burnetii* was detected by PCR in all placentas and in several organs from the aborted fetuses (Arricau-Bouvery et al. 2003), while, in a field study, the microorganism was detected in the 20-25% of the sampled material from aborted ruminants indicating that the microorganism was the causative factor of the abortion (Jones et al. 2010). However, in the latter study, the prevalence of fetal infection was very high in goat fetuses and non-existing in the cattle; despite the small number of cases, this study may reveal that the susceptibility to the infection in ruminants is species-related. In addition, in a very recent study, it has been demonstrated that almost no placenta inflammation was detected in parturient cows originating from *C. burnetii* infected herds, which is a strong evidence, that in the bovine, the disease is mainly subclinical and asymptomatic (Hansen et al. 2011, Rodolakis 2009). This is confirmed in the present study, since no difference in abortion rate was found and, most importantly, no association could be made in reproductive indices between seropositive and seronegative herdmates.
The present study revealed for the first time the presence of C. burnetii in dairy cows throughout central and Northern Greece. Though the present study does not elucidate associations between antibody titres and reproductive failures, the zoonotic nature of the disease dictates the need of a large national surveillance to be conducted.
