**ABSTRACT.** This study is aimed to determine the prevalence of *staphylococcus aureus* (*S.aureus*) by biochemical tests in poultry carcasses. It is also intend to detect the distribution of genes for classical staphylococcal enterotoxins A, B, C, D and E (*sea, seb, sec, sed* and *see*) and for gene *femA*, specific for *S.aureus* species, using multiplex PCR. A total of 385 samples of neck skins from fresh poultry carcasses were collected during the period 2012-2013 from 16 different slaughterhouses located in the region of Algiers, Algeria. The overall prevalence of *S.aureus* in freshly slaughtered poultry carcasses was 41.56%, with an individual prevalence of 40.63% and 45.71% for chicken and turkey respectively. From the 95 strains of *S.aureus* identified by biochemical tests, 82 (86.32%) isolates were *femA* positive using multiplex PCR. The investigation has also revealed the presence of both enterotoxins B and D, with a predominance of *seb* (13.33%) followed by *sed* (1.67%), in the chicken carcasses while in turkey only *sed* was detected (4.55%). It has been found that strains of *S.aureus* of poultry origin can be enterotoxigenic with the predominance of genes encoding for enterotoxins *seb* in chicken and *sed* in turkey. As enterotoxins can be produced in adequate amounts to induce foodborne illnesses, these potential dangers must be considered in terms of a real risk to public health.

**Keywords:** *Staphylococcus aureus*, Poultry carcasses, Staphylococcal enterotoxins, Algiers.
INTRODUCTION
Recent studies have revealed that high risk of foodborne diseases is often related to the contamination of poultry carcasses by pathogens micro-organisms (Escudero-Gilete et al., 2007). Among the pathogen bacteria that maybe present in poultry carcasses is Staphylococcus aureus. Its presence in food indicates poor hygiene and improper storage conditions (Gundogan et al., 2005).

S. aureus is an opportunistic pathogen that can colonize the skin and mucous membranes particularly in the nose of both healthy humans and animals (Nader et al., 2016). In addition to colonizing various hosts, it can also be the origin of a wide range of different infections in poultry ranging from septicaemia, pneumonia, endocarditis, and arthritis (Smyth and McNamie, 2008). Amongst the foodborne pathogens S. aureus is a major one contaminating meat products. It is considered the third largest cause of food related illnesses throughout the world (Achi and Madubuik, 2007; Aydin et al., 2011; Sasidharan et al., 2011).

S. aureus is characterized by its ability to produce a large variety of Staphylococcal enterotoxins (SEs) (A, B, C, D, E, G, H, I, J, K, L, M, N, O, P, Q, R and U), but 95 % of food poisoning are caused by the enterotoxins A, B, C, D and E (Letertre et al., 2003). It is notable that SEs are heat stable toxins. Indeed, the heat used in cooking and pasteurization is insufficient to destroy them. Moreover, they are difficult to be perceived in food due to the lack of taste and food appearance (Ayicek et al., 2005). For the case of food ingestion contaminated with SEs, food poisoning occurs shortly after, 30 min to 8 hrs while infected individuals usually recover from the toxicity within 24 - 48 hours (Argudin et al., 2010).

Based on recent published studies, just a little is known about enterotoxigenic S. aureus strains from poultry. Particularly in Algeria, the number of studies discussing the prevalence of enterotoxins genes of S. aureus in poultry meats is really limited. Therefore, the present study is aimed to determine the prevalence of staphylococcus aureus (S. aureus) by biochemical tests in poultry carcasses. It is also intend to detect the distribution of genes for classical staphylococcal enterotoxins A, B, C, D and E (sea, sel, sec, sed and see) and for gene femA, specific for S. aureus species, using multiplex PCR.

MATERIALS AND METHODS
Sample collection and microbiological analysis
A total of 385 samples of neck skins from fresh poultry carcasses were collected from 16 different slaughterhouses located in the region of Algiers, Algeria. These samples has been examined during 2012-2013. They consist of chicken carcasses (n=315), and turkey carcasses (n = 70). All samples were placed in sterile plastic bags and brought to the laboratory in cold chain and analyzed within the following 3 h. Microbiological analysis in this study has been carried out according to the international standard NF EN ISO 6888-1/A1 (ISO, 2004). Twenty-five portions of the samples were weighed into sterile stomacher bags diluted with 225 ml sterile buffered peptone water (BPW; Oxoid CM 509) and homogenized in a stomacher (Seward 400) for 2 min. The samples were diluted with BPW, and 0.1 ml portions of dilution levels were streaked on Baird-Parker (BP) agar (Oxoid CM 275) supplemented with egg yolk-tellurite emulsion (Oxoid SR 54) and incubated at 37°C for 24 - 48 h.

The colonies suspected for Staphylococci positive coagulase were cultured on 5% blood agar and identified by catalase, coagulase tests. S. aureus was identified by Staphaurex (Bio-Rad). The reference strain used for microbiological analysis was S. aureus ATCC 25923. The pure isolates were then stored at −20°C in TSB-broth and 10% glycerol for future studies.

Statistical Analysis
Data collected from the detection of S. aureus on turkey and chicken were analyzed by SPSS Statistics 20 software, to test the significance of differences among the biochemical tests and the Polymerase-Chain Reaction (PCR), and the toxigenic potency of S. aureus between the two species (turkey and chicken).

Genomic DNA Extraction
The methodology of DNA extraction is taken from Sambrook and Russel, (2001). For nucleic acid isolation, 95 strains of Staphylococcus species isolated from poultry carcasses were activated on trypticase soya agar (TSA) (BioMérieux, France). After overnight incubation at 37°C, one to two colonies for each strain was re-suspended on 300 μl of TNE buffer (Tris- Nacl-EDTA-SDS) and then vortexed, 10 μl of lysosome was added plus 200 μl of SETS (Sodium-EDTA-Tris-SDS). The mix was incubated at 37°C for 1 hour. After incubation
each tube was vortexed once every 15 min. Then, 10 μl of proteinase- K (Vivantis Technologies, Malaysia) and 100 μl of TNE were added. The final solution was vortexed and incubated at 50°C for 1 h. After that each microcentrifuge tube was vortexed once every 15 min. A volume of 150 μl of NaCl (5M) was added and vortexed. The obtained DNA was harvested by centrifugation at 10,000 rpm for 10 min at room temperature. The supernatant was transferred to a new microcentrifuge tube for washing by 99% cold ethanol and then stored at -20°C overnight. A second washing of DNA was done by 70% cold ethanol. The sample was dried for 10-30 min and re-suspend in 100 µl sterile distilled water and stored at -20°C until PCR analysis.

Multiplex PCR Conditions

The multiplex PCR has been performed as described by Mehrotra et al. (2000). The primers used in the multiplex PCR are presented in Table 2. Multiplex PCR mix contained 400 μM deoxynucleoside triphosphates (dNTPs); 5 μl of 10X reaction buffer (100 mM Tris-HCl [pH 8.3], 500 mM KCl); 4 mM MgCl2; 20 pmol of each sea, seb, sec, see, and femA primers; 40 pmol of sed primers; 2.5 U of Taq DNA polymerase (AmpliTaq DNA polymerase, Perkin-Elmer), and 5μl of template DNA. The final volume was adjusted by adding 50μl with sterile ultra-pure water. DNA thermocycling (CFX 96 thermal cycler, Bio-Rad) was carried out with the following thermal cycling profile: an initial denaturation at 94°C for 2 min, annealing at 57°C for 2 min, and extension at 72°C for 1 min), ending with a final extension at 72°C for 7 min. Ten microliters of the PCR products were then analyzed by electrophoresis on 2% agarose (BIOMAX) gel, stained with ethidium bromide. Note that the DNA fragments were visualized using a UV transluminator (EC3, UVP Bimmaging systems, Inc (BioMax) while immigration was made by Electrophoresis Power Supply (Model EC 1000 XL Thermo Scientific, Inc.) in TBE buffer (0.09 M Tris–HCl, 0.09 M boric acid, 2 mM EDTA, pH 8.3) for 45 min at 120. Primers are shown in Table 1.

RESULTS

Table 2 illustrates the overall prevalence of S. aureus in freshly slaughtered poultry carcasses that are collected from 16 slaughterhouses. The prevalence was 160 of

385 samples (41.56%), with an individual prevalence of (40.63%) and (45.71%) for chicken and turkey respectively.

Table 3 shows the confirmation of the isolated strains as *S. aureus* by multiplex PCR. The multiplex PCR has revealed that 82 (86.32%) from these isolates were *femA* positive, i.e., 60 (85.71%) in chicken and 22 (88%) for turkey. Statistical analysis showed no significant difference between the two methods (Classical method and PCR) (p< 0.05).

It has also been observed that 12.19% of *S. aureus* isolates encoded classical staphylococcal enterotoxins, i.e., nine (15%) from chicken and 1 (4%) from turkey carcasses. Statistical analysis showed no significant difference for the prevalence of enterotoxigenic isolates from chicken carcasses and turkey for p< 0.05. Moreover, detected the presence of both enterotoxins B and D in poultry carcasses with a prevalence of 9.76% and 2.44% respectively.

As indicates in Figure 1 and Table 4, isolates from chicken present both enterotoxins B and D, with a predominance of *seb* (13.33%) followed by *sed* (1.67%), while in turkey only *sed* was detected (4.55 %). It is notable that none of the isolates was positive for *sea*, *sec* or *see* genes.

**DISCUSSION**

The isolation of *S. aureus* from chicken and turkey carcasses (41.56%) confirms the contamination of the poultry carcasses by *Staphylococcus aureus*. Indeed, the present study is mainly focused on the determination of the prevalence of *S. aureus* in freshly slaughtered chicken and turkey, in 16 slaughterhouses in the Wilaya of Algiers. Moreover, it also aims to the molecular characterization of the isolated strains by highlighting the presence of enterotoxins genes.

The prevalence of *S. aureus* recorded for chicken (40.63%) was in good agreement with those advocated

by Citak and Duman (2011) and Nader et al. (2016). In Algeria a study conducted in the region of Biskra, carried out on 60 chicken carcasses revealed a prevalence similar to that obtained in the present study (Alloui et al., 2013). However, lower prevalence rates of S. aureus were found by others studies (Khallaf et al., 2014; Sarrafzadeh Zargar et al., 2014). Two other studies that have been carried out in Turkey recorded a prevalence of 9.61% (Kiliç et al., 2009) and 48% (Bystron et al., 2005) of coagulase-positive Staphylococcus from meat and hash meat respectively.

In our study, the recorded prevalence of S. aureus present in turkey carcasses (45.71%) was higher than that obtained by Sarrafzadeh Zargar et al. (2014) (16.6%) and El Alloufi (2013) (41.6%).

The high prevalence recorded in both species often indicates a lack of good hygiene practices (Lindblad et al., 2006; Pacholewicz et al., 2016) which are linked to the multiple handling of carcasses during slaughter processing. The staff represents a source of contamination spreading the germs by inadequate clothing hygiene, or by hosting (sores, angina, sinusitis and nasopharyngitis).

The lack of control of good manufacturing practices can also be at the origin of these contaminations-multiple contacts with the equipment: tables, bags, knives, towels, scalding bath and feathery (Azelmad et al., 2017; Kotula and Pandya, 1995; Mead et al., 1993).

It could also be related to the sanitary status of poultry intended for slaughter (carried by the skin and feathers, or various pathologies as osteomyelitis, arthritis and synovitis).

The variations in the prevalence between our results and other studies, that have been carried-out in other countries, can be attributed to several factors, including the size of the samples tested, the sampling mode (Whole chicken or parts of carcasses), the seasons in which the sampling was done, the methods of isolation used and the hygiene conditions of the slaughterhouse (Teramoto et al., 2016; Wang et al., 2013).

The use of PCR and biochemical identification to confirm S. aureus strains revealed similar results (average 86.32%), which confirms the concordance between the two techniques, already reported by the study of Benhamed (2014).

The present study shows that the poultry isolates can be enterotoxigenic (12.19%). These results are in good agreement with the previous published studies which revealed that the percentage of S. aureus strains producing enterotoxin A to E, bovine and avian, can vary from 0 to 15% (Bergdoll, 1991; Genigeorgis, 1989; Rosec et al., 1997). More recent studies showed that the genes encoding the classical enterotoxins, were absent or occur in less than 3% in S. aureus strains isolated from poultry (Hazariwala et al., 2002; Normanno et al., 2007; Smyth et al., 2005).

As for the chicken some authors note relatively higher percentages. For instance, Nader et al. (2016) show that 7 strains out of 12 (58.3%) of S. aureus isolated from chicken meat were enterotoxigenic. They also reported the presence of sea, seb and sed genes in chicken meat isolates, with percentages of 33.3%; 8.3% and 16.7% respectively.

Kitai et al. (2005) revealed that 21.7% of S. aureus strains, isolated from chicken carcasses were enterotoxigenic. Moreover, Nemati (2013) observed that 71% of S. aureus strains isolated from chicken nose and cloaca were enterotoxigenic. As for the turkey isolates, Koluman et al. (2011) showed that the production of enterotoxins in turkey meat was 36%.

However, the present study demonstrated that the prevalence of enterotoxigenic isolates from chicken carcasses (15%) and turkey (4.54%) is relatively lower.

Although, there was a variability in the frequency of different enterotoxins types production, in chicken we observed the dominance of seb gene with a rate of 13.33% compared to the sed gene (1.67%). Similar results were stated by Kitai et al. (2005). Nevertheless, only type D enterotoxins (4.54%) were detected in turkey isolates. This variability between the two species had not yet been defined.

Madahi et al. (2014) showed that S. aureus strains isolated from chicken nuggets present staphylococcus enterotoxins genes, with values of 33.33%; 4.16%; 12.50%; 8.33%; 12.50%; 12.50% for sea, seb, sec, sed, sea + sec and sea + sed respectively. No see gene was detected. Another study by Nemati (2013) also reported that 33.3% of S. aureus strains isolated from the nose and cloaca of healthy chicken were positive for sea and 5% had a mixed sea + ege enterotoxins production, whereas the genes encoding seb, sec, sed and see were absent.

A study of the incidence of enterotoxigenic S. aureus strains in turkey meat, was carried out by Bystron et al.
CONCLUSION

We have experimentally determined the prevalence and enterotoxins genes of S. aureus in fresh poultry carcasses that are collected from 16 different slaughterhouses located in the region of Algiers, Algeria. The investigation has revealed that the microbial risk by S. aureus in poultry carcasses is not negligible. It has been found that the prevalence of S. aureus in 385 carcasses was 41.56% with an individual prevalence of 40.63% and 45.71% for chicken and turkey respectively. The strains of S. aureus of avian origin can be enterotoxigenic with the predominance of the genes encoding for enterotoxin seb in chicken and sed in turkey.

When meat is preserved under favorable conditions for germs multiplication and toxinogesene, enterotoxins can be produced in sufficient amount to trigger foodborne illnesses. These potential dangers must be considered in terms of real risk to public health. To ensure the safety and hygienic quality of meat, the application of good hygiene practice (GHP) and the implementation of HACCP in poultry slaughterhouses has become an absolute necessity to protect consumer’s health.

ACKNOWLEDGEMENT

We are grateful for the staff of laboratory of microbiology of University Mustafa Kemal, Hatay for their excellent technical support.

The first author would like to thanks Omar Behar for his assistance during preparation of the article.

CONFLICT OF INTEREST

The authors declare that they have no conflict of interest.

al. (2005) presenting that from the 4 coagulase-positive Staphylococcus strains, isolated from 11 samples of turkey meat the 3 strains had enterotoxin genes of type B and one had type C. Adams and Mead (1983) isolated enterotoxigenic Staphylococci in 2 of the 3 turkey’ slaughterhouses studied. They reported that in the first slaughterhouse 60% of the 55 isolates produced enterotoxin C while in slaughterhouse B, 4% of the 41 isolates produced enterotoxin D and 2% produced enterotoxin F. No enterotoxigenicity was detected from the 50 isolates in the third slaughterhouse.

As type A enterotoxin is usually typical for the human origin isolates (Orden et al., 1992) and type C enterotoxin is frequently produced by bovine origin isolates (da Silva et al., 2005; Jorgensen et al., 2005; Katsuda et al., 2005) could explain their absence in poultry studies.

The variability observed in the frequency of enterotoxin production by S. aureus strains may be related to the origin of the studied isolates (food or other) and their geographic origin (Bergdoll, 1991; Genigeorgis, 1989; Larsen et al., 2000; Rosec et al., 1997).

Type A, B and D enterotoxins are implicated in 95% of reported foodborne illness outbreaks (Letertre et al., 2003). During the years 2001-2003 in Taiwan, enterotoxins A, B, C, and D were detected with respective percentages of 29.2%; 19.7%; 6.8% and 2.0% in patients associated with staphylococcal foodborne illness outbreaks (Chiang et al., 2008). Furthermore, more than 50% of staphylococcal food-borne infections were caused by type A enterotoxin. In addition, sea and seb enterotoxins are the two most important agents causing gastroenteritis, they are also the most implicated in foodborne illness (> 60%) in the United States and England (Kluytmans and Wertheim, 2005).
