**ABSTRACT:** This study was conducted to determine parasite infection with *Posthodiplostomum cuticola* in eight fish species collected from five Rivers Basins of Turkey (Aras, Çoruh, Sakarya, Marmara and Susurluk River Basins). Five of eight fish species are endemic to Turkey. The highest values of prevalence and mean intensity (60.87%; 4.86) of cysts with metacercaria of *P. cuticola* were recorded in *Alburnus filippii*, a native fish species in Ağıl Creek. At the gross examination numerous black lesions were observed at the skin of the fishes. Microscopically black-spot disease was revealed by melanin pigmentation and atrophy of fish muscles in lesioned areas. Parasites were covered by thin connective tissue capsule. *Alburnus escherichii, Alburnus filippii, Capeota tinca, Chondrostoma angorensis, Chondrostoma colchicum, Squalius pursakensis* and *Squalius turcicus* were found as new host records for *P. cuticola*.

INTRODUCTION

Posthodiplostomum cuticola (Nordmann, 1832) is a digenean parasitic fluke, responsible for black-spot disease, a pathological condition manifested by an intensive pigmentation of the cyst wall located in the skin, muscle tissue and fins of freshwater fish hosts throughout the world (Ondračková et al., 2004; Zrnčić et al., 2009; Kvach et al., 2017).

In the complex life-cycle of P. cuticola involving piscivorous birds as definitive hosts and planorbid snails as first intermediate host, various fishes belonging mainly to Cyprinidae and Cobitidae families play the role of the second intermediate host (Ondračková et al., 2004; Markovic and Krsmanovic, 2008; Zrnčić et al., 2009). Members of Escoidae, Percidae and Salmonidae could also represent hosts for P. cuticola (Mierzejewska et al., 2004).

Fish reaction to the parasite presence consists in dark pigment produced by decomposition of hemoglobin and chromatophores disposed around metacercaria, the penultimate development stage of P. cuticola (Markovic and Krsmanovic, 2008; Markovic et al., 2012). Although the black-spot disease is not deadly to fish hosts in general, symptoms such as body deformation, muscle fibers necrosis, kidney and liver dystrophy may occur and could be harmful to fry (Robbiecki, 2004; Markovic and Krsmanovic, 2008; Iqbal et al., 2014).

To date, occurrence of P. cuticola infection was reported only in six cyprind species from ichthyofauna of Turkey: Alburnus chalcoides, Blicca bjoerkna, Cobitis cf. turcica, Cyprinus carpio, Scardinius erythrophthalmus and Vimba vimba (Öztürk, 2005; Kırkankaya and Ekmekçi, 2011; Öktener, 2014; Altan and Soylu, 2018). Therefore, the aim of this paper was to assess new host-parasite relationships in native and endemic fish species from Turkish inland waters in which the causal agent of black-spot disease is spread.

MATERIALS AND METHODS

Overall, 153 individuals from eight fish species belong to 2 families (Cyprinidae and Cobitidae) and 5 genera were analysed: Alburnus escherichii Stein-dachner, 1897 (Caucasian bleak); Alburnus filippii Kessler, 1877 (Kura bleak); Capoeta tinca Heckel, 1843 (Anatolian khramulya); Chondrostoma angorense Elvira, 1987 (Ankara nase); Chondrostoma colchicum Derjugin, 1899 (Colchic nase); Cobitis taenia Linnaeus 1758 (Spined loach); Squalius pursakensis Hankó, 1925 (Sakarya chub) and Squalius turcicus De Filippi, 1865 (Transcaucasian chub). The study was carried out during 2010-2018 years. Fishes were collected from seven different locations (Seydisuyu Creek, Pasinler Creek, Süvari Creek, Düzköy Creek, Çerpeş Creek, Karaçaltı Creek, Ağıl Creek) (Figure 1) capturing five different river basins of Turkey: Aras, Çoruh, Sakarya, Marmara and Susurluk.

![Figure 1. Map of sampling localities](image-url)
For parasitic isolation, the skin and fins of the host fish specimens were taken into Petri dishes with physiological water. The parasites were separated by a scalpel. Subsequently, the parasites were fixed in 70% ethyl alcohol medium between the lamella for 24 hours. The parasite samples were then stained with hematoxylin (Pritchard & Kruse, 1982) and species identified, according to Bykhovskaya et al (1962).

During the necropsy, clinically lesioned and abnormal pigmented samples of analyzed fish species were collected and fixed in 10% neutral formalin solution for histopathological examination. After fixation tissue samples were routinely prepared by automatic tissue processing equipment (Leica ASP300S; Leica Microsystem, Nussloch, Germany). The samples were embedded in paraffin, and 5 μm serial sections taken from sections were prepared using a Leica RM 2155 rotary microtome (Leica Microsystem, Nussloch, Germany). Then sections were stained with hematoxylin and eosin (HE) and examined under the 40X a light microscope. Morphometric evaluation and microphotography were performed using the Database Manual cellSens Life Science Imaging Software System (Olympus Corporation, Tokyo, Japan).

Prevalence (Pr %), as the percentage of hosts infected with a particular parasite species or taxonomic group and intensity (Int), as the number of individuals of a parasite species in/on a single infected host were calculated following Bush et al. (1997).

**RESULTS**

Among eight host species (Table 1) examined for infestation with *Posthodiplostomum cuticola* (Nordmann, 1832), the highest prevalences (60.87%) of infection were reached in *Alburnus filippii*, a native fish from Ağıl Creek, followed by *A. escherichii* (57.14%) and *Squalius pursakensis*, endemic fish in Seydisuyu Creek (55%) (Table 2). With respect of mean intensity, the highest values were recorded in *A. filippii* (Ağıl Creek), *A. escherichii* (Seydisuyu Creek) and *Capoeta tinca* (Süvari Creek) (4.86; 4.75; 3.75 parasites/fish, respectively).

At the histopathological analysis, most of the black spots were composed of parasites surrounding by thick fibrous capsule around the encysted parasite developmental stages with periphery of the capsule containing numerous melanocytes. Most of the lesions contained one or more metacercariae of the parasites.

The melanin capsules often presented an opening on the surface of cuticle layer. Amount of the melanocytes was different in each nodule. Either not observed at all or slight inflammatory reaction was observed near the lesions (Figure 2). The lesions were usually associated with migration of developmental stages of the parasite within the host tissues. Atrophy of the muscle near the parasitic lesion was commonly noticed. Melanocytes were also observed between the muscles near the cysts.

Figure 2. Histopathology of the black spot lesions in fish muscle related to parasite developmental stages, with different severity of melanocytic reaction. HE, Bars=200µm (A, B), 100 µm (C, D, E) and 50 µm (F).
Grossly affected fishes exhibit multifocal black spots in the skin which were different in shape and diameter. Black spots were localized in all skin regions from mouth to caudal fin (Figure 3). In some fish hyperemia was observed around the lesions.

**DISCUSSION**

Black-spot disease induced by *P. cuticola* was reported before in freshwater fish of Turkey, however there was no histopathological information available up to date. Worldwide, there is still a paucity of data concerning histological examination of fish diagnosed with posthodiplostomatosis. Nevertheless, few observations similar to ours on melanin deposits were made on: *Ctenopharyngodon idella* from a fishpond in Serbia (Markovic et al., 2012) and *Blicca bjoerkna*, *Rutilus rutilus*, *Scardinius erythrophthalmus* from a freshwater lake from Romania (Negrea et al., 2015). Parasitological data have been reported just for four species including *Alburnus escherichii*, *Capoeta tinca*, *Squalius pursakensis* and *Cobitis taenia* (Öktener, 2014; Innal et al., 2016). On the other hand, *P. cuticola* was reported only in *Cobitis taenia* of eight host species. The prevalence and intensity levels of infection among host species differed by host and area. The prevalence of *P. cuticola* infection in all host species ranged from 6.25% to 60.87%. The difference in the prevalence is likely due to abiotic parameters of systems and also biotic factors such as host health status, age and size and fish community structure.

Bykhovskaya-Pavlovskaya et al (1962) stated that this parasite is found in the most common cyprinids, rarely seen in sturgeon, catfish and freshwater perch. Fish specimens which were examined in this study and recorded with *P. cuticola* infection support this view. Öztürk (2005) which recorded *P. cuticola* infection in skin and fins of *Cyprinus carpio* stated that the occurrence of parasite decreases in autumn and winter reaching its highest level during the summer period. The same research determined that *P. cuticola*
infection was found in carp fishes of 15-20 cm in size, but it was not found in fishes of 13 cm and smaller. In contrast to Öztürk (2005), in the present study small sized fish individuals were found infected by *P. cuticola*.

There is a little knowledge about pathology of the black spot disease in fishes. Histopathological observations revealed that the black spots on the fishes are melanized nodules formed against metacercaria of *P. cuticola*. In addition, inflammatory cell infiltration and atrophy of the skeletal muscle around the metacercaria of the parasite were common findings indicating inflammatory reaction. The parasites were penetrated under the skin of the fish and formed encysted metacercaria and covered by a thick fibrous capsule these findings being in agreement with classical knowledge (Lane and Morris, 2000; Bush et al., 2001).

As a result, in this study, *P. cuticola* was determined to be a parasite species found in various fish species in different regions of Turkey. In addition, histopathological effects of this parasite species on host fish tissues were identified. In future studies, water birds in the study areas where parasitized fish live may be investigated whether they are infected with *P. cuticola*.
